Preface

Since the second edition of this book was published in 2002 there have, of course, been continual methodological developments in the field of protein chemistry. Consequently, for this third edition, I introduced 57 chapters/protocols not present in the second edition, significantly updated a number of chapters remaining from the second edition and increased the overall length of the book from 164 to 208 chapters. The new chapters are generally spread across the various sections of the book, but in particular we have expanded the section on post-translational modifications to reflect the increasing importance of these modifications in understanding of protein function.

As in the earlier editions, *The Protein Protocols Handbook* aims to provide a cross-section of analytical techniques commonly used to study proteins and peptides, thus providing a benchtop manual and guide for both those who are new to the protein chemistry laboratory and for more established workers who wish to use a technique for the first time.

All chapters are written in the same format as that used in the *Methods in Molecular Biology* series. Each chapter opens with a description of the basic theory behind the method being described. The Materials section lists all the chemicals, reagents, buffers, and other materials necessary for carrying out the protocol. Since the principal goal of the book is to provide experimentalists with a full account of the practical steps necessary for carrying out each protocol successfully, the Methods section contains detailed step-by-step descriptions for every protocol that should result in the successful execution of each method. The Notes section complements the Methods material by indicating how best to deal with any problem or difficulty that may arise when using a given technique, by providing useful hints and tips, and by explaining how to go about making appropriate modifications or alterations to the protocol.

John M. Walker

Contents

Preface ..... *v*
Contributors ..... *xxiii*

PART I QUANTITATION OF PROTEINS

1 Protein Determination by UV Absorption *3*
Alastair Aitken and Michèle P. Learmonth

2 The Lowry Method for Protein Quantitation *7*
Jakob H. Waterborg

3 The Bicinchoninic Acid (BCA) Assay for Protein Quantitation *11*
John M. Walker

4 The Bradford Method For Protein Quantitation *17*
Nicholas J. Kruger

5 Ultrafast Protein Determinations Using Microwave Enhancement *25*
Robert E. Akins and Rocky S. Tuan

6 The Nitric Acid Method for Protein Estimation in Biological Samples *35*
Scott A. Boerner, Crescent R. Isham, Yean Kit Lee, Jennifer D. Tibodeau, Scott H. Kaufmann, and Keith C. Bible

7 Quantitation of Tryptophan in Proteins *47*
Alastair Aitken and Michèle P. Learmonth

8 Kinetic Silver Staining of Proteins *51*
Douglas D. Root and Kuan Wang

9 Quantitation of Cellular Proteins by Flow Cytometry *55*
Thomas D. Friedrich, F. Andrew Ray, Ralph L. Smith, and John M. Lehman

10 Quantitation of Cellular Proteins by Laser Scanning Cytometry *63*
Thomas D. Friedrich, Ralph L. Smith, and John M. Lehman

PART II ELECTROPHORESIS OF PROTEINS AND PEPTIDES AND DECTECTION IN GELS

11 Protein Solubility in Two-Dimensional Electrophoresis: *Basic Principles and Issues* *73*
Thierry Rabilloud

12 Mouse and Human Tissue Sample Preparation for 2-D Electrophoresis *85*
Claus Zabel and Joachim Klose

13 Plant Protein Sample Preparation for 2-DE *109*
Sebastien Christian Carpentier, Rony Swennen, and Bart Panis

14 Preparation of Bacterial Samples for 2-D PAGE *121*
Brian B. Vandahl, Gunna Christiansen, and Svend Birkelund

15 Preparation of Bodily Fluids for 2-D PAGE *131*
Anthony G. Sullivan, Henry Brzeski, Jeban Ganesalingam, and Manuel Mayr

16 Immunoaffinity Depletion of High Abundance Plasma and Serum Proteins *139*
Lynn A. Echan and David W. Speicher

17 Preparation of Yeast Samples for 2-D PAGE *155*
Joakim Norbeck

18 Membrane Protein Preparation Using Aqueous Polymer Two-Phase Systems *159*
Jens Schindler and Hans Gerd Nothwang

19 Subcellular Fractionation of Small Sample Amounts *165*
Hans Gerd Nothwang, Isabelle Guillemin, and Jens Schindler

20 Nondenaturing Polyacrylamide Gel Electrophoresis of Proteins *171*
John M. Walker

21 SDS Polyacrylamide Gel Electrophoresis of Proteins *177*
John M. Walker

22 Gradient SDS Polyacrylamide Gel Electrophoresis of Proteins *187*
John M. Walker

23 SDS-Polyacrylamide Gel Electrophoresis of Peptides *193*
Ralph C. Judd

24 Separation of Proteins by Blue Native Electrophoresis (BN-PAGE) *201*
Elke A. Dian, Joachim Rassow, and Christian Motz

25 Separation of Proteins by Gel Electrophoresis in the Tris-Taurine-HCl System *211*
Sylvie Luche, Mireille Chevallet, Cécile Lelong, and Thierry Rabilloud

26 Cetyltrimethylammonium Bromide Discontinuous Gel Electrophoresis of Proteins: *M_r-Based Separation of Proteins with Retained Native Activity* *221*
Robert E. Akins and Rocky S. Tuan

27 Acetic Acid–Urea Polyacrylamide Gel Electrophoresis of Basic Proteins *239*
Jakob H. Waterborg

28 Acid–Urea–Triton Polyacrylamide Gel Electrophoresis of Histones *251*
Jakob H. Waterborg

29 Isoelectric Focusing of Proteins in Ultra-Thin Polyacrylamide Gels *263*
John M. Walker

30 Serial Immobilized pH Gradient Isoelectric Focusing over pH 4–9 ..... *269*
Slobodan Poznanović, Wojciech Wozny, Helmut Zengerling, Gerhard P. Schwall, and Michael A. Cahill

31 Radiolabeling of Eukaryotic Cells and Subsequent Preparation for 2-Dimensional Electrophoresis *279*
Nick Bizios

32 Two-Dimensional Polyacrylamide Gel Electrophoresis of Proteins Using Carrier Ampholyte pH Gradients in the First Dimension *285*
Patricia Gravel

33 Vertical Agarose Electrophoresis and Electroblotting of High-Molecular-Weight Proteins *293*
Marion L. Greaser and Chad M. Warren

34 Two-Dimensional PAGE of High-Molecular-Mass Proteins *299*
Masamichi Oh-Ishi and Tadakazu Maeda

35 Casting Immobilized pH Gradients *305*
Elisabetta Gianazza

36 A Modified Nonequilibrium pH Gradient Electrophoresis (NEPHGE) Technique for Protein Separation *323*
James A. Carroll

37 Microchip Capillary Electrophoresis: *Application to Peptide Analysis* *329*
Barbara A. Fogarty, Nathan A. Lacher, and Susan M. Lunte

38 Protein Separations in Microfluidic Chips *361*
Andrea W. Chow and Bahram Fathollahi

39 Difference Gel Electrophoresis (DIGE) *379*
David B. Friedman and Kathryn S. Lilley

40 Comparing 2D Electrophoretic Gels Across Internet Databases: An Open Source Application *409*
Peter F. Lemkin, Gregory C. Thornwall, and Jai A. Evans

41 Quantification of Radiolabeled Proteins in Polyacrylamide Gels *443*
Wayne R. Springer

42 Differential ProteoTope Radioactive Quantification of Protein Abundance Ratios *449*
Wojciech Wozny, Gerhard P. Schwall, Chaturvedula S. Sastri, Slobodan Poznanović, Werner Stegmann, Christian Hunzinger†, Karlfried Groebe, and Michael A. Cahill

43 Quantification of Proteins on Polyacrylamide Gels *479*
Bryan John Smith

44 Using SDS-PAGE and Scanning Laser Densitometry to Measure Yield and Degradation of Proteins *487*
Aaron P. Miles and Allan Saul

45 Rapid and Sensitive Staining of Unfixed Proteins in Polyacrylamide Gels with Nile Red *497*
Joan-Ramon Daban, Salvador Bartolomé, Antonio Bermúdez, and F. Javier Alba

46 Zn^{2+}-Reverse Staining Technique *505*
Carlos Fernandez-Patron

47 Protein Staining with Calconcarboxylic Acid in Polyacrylamide Gels *515*
Wei-Tao Cong, Sun-Young Hwang, Li-Tai Jin, and Jung-Kap Choi

48 Detection of Proteins in Polyacrylamide Gels by Silver Staining *521*
Michael J. Dunn

49 Background-Free Protein Detection in Polyacrylamide Gels and on Electroblots Using Transition Metal Chelate Stains *529*
Wayne F. Patton

50 Detection of Proteins in Polyacrylamide Gels by Fluorescent Staining 547
Michael J. Dunn

51 Detection of Glycoproteins in Gels and Blots..... 555
Nicolle H. Packer, Malcolm S. Ball, Peter L. Devine, and Wayne F. Patton

52 Staining of Glycoproteins/Proteoglycans on SDS-Gels 569
Holger J. Møller and Jørgen H. Poulsen

53 Detection of Proteins and Sialoglycoproteins in Polyacrylamide Gels Using Eosin Y Stain 575
Fan Lin and Gary E. Wise

54 A Modified Pro-Q Diamond Staining Protocol for Phosphoprotein Detection in Polyacrylamide Gels 579
Ganesh Kumar Agrawal and Jay J. Thelen

55 Electroelution of Proteins from Polyacrylamide Gels 587
Paul Jenö and Martin Horst

56 Autoradiography and Fluorography of Acrylamide Gels..... 595
Antonella Circolo and Sunita Gulati

57 Proteolytic Activity Detection by Two-Dimensional Zymography 605
Jeff Wilkesman

PART III BLOTTING AND DETECTION METHODS

58 Protein Blotting by Electroblotting 617
Mark Page and Robin Thorpe

59 Protein Blotting by the Semidry Method..... 621
Patricia Gravel

60 Protein Blotting by the Capillary Method..... 631
John M. Walker

61 Western Blotting of Basic Proteins Electrophoretically Resolved on Acid-Urea-Triton-Polyacrylamide Gels 635
Geneviève P. Delcuve and James R. Davie

62 Immunoblotting of 2-DE Separated Proteins..... 641
Barbara Magi and Laura Bianchi

63 High-Efficiency Blotting of High-Molecular Weight Proteins..... 663
Marion L. Greaser and Darl R. Swartz

64 Alkaline Phosphatase Labeling of IgG Antibody 673
G. Brian Wisdom

65 β-Galactosidase Labeling of IgG Antibody 677
G. Brian Wisdom

66 Horseradish Peroxidase Labeling of IgG Antibody 681
G. Brian Wisdom

67 Digoxigenin Labeling of IgG Antibody 685
G. Brian Wisdom

68 Conjugation of Fluorochromes to Antibodies 687
Su-Yau Mao

69 Coupling of Antibodies with Biotin 693
Rosaria P. Haugland and Wendy W. You

70 Preparation of Avidin Conjugates 705
Rosaria P. Haugland and Mahesh K. Bhalgat

71 MDPF Staining of Proteins on Western Blots 717
F. Javier Alba and Joan-Ramon Daban

72 Copper Iodide Staining of Proteins and Its Silver Enhancement 723
Douglas D. Root and Kuan Wang

73 Detection of Proteins on Blots Using Direct Blue 71 729
Wei-Tao Cong, Sun-Young Hwang, Li-Tai Jin, and Jung-Kap Choi

74 Detection of Proteins on Western Blots Using Colorimetric and Radiometric Visualization of Secondary Ligands 737
Nicholas J. Kruger

75 Identification of Glycoproteins on Nitrocellulose Membranes Using Lectin Blotting 755
Patricia Gravel

76 A Sensitive Method to Quantitatively Detect Total Protein on Membranes after Electrophoretic Transfer Using Avidin- or Streptavidin-Biotin 771
William J. LaRochelle

77 Detection and Quantification of Proteins on Immunoblots using Enhanced Chemiluminescence 779
Jennifer J. Young

78 Reutilization of Western Blots After Chemiluminescent or Autoradiographic Detection 789
Scott H. Kaufmann

79 The Use of Quantum Dot Luminescent Probes for Western Blot Analysis 807
Savvas C. Makrides, Christina Gasbarro, and Job M. Bello

80 The Use of Infrared Fluorescent Dyes in Quantitative Immunoblotting *819*
Ching-Hui Yang, Christopher Kasbek, and Harold A. Fisk

81 The Use of Infrared Fluorescent Dyes in Immunofluorescence Microscopy *827*
Christopher Kasbek, Ching-Hui Yang, and Harold A. Fisk

PART IV CHEMICAL MODIFICATION OF PROTEINS AND PEPTIDE PRODUCTION AND PURIFICATION

82 Carboxymethylation of Cysteine Using Iodoacetamide/Iodoacetic Acid *837*
Alastair Aitken and Michèle Learmonth

83 Performic Acid Oxidation *841*
Alastair Aitken and Michèle Learmonth

84 Succinylation of Proteins *845*
Alastair Aitken and Michèle Learmonth

85 Pyridylethylation of Cysteine Residues 847
Malcolm Ward

86 Side Chain Selective Chemical Modifications of Proteins 851
Dan S. Tawfik

87 Nitration of Tyrosines *855*
Dan S. Tawfik

88 Ethoxyformylation of Histidine 859
Dan S. Tawfik

89 Modification of Arginine Side Chains with *p*-Hydroxyphenylglyoxal *863*
Dan S. Tawfik

90 Amidation of Carboxyl Groups *865*
Dan S. Tawfik

91 Amidination of Lysine Side Chains *867*
Dan S. Tawfik

92 Modification of Tryptophan with 2-Hydroxy-5-Nitrobenzylbromide *871*
Dan S. Tawfik

93 Modification of Sulfhydryl Groups with DTNB *873*
Dan S. Tawfik

94 Chemical Cleavage of Proteins at Methionyl-X Peptide Bonds *875*
Bryan John Smith

95 Chemical Cleavage of Proteins at Tryptophanyl-X Peptide Bonds 883
Bryan John Smith

96 Chemical Cleavage of Proteins at Aspartyl-X Peptide Bonds 891
Bryan John Smith

97 Chemical Cleavage of Proteins at Cysteinyl-X Peptide Bonds 895
Bryan John Smith

98 Chemical Cleavage of Proteins at Asparaginyl-Glycyl Peptide Bonds 899
Bryan John Smith

99 Enzymatic Digestion of Proteins in Solution and in SDS Polyacrylamide Gels 905
Kathryn L. Stone, Erol E. Gulcicek, and Kenneth R. Williams

100 On-PVDF Protein Digestions for N-terminal Sequencing and Peptide Mass Fingerprinting 919
Victoria Pham, William Henzel, and Jennie R. Lill

101 Enzymatic Digestion of Membrane-Bound Proteins for Peptide Mapping and Internal Sequence Analysis 927
Joseph Fernandez and Sheenah M. Mische

102 Reverse-Phase HPLC Separation of Enzymatic Digests of Proteins 941
Kathryn L. Stone and Kenneth R. Williams

103 Peptide Mapping by Two-Dimensional Thin-Layer Electrophoresis-Thin-Layer Chromatography 951
Ralph C. Judd

104 Peptide Mapping by Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis 963
Ralph C. Judd

105 Peptide Mapping for Protein Characterization 969
Peter Højrup

106 Production of Protein Hydrolysates Using Enzymes 989
John M. Walker and Patricia J. Sweeney

107 Amino Acid Analysis by Precolumn Derivatization with 1-Fluoro-2,4-Dinitrophenyl-5-L-Alanine Amide (Marfey's Reagent) 995
Sunil Kochhar and Philipp Christen

108 Amino Acid Analysis of Protein Hydrolysates Using Anion Exchange Chromatography and IPAD Detection 1001
Petr Jandik, Jun Cheng, and Nebojsa Avdalovic

109 Validation of Amino Acid Analysis Methods *1015*
Andrew J. Reason

110 Molecular Weight Estimation for Native Proteins Using High-Performance Size-Exclusion Chromatography *1029*
G. Brent Irvine

111 Detection of Disulfide-Linked Peptides by HPLC *1039*
Alastair Aitken and Michèle Learmonth

112 Detection of Disulfide-Linked Peptides by Mass Spectrometry *1043*
Alastair Aitken and Michèle Learmonth

113 Diagonal Electrophoresis for Detecting Disulfide Bridges..... *1047*
Alastair Aitken and Michèle Learmonth

114 Estimation of Disulfide Bonds Using Ellman's Reagent..... *1053*
Alastair Aitken and Michèle Learmonth

115 Quantitation of Cysteine Residues and Disulfide Bonds by Electrophoresis *1057*
Alastair Aitken and Michèle Learmonth

116 N-Terminal Sequencing of N-Terminally Modified Proteins *1063*
Roza Maria Kamp and Hisashi Hirano

117 Deblocking of Proteins Containing N-Terminal Pyroglutamic Acid *1075*
Jacek Mozdzanowski

118 Detection and Characterization of Protein Mutations by Mass Spectrometry..... *1081*
Yoshinao Wada

119 Peptide Sequencing by Nanoelectrospray Tandem Mass Spectrometry *1095*
Ole Nørregaard Jensen and Matthias Wilm

120 Protein Identification by Peptide Mass Fingerprinting using MALDI-TOF Mass Spectrometry *1117*
Judith Webster and David Oxley

121 Protein Ladder Sequencing *1131*
Rong Wang and Brian T. Chait

122 Sequence Analysis with WinGene/WinPep..... *1141*
Lars Hennig

123 HPLC and Mass Spectrometry of Integral Membrane Proteins..... *1149*
Julian P. Whitelegge

124 Enrichment of Serum Peptides and Analysis by MALDI-TOF Mass Spectrometry *1167*
Yanming An, Habtom W. Ressom, and Radoslav Goldman

125 Computational Methods for Analysis of MALDI-TOF Spectra to Discover Peptide Serum Biomarkers *1175*
Habtom W. Ressom, Rency S. Varghese, and Radoslav Goldman

PART V POSTTRANSLATIONAL MODIFICATIONS

126 Simple Tools for Complex *N*-Glycan Analysis *1187*
Anne-Catherine Fitchette, Meriem Benchabane, Thomas Paccalet, Loïc Faye, and Véronique Gomord

127 A Lectin-Binding Assay for the Rapid Characterization of the Glycosylation of Purified Glycoproteins *1205*
Mohammad T. Goodarzi, Angeliki Fotinopoulou, and Graham A. Turner

128 Chemical Methods of Analysis of Glycoproteins *1215*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

129 Monosaccharide Analysis by HPAEC *1219*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

130 Monosaccharide Analysis by Gas Chromatography (GC) *1223*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

131 Determination of Monosaccharide Linkage and Substitution Patterns by GC-MS Methylation Analysis *1227*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

132 Sialic Acid Analysis by HPAEC-PAD *1231*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

133 Chemical Release of *O*-Linked Oligosaccharide Chains *1233*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

134 *O*-Linked Oligosaccharide Profiling by HPLC *1235*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

135 *O*-Linked Oligosaccharide Profiling by HPAEC-PAD *1237*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

136 Release of *N*-Linked Oligosaccharide Chains by Hydrazinolysis *1239*
Tsuguo Mizuochi and Elizabeth F. Hounsell

137 Enzymatic Release of *O*-and *N*-Linked Oligosaccharide Chains *1243*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

138 *N*-Linked Oligosaccharide Profiling by HPLC on Porous Graphitized Carbon (PGC) *1247*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

139 *N*-Linked Oligosaccharide Profiling by HPAEC-PAD *1249*
Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

140 HPAEC-PAD Analysis of Monosaccharides Released by Exoglycosidase Digestion Using the CarboPac MA1 Column *1253*
Michael Weitzhandler, Jeffrey Rohrer, James R. Thayer, and Nebojsa Avdalovic

141 Microassay Analyses of Protein Glycosylation *1261*
Nicky K. C. Wong, Nnennaya Kanu, Natasha Thandrayen, Geert Jan Rademaker, Christopher I. Baldwin, David V. Renouf, and Elizabeth F. Hounsell

142 Polyacrylamide Gel Electrophoresis of Fluorophore-Labeled Carbohydrates from Glycoproteins *1273*
Brian K. Brandley, John C. Klock, and Christopher M. Starr

143 HPLC Analysis of Fluorescently Labeled Glycans *1289*
Tony Merry and Sviatlana Astrautsova

144 Glycoprofiling Purified Glycoproteins Using Surface Plasmon Resonance *1313*
Angeliki Fotinopoulou and Graham A. Turner

145 Sequencing Heparan Sulfate Saccharides *1321*
Jeremy E. Turnbull

146 Analysis of Glycoprotein Heterogeneity by Capillary Electrophoresis and Mass Spectrometry *1335*
Andrew D. Hooker and David C. James

147 Affinity Chromatography of Oligosaccharides and Glycopeptides with Immobilized Lectins *1347*
Kazuo Yamamoto

148 In-Gel Enzymatic Release of *N*-Glycans *1363*
David J. Harvey

149 Analysis of *N*-Linked Glycans by Mass Spectrometry *1371*
David J. Harvey

150 MS Analysis of Protein Glycosylation *1387*
Nobuaki Takemori, Naoka Komori, and Hiroyuki Matsumoto

151 Mapping protein *N*-Glycosylation by COFRADIC *1395*
Bart Ghesquière, Joël Vandekerckhove, and Kris Gevaert

152 Mass Spectrometric Analysis of *O*-Linked Glycans Released Directly from Glycoproteins in Gels Using β-Elimination *1403*
Adrian M. Taylor and Jane Thomas-Oates

153 Glycopeptide Analysis Using LC/MS and LC/MS^n: *Site-Specific Glycosylation Analysis of a Glycoprotein* *1419*
Satsuki Itoh, Daisuke Takakura, Nana Kawasaki, and Teruhide Yamaguchi

154 Identification of Vitamin K-Dependent Proteins Using a Gla-Specific Monoclonal Antibody *1431*
Karin Hansson

155 The Identification of Protein S-Nitrosocysteine *1451*
Todd M. Greco, Sheryl L. Stamer, Daniel C. Liebler, and Harry Ischiropoulos

156 Detection of Nitrotyrosine-Containing Proteins *1467*
Xianquan Zhan and Dominic M. Desiderio

157 Mass Spectrometric Determination of Protein Ubiquitination *1491*
Carol E. Parker, Maria Warren Hines, Viorel Mocanu, Susanna F. Greer, and Christoph H. Borchers

158 Detection of Sumoylated Proteins *1519*
Ok-Kyong Park-Sarge and Kevin D. Sarge

159 Efficient Enrichment of Intact Phosphorylated Proteins by Modified Immobilized Metal-Affinity Chromatography *1531*
Anna Dubrovska

160 Analyzing Protein Phosphorylation *1547*
John Colyer

161 Mass Spectrometric Analysis of Protein Phosphorylation *1555*
Stefan Gander, Alessio Cremonesi, Johana Chicher, Suzette Moes, and Paul Jenö

162 Protein Microarrays for Phosphorylation Studies *1567*
Birgit Kersten and Tanja Feilner

163 Two-Dimensional Phosphopeptide Mapping *1579*
Hikaru Nagahara, Robert R. Latek, Sergei A. Ezhevsky, and Steven F. Dowdy

164 Identification of Proteins Modified by Protein (D-Aspartyl/L-Isoaspartyl) Carboxyl Methyltransferase *1589*
Darin J. Weber and Philip N. McFadden

165 Analysis of Tyrosine-*O*-Sulfation *1601*
Jens R. Bundgaard, Jette W. Sen, Anders H. Johnsen, and Jens F. Rehfeld

166 Analysis of Protein Palmitoylation by Metabolic Radiolabeling Methods *1623*
Katherine H. Pedone, Leah S. Bernstein, Maurine E. Linder, and John R. Hepler

167 Incorporation of Radiolabeled Prenyl Alcohols and Their Analogs into Mammalian Cell Proteins: *A Useful Tool for Studying Proteins Prenylation* *1637*
Alberto Corsini, Christopher C. Farnsworth, Paul McGeady, Michael H. Gelb, and John A. Glomset

168 The Metabolic Labeling and Analysis of Isoprenylated Proteins *1657*
Douglas A. Andres, Dean C. Crick, H. Peter Spielmann, and Charles J. Waechter

PART VI ANTIBODY TECHNIQUES

169 AntibodyP roduction *1679*
Robert Burns

170 Production of Antibodies Using Proteins in Gel Bands *1687*
Sally Ann Amero, Tharappel C. James, and Sarah C. R. Elgin

171 Raising Highly Specific Polyclonal Antibodies Using Biocompatible Support-Bound Antigens *1693*
Monique Diano and André Le Bivic

172 Production of Antisera Using Peptide Conjugates *1705*
Thomas E. Adrian

173 Small-Molecule–Protein Conjugation Procedures *1715*
Stephen Thompson

174 The Chloramine T Method for Radiolabeling Protein *1727*
Graham S. Bailey

175 The Lactoperoxidase Method for Radiolabeling Protein *1731*
Graham S. Bailey

176 The Bolton and Hunter Method for Radiolabeling Protein *1733*
Graham S. Bailey

177 Preparation of ^{125}I-Labeled Peptides and Proteins with High Specific Activity Using IODO-GEN *1735*
J. Michael Conlon

178 Purification and Assessment of Quality of Radioiodinated Protein *1743*
Graham S. Bailey

179 Purification of IgG by Precipitation with Sodium Sulfate or Ammonium Sulfate *1749*
Mark Page and Robin Thorpe

180 Purification of IgG Using Caprylic Acid *1753*
Mark Page and Robin Thorpe

181 Purification of IgG Using DEAE-Sepharose Chromatography *1755*
Mark Page and Robin Thorpe

182 Purification of IgG Using Ion-Exchange HPLC *1757*
Carl Dolman, Mark Page, and Robin Thorpe

183 Purification of IgG by Precipitation with Polyethylene Glycol (PEG) *1759*
Mark Page and Robin Thorpe

184 Purification of IgG Using Protein A or Protein G *1761*
Mark Page and Robin Thorpe

185 Analysis and Purification of IgG Using Size-Exclusion High Performance Liquid Chromatography (SE-HPLC) *1765*
Carl Dolman and Robin Thorpe

186 Purification of IgG Using Affinity Chromatography on Antigen-Ligand Columns *1769*
Mark Page and Robin Thorpe

187 Purification of IgG Using Thiophilic Chromatography *1773*
Mark Page and Robin Thorpe

188 Analysis of IgG Fractions by Electrophoresis *1775*
Mark Page and Robin Thorpe

189 Purification of Immunoglobulin Y (IgY) from Chicken Eggs *1779*
Christopher R. Bird and Robin Thorpe

190 Affinity Purification of Immunoglobulins Using Protein A Mimetic (PAM) *1783*
Giorgio Fassina, Giovanna Palombo, Antonio Verdoliva, and Menotti Ruvo

191 Detection of Serological Cross-Reactions by Western Cross-Blotting *1799*
Peter Hammerl, Arnulf Hartl, Johannes Freund, and Josef Thalhamer

192 Enzymatic Digestion of Monoclonal Antibodies *1811*
Sarah M. Andrew

193 How to Make Bispecific Antibodies *1819*
Ruth R. French

194 Antigen Measurement Using ELISA *1827*
William Jordan

195 Enhanced Chemiluminescence Immunoassay *1835*
Richard A. W. Stott

196 Immunoprecipitation and Blotting: *The Visualization of Small Amounts of Antigens Using Antibodies and Lectins* 1845
Stephen Thompson

197 Determination of Epitopes by Mass Spectrometry *1859*
Christine Hager-Braun and Kenneth B. Tomer

198 Immunogen Preparation and Immunization Procedures for Rats and Mice *1873*
Mark Page and Robin Thorpe

199 Making Hybridomas *1877*
Robert Burns

200 Growing Hybridomas *1887*
Gary Entrican, Catherine Jepson, and David Deane

201 Mouse Hybridomas as an Entryway to Monoclonal Antibody Design and Production *1901*
Eugene Mechetner

202 Potential Pitfalls in Monoclonal Antibody Development and Applications *1911*
Eugene Mechetner

203 Recombinant Antibody Expression and Purification *1929*
Achim Knappik and Ralf Brundiers
204 Screening Hybridoma Culture Supernatants Using Solid-Phase Radiobinding Assay *1945*
Mark Page and Robin Thorpe
205 Screening Hybridoma Culture Supernatants Using ELISA *1947*
Mark Page and Robin Thorpe
206 Growth and Purification of Murine MonoclonalA ntibodies *1949*
Mark Page and Robin Thorpe
207 Affinity Purification Techniques for Monoclonal Antibodies *1951*
Alexander Schwarz
208 A Rapid Method for Generating Large Numbers of High-Affinity Monoclonal Antibodies from a Single Mouse *1961*
Nguyen Thi Man and Glenn E. Morris
Index *1975*

Protein Determination by UV Absorption

Alastair Aitken and Michèle P. Learmonth

1. Introduction

1.1. Near UV Absorbance (280 nm)

Quantitation of the amount of protein in a solution is possible in a simple spectrometer. Absorption of radiation in the near UV by proteins depends on the Tyr and Trp content (and to a very small extent on the amount of Phe and disulfide bonds). Therefore the A_{280} varies greatly between different proteins (for a 1 mg/mL solution, from 0 up to 4 [for some tyrosine-rich wool proteins], although most values are in the range 0.5–1.5 ***[1]***). The advantages of this method are that it is simple, and the sample is recoverable. The method has some disadvantages, including interference from other chromophores, and the specific absorption value for a given protein must be determined. The extinction of nucleic acid in the 280-nm region may be as much as 10 times that of protein at their same wavelength, and hence, a few percent of nucleic acid can greatly influence the absorption.

1.2. Far UV Absorbance

The peptide bond absorbs strongly in the far UV with a maximum at about 190 nm. This very strong absorption of proteins at these wavelengths has been used in protein determination. Because of the difficulties caused by absorption by oxygen and the low output of conventional spectrophotometers at this wavelength, measurements are more conveniently made at 205 nm, where the absorbance is about half that at 190 nm. Most proteins have extinction coefficients at 205 nm for a 1 mg/mL solution of 30–35 and between 20 and 24 at 210 nm ***(2)***.

Various side chains, including those of Trp, Phe, Tyr, His, Cys, Met, and Arg (in that descending order), make contributions to the A_{205} ***(3)***.

The advantages of this method include simplicity and sensitivity. As in the method outlined in **Subheading 3.1.** the sample is recoverable and in addition there

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

is little variation in response between different proteins, permitting near-absolute determination of protein. Disadvantages of this method include the necessity for accurate calibration of the spectrophotometer in the far UV. Many buffers and other components, such as heme or pyridoxal groups, absorb strongly in this region.

2. Materials

1. 0.1 *M* K_2SO_4 (pH 7.0).
2. 5 m*M* potassium phosphate buffer, pH 7.0.
3. Nonionic detergent (0.01% Brij 35)
4. Guanidinium-HCl.
5. 0.2-µm Millipore (Watford, UK) filter.
6. UV-visible spectrometer: The hydrogen lamp should be selected for maximum intensity at the particular wavelength.
7. Cuvets, quartz, for <215 nm.

3. Methods

3.1. Estimation of Protein by Near UV Absorbance (280 nm)

1. A reliable spectrophotometer is necessary. The protein solution must be diluted in the buffer to a concentration that is well within the accurate range of the instrument (*see* **Notes 1** and **2**).
2. The protein solution to be measured can be in a wide range of buffers, so it is usually no problem to find one that is appropriate for the protein which may already be in a particular buffer required for a purification step or assay for enzyme activity, for example (*see* **Notes 3** and **4**).
3. Measure the absorbance of the protein solution at 280 nm, using quartz cuvets or cuvets that are known to be transparent to this wavelength, filled with a volume of solution sufficient to cover the aperture through which the light beam passes.
4. The value obtained will depend on the path length of the cuvet. If not 1 cm, it must be adjusted by the appropriate factor. The Beer-Lambert law states that:

$$A\,(\text{absorbance}) = \varepsilon\, c\, 1 \tag{1}$$

where ε = extinction coefficient, c = concentration in mol/L and l = optical path length in cm. Therefore, if ε is known, measurement of A gives the concentration directly, ε is normally quoted for a 1-cm path length.

5. The actual value of UV absorbance for a given protein must be determined by some absolute method, e.g., calculated from the amino acid composition, which can be determined by amino acid analysis ***(4)***. The UV absorbance for a protein is then calculated according to the following formula:

$$A_{280}\,(1\,\text{mg/mL}) = (5690 n_w + 1280 n_y + 120 n_c) / M \tag{2}$$

where n_w, n_y, and n_c are the numbers of Trp, Tyr, and Cys residues in the polypeptide of mass M and 5690, 1280 and 120 are the respective extinction coefficients for these residues (*see* **Note 5**).

3.2. Estimation of Protein by Far UV Absorbance

1. The protein solution is diluted with a sodium chloride solution (0.9% w/v) until the absorbance at 215 nm is <1.5 (*see* **Notes 1** and **6**).
2. Alternatively, dilute the sample in another non-UV-absorbing buffer such as 0.1 *M* K_2SO_4, containing 5 m*M* potassium phosphate buffer adjusted to pH 7.0 (*see* **Note 6**).
3. Measure the absorbances at the appropriate wavelengths (either A_{280} and A_{205}, or A_{225} and A_{215}, depending on the formula to be applied), using a spectrometer fitted with a hydrogen lamp that is accurate at these wavelengths, using quartz cuvets filled with a volume of solution sufficient to cover the aperture through which the light beam passes (details in **Subheading 3.1**).
4. The A_{205} for a 1 mg/mL solution of protein ($A_{205}^{1\,mg/mL}$) can be calculated within ±2%, according to the empirical formula proposed by Scopes ***(2)*** (*see* **Notes 7–10**):

$$A_{205}^{1\,mg/mL} = 27 + 120\,(A_{280} / A_{205}) \quad (3)$$

5. Alternatively, measurements may be made at longer wavelengths ***(5)***:

$$\text{Protein concentration}\,(\mu g/mL) = 144\,(A_{215} - A_{225}) \quad (4)$$

The extinction at 225 nm is subtracted from that at 215 nm; the difference multiplied by 144 gives the protein concentration in the sample in µg/mL. With a particular protein under specific conditions accurate measurements of concentration to within 5 µg/L are possible.

4. Notes

1. It is best to measure absorbances in the range 0.05–1.0 (between 10 and 90% of the incident radiation). At around 0.3 absorbance (50% absorption), the accuracy is greatest.
2. Bovine serum albumin is frequently used as a protein standard; 1 mg/mL has an A_{280} of 0.66.
3. If the solution is turbid, the apparent A_{280} will be increased by light scattering. Filtration (through a 0.2-µm Millipore filter) or clarification of the solution by centrifugation can be carried out. For turbid solutions, a convenient approximate correction can be applied by subtracting the A_{310} (proteins do not normally absorb at this wavelength unless they contain particular chromophores) from the A_{280}.
4. At low concentrations, protein can be lost from solution by adsorption on the cuvet; the high ionic strength helps to prevent this. Inclusion of a nonionic detergent (0.01% Brij 35) in the buffer may also help to prevent these losses.
5. The presence of non-protein chromophores (e.g., heme, pyridoxal) can increase A_{280}. If nucleic acids are present (which absorb strongly at 260 nm), the following formula can be applied. This gives an accurate estimate of the protein content by removing the contribution to absorbance by nucleotides at 280 nm, by measuring the A_{260} which is largely owing to the latter ***(6)***.

$$\text{Protein (mg/mL)} = 1.55\,A_{280} - 0.76\,A_{260} \quad (5)$$

Other formulae (using similar principles of absorbance differences) employed to determine protein in the possible presence of nucleic acids are the following *(7,8)*:

$$\text{Protein (mg/mL)} = (A_{235} - A_{280}) / 2.51 \quad (6)$$

$$\text{Protein (mg/mL)} = 0.183\,A_{230} - 0.075.8\,A_{260} \quad (7)$$

6. Protein solutions obey Beer-Lambert's Law at 215 nm provided the absorbance is <2.0.
7. Strictly speaking, this value applies to the protein in 6 *M* guanidinium-HCl, but the value in buffer is generally within 10% of this value, and the relative absorbances in guanidinium-HCl and buffer can be easily determined by parallel dilutions from a stock solution.
8. Sodium chloride, ammonium sulfate, borate, phosphate, and Tris do not interfere, whereas 0.1 *M* acetate, succinate, citrate, phthalate, and barbiturate show high absorption at 215 nm.
9. The absorption of proteins in the range 215–225 nm is practically independent of pH between pH values 4–8.
10. The specific extinction coefficient of a number of proteins and peptides at 205 nm and 210 nm ***(3)*** has been determined. The average extinction coefficient for a 1 mg/mL solution of 40 serum proteins at 210 nm is 20.5 ± 0.14. At this wavelength, a protein concentration of 2 µg/mL gives $A = 0.04$ ***(5)***.

The Lowry Method for Protein Quantitation

Jakob H. Waterborg

1. Introduction

The most accurate method of determining protein concentration is probably acid hydrolysis followed by amino acid analysis. Most other methods are sensitive to the amino acid composition of the protein, and absolute concentrations cannot be obtained ***(1)***. The procedure of Lowry et al. ***(2)*** is no exception, but its sensitivity is moderately constant from protein to protein, and it has been so widely used that Lowry protein estimations are a completely acceptable alternative to a rigorous absolute determination in almost all circumstances in which protein mixtures or crude extracts are involved.

The method is based on both the Biuret reaction, in which the peptide bonds of proteins react with copper under alkaline conditions to produce Cu^{+}, which reacts with the Folin reagent, and the Folin–Ciocalteau reaction, which is poorly understood but in essence phosphomolybdotungstate is reduced to heteropolybdenum blue by the copper-catalyzed oxidation of aromatic amino acids. The reactions result in a strong blue color, which depends partly on the tyrosine and tryptophan content. The method is sensitive down to about 0.01 mg of protein/mL, and is best used on solutions with concentrations in the range 0.01–1.0 mg/mL of protein.

2. Materials

1. Complex-forming reagent: Prepare immediately before use by mixing the following stock solutions in the proportion 100:1:1 (by vol), respectively:
   Solution A: 2% (w/v) Na_2CO_3 in distilled water.
   Solution B: 1% (w/v) $CuSO_4$ $5H_2O$ in distilled water.
   Solution C: 2% (w/v) sodium potassium tartrate in distilled water.
2. 2 *N* NaOH.
3. Folin reagent (commercially available): Use at 1 *N* concentration.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

4. Standards: Use a stock solution of standard protein (e.g., bovine serum albumin fraction V) containing 2 mg/mL protein in distilled water, stored frozen at −20°C. Prepare standards by diluting the stock solution with distilled water as follows:

Stock solution (µL)	0	2.5	5	12.5	25	50	125	250	500
Water (µL)	500	498	495	488	475	450	375	250	0
Protein conc. (µg/mL)	0	10	20	50	100	200	500	1000	2000

3. Method

1. To 0.1 mL of sample or standard (*see* **Notes 1–4**), add 0.1 mL of 2 *N* NaOH. Hydrolyze at 100°C for 10 min in a heating block or boiling water bath.
2. Cool the hydrolysate to room temperature and add 1 mL of freshly mixed complex-forming reagent. Let the solution stand at room temperature for 10 min (*see* **Notes 5** and **6**).
3. Add 0.1 mL of Folin reagent, using a vortex mixer, and let the mixture stand at room temperature for 30–60 min (do not exceed 60 min) (*see* **Note 7**).
4. Read the absorbance at 750 nm if the protein concentration was below 500 µg/mL or at 550 nm if the protein concentration was between 100 and 2000 µg/mL.
5. Plot a standard curve of absorbance as a function of initial protein concentration and use it to determine the unknown protein concentrations (*see* **Notes 8–13**).

4. Notes

1. If the sample is available as a precipitate, then dissolve the precipitate in 2 *N* NaOH and hydrolyze as described in **Subheading 3., step 1**. Carry 0.2-mL aliquots of the hydrolyzate forward to **Subheading 3., step 2**.
2. Whole cells or other complex samples may need pretreatment, as described for the Burton assay for DNA ***(3)***. For example, the perchloroacetic acid (PCA)/ethanol precipitate from extraction I may be used directly for the Lowry assay, or the pellets remaining after the PCA hydrolysis step (**Subheading 3., step 3** of the Burton assay) may be used for Lowry. In this latter case, both DNA and protein concentration may be obtained from the same sample.
3. Peterson ***(4)*** has described a precipitation step that allows the separation of the protein sample from interfering substances and also consequently concentrates the protein sample, allowing the determination of proteins in dilute solution. Peterson's precipitation step is as follows:
   a. Add 0.1 mL of 0.15% deoxycholate to 1.0 mL of protein sample.
   b. Vortex-mix, and stand at room temperature for 10 min.
   c. Add 0.1 mL of 72% trichloroacetic acid (TCA), vortex-mix, and centrifuge at 1000–3000 *g* for 30 min.
   d. Decant the supernatant and treat the pellet as described in **Note 1**.
4. Detergents such as sodium dodecyl sulfate (SDS) are often present in protein preparations, added to solubilize membranes or remove interfering

substances ***(5–7)***. Protein precipitation by TCA may require phosphotungstic acid (PTA) ***(6)*** for complete protein recovery:

a. Add 0.2 mL of 30% (w/v) TCA and 6% (w/v) PTA to 1.0 mL of protein sample.
b. Vortex-mix, and stand at room temperature for 20 min.
c. Centrifuge at 2000 *g* and 4°C for 30 min.
d. Decant the supernatant completely and treat the pellet as described in **Note 1**.

5. The reaction is very pH dependent, and it is therefore important to maintain the pH between 10 and 10.5. Therefore, take care when analyzing samples that are in strong buffer outside this range.
6. The incubation period is not critical and can vary from 10 min to several hours without affecting the final absorbance.
7. The vortex-mixing step is critical for obtaining reproducible results. The Folin reagent is reactive only for a short time under these alkaline conditions, being unstable in alkali, and great care should therefore be taken to ensure thorough mixing.
8. The assay is not linear at higher concentrations. Ensure that you are analyzing your sample on the linear portion of the calibration curve.
9. A set of standards is needed with each group of assays, preferably in duplicate. Duplicate or triplicate unknowns are recommended.
10. One disadvantage of the Lowry method is the fact that a range of substances interferes with this assay, including buffers, drugs, nucleic acids, and sugars. (The effect of some of these agents is shown in Table 1 in Chapter 3.) In many cases, the effects of these agents can be minimized by diluting them out, assuming that the protein concentration is sufficiently high to still be detected after dilution. When interfering compounds are involved, it is, of course, important to run an appropriate blank. Interference caused by detergents, sucrose, and EDTA can be eliminated by the addition of SDS ***(5)*** and a precipitation step (*see* **Note 4**).
11. Modifications to this basic assay have been reported that increase the sensitivity of the reaction. If the Folin reagent is added in two portions, vortex-mixing between each addition, a 20% increase in sensitivity is achieved ***(8)***. The addition of dithiothreitol 3 min after the addition of the Folin reagent increases the sensitivity by 50% ***(9)***.
12. The amount of color produced in this assay by any given protein (or mixture of proteins) is dependent on the amino acid composition of the protein(s) (*see* Introduction). Therefore, two different proteins, each for example at concentrations of 1 mg/mL, can give different color yields in this assay. It must be appreciated, therefore, that using bovine serum albumin (BSA) (or any other protein for that matter) as a standard gives only an approximate measure of

the protein concentration. The only time when this method gives an absolute value for protein concentration is when the protein being analyzed is also used to construct the standard curve. The most accurate way to determine the concentration of any protein solution is amino acid analysis.

13. A means of speeding up this assay using raised temperatures ***(10)*** or a microwave oven (*see* Chapter 5) has been described.

The Bicinchoninic Acid (BCA) Assay for Protein Quantitation

John M. Walker

1. Introduction

The bicinchoninic acid (BCA) assay, first described by Smith et al. ***(1)*** is similar to the Lowry assay, since it also depends on the conversion of Cu^{2+} to Cu^{+} under alkaline conditions (*see* Chapter 2). The Cu^{+} is then detected by reaction with BCA. The two assays are of similar sensitivity, but since BCA is stable under alkali conditions, this assay has the advantage that it can be carried out as a one-step process compared to the two steps needed in the Lowry assay. The reaction results in the development of an intense purple color with an absorbance maximum at 562 nm. Since the production of Cu^{+} in this assay is a function of protein concentration and incubation time, the protein content of unknown samples may be determined spectrophotometrically by comparison with known protein standards. A further advantage of the BCA assay is that it is generally more tolerant to the presence of compounds that interfere with the Lowry assay. In particular it is not affected by a range of detergents and denaturing agents such as urea and guanidinium chloride, although it is more sensitive to the presence of reducing sugars. Both a standard assay (0.1–1.0 mg protein/mL) and a microassay (0.5–10 µg protein/mL) are described.

2. Materials

2.1. Standard Assay

1. Reagent A: sodium bicinchominate (1.0 g), Na_2CO_3 (2.0 g), sodium tartrate (dihydrate) (0.16 g), NaOH (0.4 g), $NaHCO_3$ (0.95 g), made up to 100 mL. If necessary, adjust the pH to 11.25 with $NaHCO_3$ or NaOH (*see* **Note 1**).
2. Reagent B: $CuSO_4$ $5H_2O$ (0.4 g) in 10 mL of water (*see* **Note 1**).
3. Standard working reagent (SWR): Mix 100 vol of regent A with 2 vol of reagent B. The solution is apple green in color and is stable at room temperature for 1 wk.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2.2. Microassay

1. Reagent A: Na_2CO_3 (0.8 g), NaOH (1.6 g), sodium tartrate (dihydrate) (1.6 g), made up to 100 mL with water, and adjusted to pH 11.25 with 10 *M* NaOH.
2. Reagent B: BCA (4.0 g) in 100 mL of water.
3. Reagent C: $CuSO_4$ $5H_2O$ (0.4 g) in 10 mL of water.
4. Standard working reagent (SWR): Mix 1 vol of reagent C with 25 vol of reagent B, then add 26 vol of reagent A.

3. Methods

3.1. Standard Assay

1. To a 100-µL aqueous sample containing 10–100 µg protein, add 2 mL of SWR. Incubate at 60°C for 30 min (*see* **Note 2**).
2. Cool the sample to room temperature, then measure the absorbance at 562 nm (*see* **Note 3**).
3. A calibration curve can be constructed using dilutions of a stock 1 mg/mL solution of bovine serum albumin (BSA) (*see* **Note 4**).

3.2. Microassay

1. To 1.0 mL of aqueous protein solution containing 0.5–1.0 µg of protein/mL, add 1 mL of SWR.
2. Incubate at 60°C for 1 h.
3. Cool, and read the absorbance at 562 nm.

4. Notes

1. Reagents A and B are stable indefinitely at room temperature. They may be purchased ready prepared from Pierce, Rockford, IL.
2. The sensitivity of the assay can be increased by incubating the samples longer. Alternatively, if the color is becoming too dark, heating can be stopped earlier. Take care to treat standard samples similarly.
3. Following the heating step, the color developed is stable for at least 1 h.
4. Note, that like the Lowry assay, response to the BCA assay is dependent on the amino acid composition of the protein, and therefore an absolute concentration of protein cannot be determined. The BSA standard curve can only therefore be used to compare the relative protein concentration of similar protein solutions.
5. Some reagents interfere with the BCA assay, but nothing like as many as with the Lowry assay (*see* **Table 1**). The presence of lipids gives excessively high absorbances with this assay ***(2)***. Variations produced by buffers with sulfhydryl agents and detergents have been described ***(3)***.
6. Since the method relies on the use of Cu^{2+}, the presence of chelating agents such as EDTA will of course severely interfere with the method. However,

Table 1
Effect of Selected Potential Interfering Compounds[a]

	BCA assay (µg BSA found)		Lowry assay (µg BSA found)

0.1 *M* Cesium bicarbonate	49.50	49.70	Precipitated	

[a]Reproduced from **ref**. ***1*** with permission from Academic Press Inc.

it may be possible to overcome such problems by diluting the sample as long as the protein concentration remains sufficiently high to be measurable. Similarly, dilution may be a way of coping with any agent that interferes with the assay (*see* **Table 1**). In each case it is of course necesary to run an appropriate control sample to allow for any residual color development. A modification of the assay has been described that overcomes lipid interference when measuring lipoprotein protein content ***(4)***.

7. A modification of the BCA assay, utilizing a microwave oven, has been described that allows protein determination in a matter of seconds (*see* Chapter 5).
8. A method has been described for eliminating interfering compounds such as thiols and reducing sugars in this assay. Proteins are bound to nylon membranes and exhaustively washed to remove interfering compounds; then the BCA assay is carried out on the membrane-bound protein ***(5)***.
9. A comparison of the BCA, Lowry and Bradford assays for analyzing gylcosylated and non-glycosylated proteins have been made ***(6)***. Significant differences wee observed between the assays for non-glycosylated proteins with the BCA assay giving results closest to those from amino acid analysis. Glycosylated proteins were underestimated by the Bradford the method and overestimated by the BCA and Lowry methods. The results suggest a potential interference of protein glycosylation with colorimetric assays.
10. A modification of this assay for analysis complex samples, which involves removing contaminants from the protein precipitate with 1 *M* HCl has been reported ***(7)***.

The Bradford Method For Protein Quantitation

Nicholas J. Kruger

1. Introduction

A rapid and accurate method for the estimation of protein concentration is essential in various areas of biology and biochemistry. An assay originally described by Bradford (***1***) has become the preferred method for quantifying protein in many laboratories. This technique is simpler, faster, and more sensitive than the Lowry method. Moreover, when compared with the Lowry method, it is subject to less interference by common reagents and non-protein components of biological samples (*see* **Note 1**). Despite the introduction of alternative protein assays, the Bradford method remains a popular technique, with the original article ***(1)*** being cited over 3,500 times in primary research papers in 2006, thirty years after its initial publication.

The Bradford assay relies on the binding of the dye Coomassie Blue G250 to protein. Detailed studies indicate that the free dye can exist in four different ionic forms for which the pK_a values are 1.15, 1.82 and 12.4 ***(2)***. Of the three charged forms of the dye that predominate in the acidic assay reagent solution, the more cationic red and green forms have absorbance maxima at 470 nm and 650 nm, respectively. In contrast, the more anionic blue form of the dye, which binds to protein, has an absorbance maximum at 590 nm. Thus, the quantity of protein can be estimated by determining the amount of dye in the blue ionic form. This is usually achieved by measuring the absorbance of the solution at 595 nm (*see* **Note 2**).

The dye appears to bind most strongly to arginine and lysine residues of proteins and also, to lesser extents, histidine and aromatic residues (tryptophan, tyrosine and phenylalanine) ***(3,4)***. This specificity can lead to variation in the response of the assay to different proteins, which is the main drawback of the method (*see* **Note 3**). The original Bradford assay shows large variation in

response between different proteins *(5–7)*. Several modifications to the method have been developed to overcome this problem (*see* **Note 4**). However, these changes generally result in a less robust assay that is often more susceptible to interference by other chemicals. Consequently, the original method devised by Bradford remains the most convenient and widely used formulation. Two types of assay are described here: the standard assay which is suitable for measuring between 10 and 100 µg protein, and the microassay for detecting between 1 and 10 µg protein. Although the latter is more sensitive, it is also more prone to interference from other compounds because of the greater amount of sample relative to assay reagent in this form of the assay.

2. Materials

1. Assay reagent: dissolve 100 mg of Coomassie Blue G250 in 50 mL of 95% ethanol. The solution is then mixed with 100 mL of 85% phosphoric acid and made up to 1 L with distilled water (*see* **Note 5**).

   The reagent should be filtered through Whatman No. 1 filter paper and then stored in an amber bottle at room temperature. It is stable for several weeks. However, during this time dye may precipitate from solution and so the stored reagent should be filtered before use.
2. Protein standard (*see* **Note 6**): bovine γ-globulin at a concentration of 1mg/mL (100 µg/mL for the microassay) in distilled water is used as a stock solution. This should be stored frozen in small aliquots at −20°C. Since the moisture content of solid protein may vary during storage, the precise concentration of protein in the standard solution should be determined from its absorbance at 280 nm. The absorbance of a 1 mg/mL solution of γ-globulin, in a 1-cm light path, is 1.35. The corresponding values for two alternative protein standards, bovine serum albumin and ovalbumin, are 0.66 and 0.75, respectively.
3. Plastic and glassware used in the assay should be absolutely clean and detergent-free. Quartz (silica) spectrophotometer cuvettes should not be used, since the dye in the assay reagent binds to this material and thereby interferes with the assay. Traces of dye bound to glassware or plastic can be removed by rinsing with methanol or detergent solution.

3. Methods

3.1. Standard Assay Method

1. Pipet between 10 and 100 µg of protein in 100 µL total volume into a test tube. If the approximate protein concentration in the sample is unknown, assay a range of dilutions (1, 1/10, 1/100, 1/1000). Prepare duplicates of each sample.
2. For the calibration curve, pipet duplicate volumes of 10, 20, 40, 60, 80 and 100 µL of 1 mg/mL γ-globulin standard solution into test tubes, and make each up to 100 µL with distilled water. Pipet 100 µL of distilled water into a further tube to provide the reagent blank.
3. Add 5 mL of the assay reagent to each tube and mix well by inversion or gentle vortexing. Avoid foaming, which will lead to poor reproducibility.

4. Measure the A_{595} of the samples and protein standards against the reagent blank between 5 and 60 minutes after mixing (*see* **Note 7** *and* **Note 8**). The assay of the standard containing 100 µg protein should give an A_{595} value of about 0.4. The standard curve is not linear and the precise absorbance varies depending on the age of the assay reagent. Consequently, it is essential to construct a calibration curve for each set of assays (*see* **Note 9**).

3.2. Microassay Method

This form of the assay is more sensitive than the standard assay method described in 3.1. Consequently, it is useful when the amount of protein is limited (*see also* **Note 10**).

1. Pipet duplicate samples containing between 1 and 10 µg in a total volume of 100 µL into 1.5-mL polyethylene microfuge tubes. If the approximate protein concentration in the sample is unknown, assay a range of dilutions (1, 1/10, 1/100, 1/1000).
2. For the calibration curve, pipet duplicate volumes of 10, 20, 40, 60, 80 and 100 µL of 100 µg/mL γ-globulin standard solution into 1.5-mL microfuge tubes, and adjust the volume to 100 µL with water. Pipet 100 µL of distilled water into an additional microfuge tube to provide the reagent blank.
3. Add 1 mL of the assay reagent to each microfuge tube and mix gently, but thoroughly.
4. Measure the absorbance of each sample between 5 and 60 minutes after addition of the protein reagent (*see* **Note 7** *and* **Note 8**). The A_{595} value of a sample containing 10 µg γ-globulin is about 0.45. Figure 1 shows the typical response of three common protein standards using the microassay method.

4. Notes

1. The Bradford assay is relatively free from interference by most commonly used biochemical reagents. However, a few chemicals may significantly alter the absorbance of the reagent blank or modify the response of proteins to the dye (**Table 1**). The materials that are most likely to cause problems in biological extracts are detergents and ampholyte ***(3,8)***. These can be removed from the sample solution by gel filtration, dialysis or precipitation of protein with calcium phosphate ***(9,10)***. Alternatively, they can be included in the reagent blank and calibration standards at the same concentration as that found in the sample. The presence of base in the assay increases absorbance by shifting the equilibrium of the free dye toward the anionic form. This may present problems when measuring protein content in concentrated basic buffers ***(3)***. Guanidine hydrochloride and sodium ascorbate compete with dye for protein, leading to underestimation of the protein content ***(3)***. Additional care should be taken when attempting to quantify protein content in cruder biological samples. For example, measurement of protein in soil extracts is complicated by the presence of a range of polyphenolic compounds in humus that also bind to Coomassie Blue G250 thereby potentially overestimating soil protein content ***(11)***.

Table 1
Effects of Common Reagents on the Bradford Assay

	Absorbance at 600 nm	
Compound	Blank	Immunoglobulin
Control	0.005	0.264
0.02% SDS	0.003	0.250
0.1% SDS	0.042*	0.059*
0.1% Triton	0.000	0.278
0.5% Triton	0.051*	0.311*
1 M 2-Mercaptoethanol	0.006	0.273
1 M Sucrose	0.008	0.261
4 M Urea	0.008	0.261
4 M NaCl	–0.015	0.207*
Glycerol	0.014	0.238*
0.1 M Hepes (pH 7.0)	0.003	0.268
0.1 M Tris (pH 7.5)	–0.008	0.261
0.1 M Citrate (pH 5.0)	0.015	0.249
10 mM EDTA	0.007	0.235*
1 M $(NH_4)_2SO_4$	0.002	0.269

Data were obtained by mixing 5 µL of water (blank) or a solution containing 10 µg bovine immunoglobulin G with 5 µL of the specified compound before adding 200 µL of assay reagent. The asterisks indicate measurements that differ from the control by more than 0.02 absorbance unit for blank values or more than 10% for the samples containing protein. Data taken from ***ref. 7***.

2. Binding of protein to Coomassie Blue G250 shifts the absorbance maximum of the blue ionic form of the dye from 590 nm to 620 nm ***(2)***. It might, therefore, appear more sensible to measure the absorbance at the higher wavelength. However, at the usual pH of the assay, an appreciable proportion of the dye is in the green form (λ_{max} = 650 nm) which interferes with absorbance measurement of the dye-protein complex at 620 nm. Measurement at 595 nm represents the best compromise between maximising the absorbance due to the dye-protein complex while minimizing to the contribution from the green form of the free dye (***2–4***; *but see also* **Note 10**).
3. Under normal assay conditions that involve comparatively high molar protein/dye ratios the dye binds almost exclusively to arginine and lysine residues ***(4)***. The dye does not bind to free arginine or lysine, nor to peptides smaller than about 3000 Da ***(3,12)***. Many peptide hormones and other important bioactive peptides fall into the latter category, and the Bradford assay is not suitable for quantifying the amounts of such compounds.
4. The assay technique described here is subject to variation in sensitivity between individual proteins (*see* **Table 2**). Several modifications have been

suggested that reduce this variability ***(5–7,13)***. Generally, these rely on increasing either the dye content or the pH of the solution. In one variation, adjusting the pH by adding NaOH to the assay reagent improves the sensitivity of the assay and greatly reduces the variation observed with different proteins ***(7)***. (This is presumably due to an increase the proportion of free dye in the blue form, the ionic species that reacts with protein.) However, the optimum pH is critically dependent on the source and concentration of the dye (*see* **Note 5**). Moreover, the modified assay is far more sensitive to interference from detergents in the sample.

Particular care should be taken when measuring the protein content of membrane fractions. The conventional assay consistently underestimates the amount of protein in membrane-rich samples. Pre-treatment of the samples with membrane-disrupting agents such as NaOH or detergents may reduce this problem, but the results should be treated with caution ***(14)***. A useful alternative is to precipitate protein from the sample using calcium phosphate and then remove contaminating lipids (and other interfering substances, *see* **Note 1**) by washing with 80% ethanol ***(9,10)***.

5. The amount of soluble dye in Coomassie Blue G250 varies considerably between sources, and suppliers' figures for dye purity are not a reliable estimate of the Coomassie Blue G250 content ***(15)***. Generally, Serva Blue G is regarded to have the greatest dye content and should be used in the modified assays discussed in **Note 4**. However, the quality of the dye is not critical for routine protein determination using the method described in this chapter. The data presented in **Figure 1** were obtained using Brilliant Blue G (C.I. 42655; Product code B0770, Sigma-Aldrich Co.) which has a dye content of approximately 90% as determined by elemental analysis.
6. Whenever possible the protein used to construct the calibration curve should be the same as that being determined. Often this is impractical and the dye-response of a sample is quantified relative to that of a "generic" protein. Bovine serum albumin is commonly used as the protein standard because it is inexpensive and readily available in a pure form. The major argument for using this protein is that it allows the results to be compared directly with those of the many previous studies that have used bovine serum albumin as a standard. However, it suffers from the disadvantage of exhibiting an unusually large dye-response in the Bradford assay and, thus, may under-estimate the protein content of a sample. Increasingly, bovine γ-globulin is being promoted as a more suitable general standard since the dye binding capacity of this protein is closer to the mean of those proteins that have been compared (**Table 2**). Because of the variation in response between different proteins, it is essential to specify the protein standard used when reporting measurements of protein amounts using the Bradford assay.

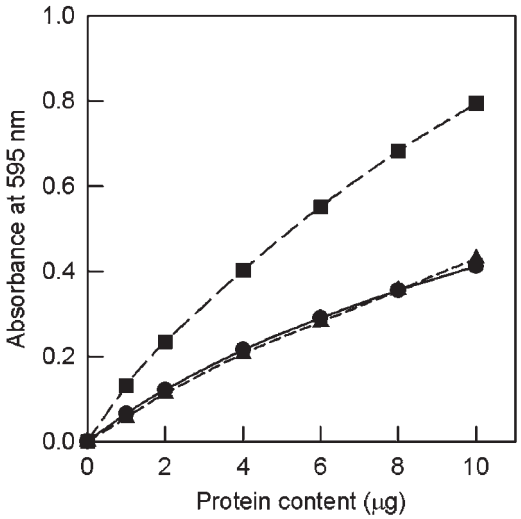

Fig. 1. Variation in the response of proteins in the Bradford assay. The extent of protein-dye complex formation was determined for bovine serum albumin (■), bovine γ-globulin (●) and chicken ovalbumin (▲) using the microassay method. Each value is the mean of four determinations. For each set of measurements the standard error was less than 5% of the mean value. The data allow comparisons to be made between estimates of protein content obtained using these protein standards.

7. The timing of these measurements is not critical, although it is better to be consistent. Sufficient time must be allowed for color development to be complete. The speed of formation of the dye-protein complex is temperature dependent, and as the reagent temperature increases so the absorbance of the assay mixture will increase. Therefore it is important that the assay reagent is at room temperature at the beginning of the assay. However, over time dye-protein aggregates form and become sufficiently large to produce a visible precipitate that interferes with accurate spectrophotometric measurement of the dye-protein complex. This is usually not a problem within the first hour after addition of the assay reagent, but if an obvious precipitate has formed before the absorbance is measured, the assay should be repeated and the absorbance measured sooner after addition of the assay reagent. Formation of a precipitate almost immediately after addition of the assay reagent is usually the result of detergent (or other interfering substances) in the protein sample.
8. Generally, it is preferable to use a single new disposable polystyrene semi-micro cuvette that is discarded after a series of absorbance measurements. Rinse the cuvette with reagent before use, zero the spectrophotometer on the reagent blank and then do not remove the cuvette from the machine. Replace the sample in the cuvette gently using a disposable polyethylene pipet.

Table 2
Comparison of the Response of Different Proteins in the Bradford Assay

	Relative absorbance	
Protein	Assay 1	Assay 2
Myelin basic protein	139	–
Histone	130	175
Cytochrome c	128	142
Bovine serum albumin	100	100
Insulin	89	–
Transferrin	82	–
Lysozyme	73	–
α-Chymotrypsinogen	55	–
Soybean trypsin inhibitor	52	23
Ovalbumin	49	23
γ-Globulin	48	55
β-Lactoglobulin A	20	–
Trypsin	18	15
Aprotinin	13	–
Gelatin	–	5
Gramicidin S	5	–

For each protein, the response is expressed relative to that of the same concentration of bovine serum albumin. The data for Assays 1 and 2 are recalculated from ***ref. 5*** *and* ***7***, respectively.

9. The standard curve is non-linear because of problems introduced by depletion of the amount of free dye. These problems can be avoided, and the linearity of the assay improved, by plotting the ratio of absorbances at 595 and 450 nm ***(16)***. If this approach is adopted, the absolute optical density of the free dye and dye-protein complex must be determined by measuring the absorbance of the mixture at each wavelength relative to that of a cuvette containing only water (and no assay reagent). As well as improving the linearity of the calibration curve, taking the ratio of the absorbances at the two wavelengths increases the accuracy and improves the sensitivity of the assay by up to 10-fold ***(16)***.
10. For routine measurement of the protein content of many samples the microassay may be adapted for use with a microplate reader ***(7,17)***. The total volume of the modified assay is limited to 210 µL by reducing the volume of each component. Ensure effective mixing of the assay components by pipetting up to 10 µL of the protein sample into each well before adding 200 µL of the assay reagent. If a wavelength of 595 nm cannot be selected on the microplate reader, absorbance may be measured at any wavelength between 570 nm and 610 nm. However, absorbance measurements at wavelengths other than 595 nm will decrease the sensitivity of response and may increase the minimum detection limit of the protocol.

Ultrafast Protein Determinations Using Microwave Enhancement

Robert E. Akins and Rocky S. Tuan

1. Introduction

In this chapter, we describe modifications of existing protein assays that take advantage of microwave irradiation to reduce assay incubation times from the standard 15–60 min down to just seconds ***(1)***. Adaptations based on two standard protein assays will be described:

1. The classic method of Lowry et al. (**ref.** *2* and *see* Chapter 2), which involves intensification of the biuret reaction through the addition of Folin-Ciocalteau phenol reagent; and
2. The recently developed method of Smith et al. ***(3)***, which involves intensification of the biuret assay through the addition of bicinchoninic acid (BCA) (*see* Chapter 3).

Performing incubations in a 2.45–GHz microwave field (i.e., in a microwave oven) for 10–20 s results in rapid, reliable, and reproducible protein determinations. We have provided here background information concerning protein assays in general and the microwave enhanced techniques in particular. The use of microwave exposure as an aid in the preparation of chemical and biological samples is well established; interested readers are directed to Kok and Boon ***(4)*** for excellent discussions concerning the application of microwave technologies in biological research.

1.1. Microwave Assay

Household microwave ovens expose materials to nonionizing electromagnetic radiation at a frequency of about 2.45 GHz (i.e., 2.45 billion oscillations/s). Such exposures have been applied to a myriad of scientific purposes including tissue fixation, histological staining, immunostaining, PCR, and many others. The

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

practical and theoretical aspects of many microwave techniques are summarized by Kok and Boon ***(4),*** and the reader is directed to this reference for excellent discussions concerning general procedures and theoretical background.

Microwave ovens are conceptually simple and remarkably safe devices (*see* **Note 1**). Typically, a magnetron generator produces microwaves that are directed toward the sample chamber by a wave guide. The beam is generally homogenized by a "modestirrer," consisting of a reflecting fan with angled blades that scatter the beam as it passes. The side walls of the chamber are made of a microwave reflective material, and the microwaves are thereby contained within the defined volume of the oven (*see* **Note 2**). Specimens irradiated in a microwave oven absorb a portion of the microwave energy depending on specific interactions between the constituent molecules of the sample and the oscillating field.

As microwaves pass through specimens, the molecules in that specimen are exposed to a continuously changing electromagnetic field. This field is often represented as a sine wave with amplitude related to the intensity of the field at a particular point over time and wavelength related to the period of oscillation. Ionically polarized molecules (or dipoles) will align with the imposed electromagnetic field and will tend to rotate as the sequential peaks and troughs of the oscillating "wave" pass. Higher frequencies would, therefore, tend to cause faster molecular rotations. At a point, a given molecule will no longer be able to reorient quickly enough to align with the rapidly changing field, and it will cease spinning. There exists, then, a distinct relationship between microwave frequency and the "molecular-size" of the dipoles that it will affect. This relationship is important, and at the 2.45–GHz frequency used in conventional microwave ovens, only small molecules may be expected to rotate; specifically, water molecules rotate easily in microwave ovens but proteins do not (*see* **Note 3**).

For most microwave oven functions, a portion of the rotational energy of the water molecules in a sample dissipates as heat. Since these molecular rotations occur throughout exposed samples, microwave ovens provide extremely efficient heating, and the effects of microwaves are generally attributed to changes in local temperature. At some as yet undetermined level, however, microwave exposure causes an acceleration in the rate of reaction product formation in the protein assays discussed here. This dramatic acceleration is independent of the change in temperature, and our observations have suggested that microwave-based heating is not the principal means of reaction acceleration.

1.2. Microwave Enhanced Protein Determinations

Modifications of the procedures of Lowry (Chapter 2) and Smith (Chapter 3) to include microwave irradiation result in the generation of linear standard curves. **Figure 1** illustrates typical standard curves for examples of each assay using bovine serum albumin (BSA). Both standard curves are linear across a practical range of protein concentrations.

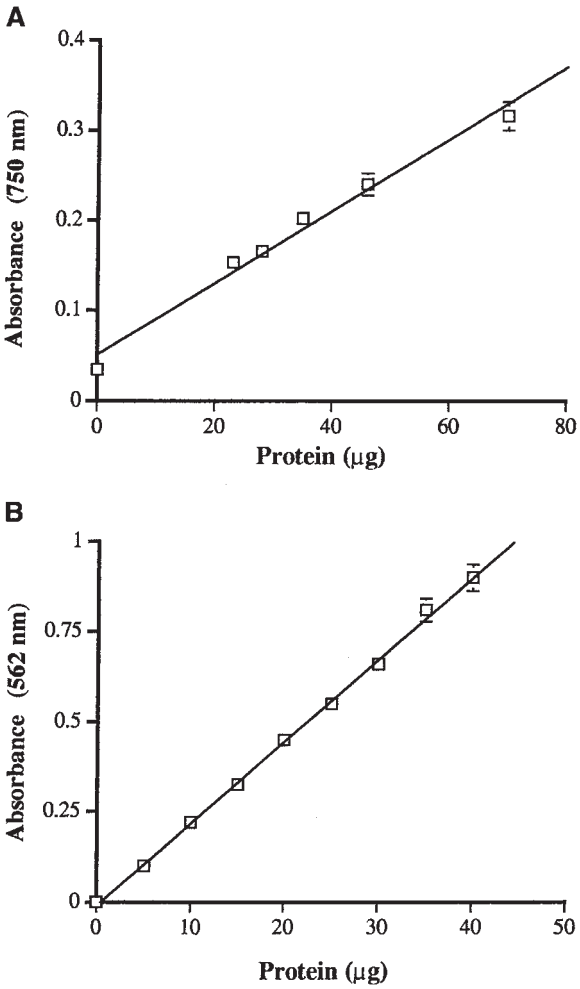

Fig. 1. Typical standard curves for microwave Lowry and BCA assays. Standard curves were generated with microwave protocols using BSA (Sigma) dissolved in water. BSA samples in 100-µL vol were prepared in triplicate for each assay and were combined with reagent as described in **Notes 1** and **2**. Tubes and a water load (total vol 100 mL, *see* **Note 5**) were placed in the center of a microwave oven. Samples for the Lowry assay were irradiated for 10 s; samples for the BCA assay were irradiated for 20 s. Results in **A** show a linear standard curve generated using a microwave Lowry assay. Results in **B** show a linear standard curve generated using a microwave BCA assay. Values presented are means ± SD.

One interesting difference between the two microwave enhanced assays concerns the relationship between irradiation time and assay sensitivity. In the *DC Protein Assay*, a modification of Lowry's ***(2)*** procedure supplied by Bio-Rad

Laboratories, Inc. (Hercules, CA), illustrated in **Fig. 1**, a colorimetric end point was reached after 10 s of microwave irradiation; no further color development occurred in the samples. This end point was identical to that achieved in a 15-min room temperature control assay.

The *BCA* Protein Assay*, a version of Smith's assay ***(3)*** supplied by Pierce Chemical Co. (Rockford, IL), afforded some flexibility in assay sensitivity because the formation of detectable reaction product was a function of the duration of microwave exposure. **Figure 2** shows the rate of reaction product formation for three different concentrations of BSA as a function of microwave exposure in a BCA assay. Absorbance values increased for each BSA concentration as a second order function of irradiation time. A linear standard curve could be generated from BSA dilutions that were irradiated for any specific time; longer irradiation times yielded more steeply sloped standard curves. In practice, then, the duration of microwave exposure can be selected to correspond to a desired sensitivity range with longer times being more suitable for lower protein concentrations. In contrast to the *DC Protein Assay*, the BCA microwave procedure described here is more sensitive than a standard, room temperature assay, and we have used it for most applications (*see* **Note 4**).

Figure 3 illustrates that the dramatic effects of microwave exposure cannot be mimicked by external heating. These results are surprising since microwave

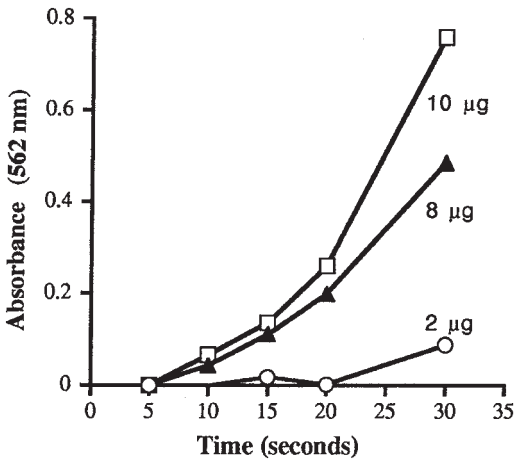

Fig. 2. Effect of Increasing microwave irradiation time on the BCA assay. Three amounts of BSA (Sigma) were prepared in water: 10 µg/tube (□), 8 µg/tube (▲), 2 µg/tube (○). Each time point was determined from triplicate samples in a single irradiation trial with the water load replaced between determinations. Each assay time resulted in the generation of a linear standard curve; the slope of each standard curve increased as a function of irradiation time. Values were normalized to the 5-s time point and presented as means ± SD.

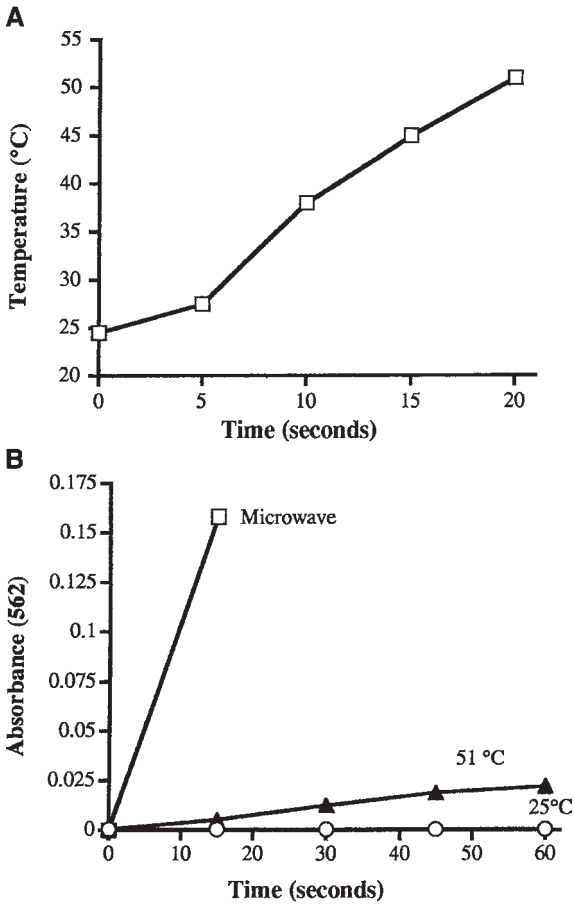

Fig. 3. Comparison of microwave irradiation with incubation at elevated temperature. (A) The change in temperature of BCA assay samples containing bovine serum albumin (BSA, Sigma). Temperatures reached 51°C during a typical 20-s irradiation. Since the assays are carried out in an open system, temperatures near 100°C would cause sample boil-over and should be avoided. (B) Development of reaction product under three different conditions: microwave irradiation (□), incubation at 51°C (▲), and incubation at 25°C (○). Incubation at 51°C, the maximal temperature reached during a 20-s irradiation, did not mirror microwave irradiation.

effects are generally attributed to increases in temperature. It is not clear at what level(s) microwaves interact with the biochemical processes involved in protein estimation; however, the acceleration is possibly related to an alteration in solvent/solute interactions. As the solvent water molecules rotate, specific structural changes may occur in the system such that interactions between

solvent and solute molecules (or among the solvent molecules themselves) tend to enhance the chemical interactions between the protein and the assay components to accelerate the rate of product formation. For example, water molecules rotating in a microwave field may no longer be available to form hydrogen bonds within the solvent/solute structure. Clearly, the nature and mechanism of nonthermal microwave effects need to be studied further.

2. Materials

2.1. Lowry Assay (see Chapter 2)

Lowry reagents are available from commercial sources. Assay reagents were routinely purchased from Bio-Rad Laboratories in the form of a detergent-compatible Lowry kit (*DC Protein Assay*). Assay reactions are typically carried out in polystyrene Rohren tubes (Sarstedt, Inc., Newtown, NC). Tubes were placed in a plastic test tube rack at the center of a suitable microwave oven (*see the following*) along with a beaker containing approx 100 mL of H_2O (*see* **Note 5**).

2.2. BCA Assay (see Chapter 3)

BCA protein reagent is available from commercial sources. Assay reagents are routinely purchased from Pierce Chemical Co. in the form of a *BCA* Protein Assay* kit. As with the Lowry assay, reactions were typically carried out in polystyrene Rohren tubes (Sarstedt). Tubes were placed in a plastic test tube rack at the center of a suitable microwave oven (*see* **Subheading 3.2**) along with a beaker containing approx 100 mL of H_2O (*see* **Note 5**).

3. Methods

3.1. Sample Preparation

Sample preparation should be carried out as specified by the manufacturers. Generally, samples are solubilized in a noninterfering buffer (*see* **Note 3**) so that the final protein concentration falls within the desired range (*see* **Note 4**). Samples should be either filtered or centrifuged to remove any debris prior to protein determination.

3.2. Selection of Microwave Oven

Microwave ovens differ substantially in their suitability for these assays. Desirable attributes include fine control of irradiation time, a chamber size large enough to easily accommodate the desired number of samples, and a configuration that results in a homogenous field of irradiation so that all samples within the central volume of the oven receive a uniform microwave dose (*see* **Note 4**). Samples should be placed in a nonmetallic test tube rack in the center of the oven. A volume of room temperature water is included in the oven chamber as

well so that the total amount of fluid (samples + additional water) is constant from one assay to another (*see* **Note 5**).

3.3. Sample Irradiation

Once the samples are placed into the center of the microwave chamber, close the door and irradiate the samples. Using the *DC Protein Assay*, a 10-s irradiation was optimal as a replacement for the standard 15–min incubation. Using the *BCA* Protein Assay*, a 20-s irradiation has proved adequate in most situations. We have found it most convenient to use the highest setting on the microwave oven and to control exposure using an accurate timer.

3.4. Reading and Interpreting Assay Results

After irradiation, the absorbance of each sample and standard should be determined spectrophotometrically. Samples from Lowry assays should be read at 750 nm and samples from BCA assays should be read at 562 nm. A standard curve of absorbance values as a function of standard protein concentration can be generated easily and used to determine the protein levels in the unknown samples. It is recommended that standard curves be generated along with each assay to avoid any difficulties that may arise from differences in reagents or alterations in total microwave exposure.

3.5. Summary

In summary, the microwave BCA protein assay protocol is as follows:

1. Combine samples and BSA standards with BCA assay reagent in polystyrene tubes;
2. Place samples into an all plastic test tube rack in the center of a microwave oven along with a beaker containing a volume of room temperature water sufficient to make the total volume of liquid in the chamber 100 mL;
3. Irradiate samples for 20 s on the highest microwave setting; and
4. Measure A_{562} for each sample and determine protein concentrations based on a BSA calibration curve.

The microwave Lowry assay protocol is virtually identical:

1. Combine samples and Lowry assay reagents in polystyrene tubes;
2. Place samples into an all plastic test tube rack in the center of a microwave oven along with a beaker containing a volume of room temperature water sufficient to make the total volume of liquid in the chamber 100 mL;
3. Irradiate samples for 10 s on the highest microwave setting; and
4. Measure A_{750} for each sample and determine protein concentrations based on a BSA calibration curve.

Microwave protein assays are suitable for all situations where standard assays are presently used. The ability to determine accurate protein concentrations in so little time should greatly facilitate routine assays and improve efficiency when

protocols require protein determination at multiple intermediate steps. Similar microwave techniques have also been applied as time-saving and efficiency-enhancing procedures by several authors (*see* **ref.** *4*). We have used microwave assays to generate chromatograms during protein purification and for general protein determinations (e.g., before electrophoretic analysis). The assays consistently yield reliable results that are comparable to those obtained by standard protocols. The modifications we present here are very easily adapted to most commercially available microwave ovens and, in the case of the BCA assay, can be adjusted to cover a wide range of protein concentrations. Since the duration of the assays is so short, it is possible to try several irradiation times and water loads to select the specific conditions required by the particular microwave and samples to be used. Microwave enhanced protein estimations should prove to be extremely useful in laboratories currently doing standard Smith ***(3)*** or Lowry ***(2)*** based protein determinations.

4. Notes

1. Although microwave radiation is nonionizing, precautions should be taken to avoid direct irradiation of parts of the body. Microwaves can penetrate the skin and cause significant tissue damage in relatively short periods of time. Most contemporary microwave ovens are remarkably safe and leakage is unlikely; however, periodic assessment of microwave containment within the microwave chamber should be carried out. Perhaps more dangerous than radiation effects are potential problems caused by the rapid heating of irradiated samples. Care should be taken when removing samples from the microwave chamber to avoid getting burned, sealed containers should not be irradiated as they may explode, and metal objects should be excluded from the chamber to avoid sparking. Users should consult their equipment manuals and institute safety offices prior to using microwave ovens. A detailed discussion of microwave hazards is included in **ref.** *4*.
2. Microwave ovens use a nominal frequency of 2.45 GHz. The energy put into the microwave chamber is actually a range of frequencies around 2.45 GHz. As the waves in the oven reflect off of the metal chamber walls, "hot" and "cold" spots may be set up by the constructive and destructive interference of the waves. The positions of these "hot" and "cold" spots is a function of the physical design of the oven chamber and the electrical properties of the materials contained in the oven. The unevenness of microwave fields can be minimized by mode stirring *(see* the preceeding*),* appropriate oven configuration, or by rotating the specimen in the chamber during irradiation. If the design of a particular microwave oven does not provide a relatively uniform irradiation volume, it may not be useful for the assays outlined here.

The suitability of a particular microwave oven may be tested easily using a number of tubes with known concentrations of protein. Uneven irradiation patterns will be detected by significant differences in the color development for a given protein concentration as a function of position within the oven chamber. We have had success with several microwave ovens including a 0.8 cu ft, 600 W, General Electric oven, model JEM18F001 and a 1.3 cu ft, 650 W, Whirlpool oven, model RJM7450.

3. The frequency used in household microwave ovens is actually below the resonance frequency for water. Above the 2.45 GHz used in household microwave ovens, water molecules are capable of rotating faster and of absorbing substantially more microwave energy. Too much absorption, however, is undesirable. It is possible that the outer layers of a sample may absorb energy so efficiently that the interior portions receive substantially less energy. The resulting uneven exposure may have adverse effects.

   It is important to note that molecules other than water may absorb microwave energy. If a compound added to a microwave enhanced assay absorbs strongly near 2.45 GHz, uneven sample exposures may result because of the presence of the compound. In addition, compounds that are degraded or converted during a microwave procedure, or compounds that have altered interactions with other assay components during irradiation, may substantially affect assay results. Although it may be possible to predict which materials would interfere with a given assay by considering the relevant chemical and electrical characteristics of the constituent compounds, potential interference is most easily assessed empirically by directly determining the effects of a given additive on the accuracy and sensitivity of the standard microwave assay.
4. Assay sensitivity may be improved by increasing irradiation time. The time required may be determined quickly by using BSA test solutions in the range of protein concentrations expected until desirable A_{562} values were obtained. By increasing microwave exposure time, it is possible to substantially increase assay sensitivity while keeping irradiation times below 60 s. The ease with which sensitivity may be adjusted within extremely short time frames places the microwave BCA assay among the quickest, most flexible assays available for protein determinations.
5. The addition of a volume of water to the microwave chamber, such that the total volume contained in the microwave chamber is constant from one assay to the next, allows irradiation conditions to be controlled easily from assay to assay. The additional water acts as a load on the oven and absorbs some of the microwave energy. Since the total amount of water remains constant from one assay to the next, the amount of

energy absorbed also remains constant. The time of irradiation, therefore, becomes independent of the number of samples included in the assay.

The Nitric Acid Method for Protein Estimation in Biological Samples

Scott A. Boerner, Crescent R. Isham, Yean Kit Lee, Jennifer D. Tibodeau, Scott H. Kaufmann, and Keith C. Bible

1. Introduction

1.1. Background

The quantitation of protein in biological samples is of great importance and utility in many research laboratories. Protein measurements are widely utilized to ensure equal loading of samples on sodium dodecyl sulfide (SDS)-polyacrylamide gels and to provide a basis for comparison of enzyme activities and other analytes.

Several methods are commonly employed for the determination of protein content in biological samples, including the measurement of absorbance at 260 ***(1)*** or 205 nm (***2***, and Chapter 1); the method of Lowry et al. (***3***, and Chapter 2), which relies on the generation of a new chromophore on reaction of an alkaline protein hydrolysate with phosphotungstic-phosphomolybdic acid in the presence of Cu^{2+} ***(4)***; the method of Smith et al. (***5***, and Chapter 3), which relies upon the reduction of Cu^{2+} to Cu^{+}, which then forms a colored complex with bicinchoninic acid (BCA); the method of Bradford (***6***, and Chapter 4), which relies on a change in absorbance on binding of Coomassie Blue to basic and aromatic amino acids under acidic conditions ***(7)***; and the method of Böhlen et al. ***(8)***, which relies on the reaction of fluorescamine with primary amines to generate a fluorescent product. Unfortunately, compounds that are constituents of biological buffers sometimes interfere with these methods, limiting their application.

Nucleic acids, neutral detergents of the polyoxyethylenephenol class, SDS, and urea interfere with spectrophotometric determinations at 260 and 205 nm ***(9)***. Several components commonly used in biological buffers, including

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

tris-hydroxymethyl-amino methane (Tris), N-2-hydroxyethylpiperazine-N-2-ethanesulfonic [acid] (HEPES), ethylenediaminetetraacetic acid (EDTA), neutral detergents, and reducing agents, interfere with the method of Lowry et al. ***(10)***. In addition, Tris, ammonium sulfate, EDTA, and reducing agents interfere with the BCA method, although neutral detergents and SDS do not ***(5)***. Finally, many commonly used reagents, including neutral detergents and SDS, interfere with the method of Bradford ***(6)***. Details of compounds that interfere with these assays can be found in **Table 1**, Chapter 3.

Several approaches have been proposed to circumvent the aforementioned difficulties. Protein precipitation with deoxycholate and trichloroacetic acid will eliminate many interfering substances ***(10)***, but the inclusion of this step is laborious when multiple samples are being analyzed simultaneously. Alternatively, samples can be lysed in a buffer that is compatible with a particular assay, then diluted into a second buffer after analysis. For example, cells lysed in Triton X-100 can be assayed for protein and then diluted into SDS sample buffer in preparation for SDS-polyacrylamide gel electrophoresis (SDS-PAGE). This approach, however, can lead to false results, as illustrated by the demonstration that caspase-3 activation in lysates of mitogen-stimulated lymphocytes reflects proteolytic cleavage occurring in the cell lysate rather than in the intact cells prior to lysis ***(11, 12)***. Finally, protein can be estimated by solubilizing samples directly in SDS sample buffer, spotting them onto a solid support (e.g., glass or nitrocellulose), washing away interfering substances, reacting the immobilized polypeptides with Coomassie Blue, and eluting the Coomassie Blue to estimate the protein content ***(13, 14)***, but this process is time and labor intensive.

As a result of these shortcomings, there is still a need for alternative methods of protein determination in biological samples. The nitric acid method detailed in this chapter represents one such method ***(15)***. This method is based upon studies dating to the 1800s demonstrating that aromatic molecules undergo nitration when treated with nitric acid. In particular, treatment of tyrosine with nitric acid produces 3-nitrotyrosine ***(16)***, which is distinguished from the parent compound by the appearance of a new absorbance peak at 358 nm. The method detailed in this chapter utilizes this chemistry to create a one-step method for protein determination in biological samples.

1.2. Nitric Acid Method for Protein Determination

1.2.1. Technique Derivation

Our laboratory has frequently examined the cellular accumulation of cytotoxic therapeutic drugs ***(17, 18)***. Because of concern about drug efflux from cells during the course of manipulation (e.g., trypsinization and centrifugation), we sought a method for the assessment of protein content after cells were washed

in situ and then solubilized directly in nitric acid, a matrix used for platinum-DNA adduct determination.

During the course of solubilizing cells in nitric acid, we noted a brownish color change that varied in intensity with the quantity of cells. Examination of the absorbance spectrum of these nitric acid lysates demonstrated a peak at 358 nm (**Fig. 1A**, inset) that was not present in cells solubilized in SDS sample buffer. Comparison of two human leukemia cell lines, HL-60 (diameter 11 μm) and K562 (diameter 15 μm), revealed that the absorbance at 358 nm increased linearly with cell number and that the slope was two-fold higher in the larger cell line (**Fig. 1A**). We hypothesized that the new absorbance peak at 358 nm reflected a reaction of nitric acid with one or more amino acids. While nitric acid solubilization of L-tyrosine produced a sharp peak at 358 nm and similar treatment of L-tryptophan produced a shoulder at the same wavelength, other amino acids, including L-serine, L-arginine, L-phenylalanine, L-threonine, L-alanine, L-proline, L-valine, L-histidine, L-methionine, L-isoleucine, L-glutamic acid, L-aspartic acid and L-asparagine failed to yield products that absorbed at 358 nm (**Fig. 1B** and data not shown). Nucleotides (ATP, CTP, GTP, TTP, UTP), RNA, and DNA also failed to yield products that absorbed at 358 nm (data not shown). These investigations led us to propose that the 358 nm absorbance peak observed after nitric acid solubilization of cells primarily reflects the tyrosine content of cellular proteins.

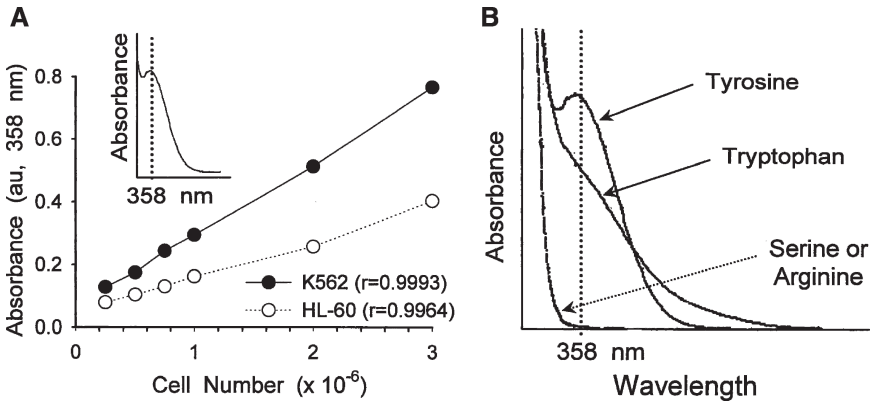

Fig. 1. Treatment of cells or L-tyrosine with nitric acid results in an increase in absorbance at 358 nm. **(A)** Relationship between cell number and absorbance at 358 nm in HL-60 and K562 cells solubilized in nitric acid for 24 h. *Inset*, absorbance spectrum resulting from treatment of OV202 cells with nitric acid. **(B)** Absorbance spectra resulting from treatment of L-tyrosine, L-tryptophan, L-serine, or L-arginine with nitric acid for 1 h. Amino acid concentrations in nitric acid were all 0.1 mg/mL.

To better understand the chemistry responsible for these observations, we solubilized L-tyrosine in nitric acid for 1 h. A single reaction product was formed that co-migrated with authentic 3-nitrotyrosine by high performance liquid chromatography (HPLC) and had an absorbance maximum at 358 nm (**Fig. 2**). Incubation for prolonged periods of time resulted in disappearance of

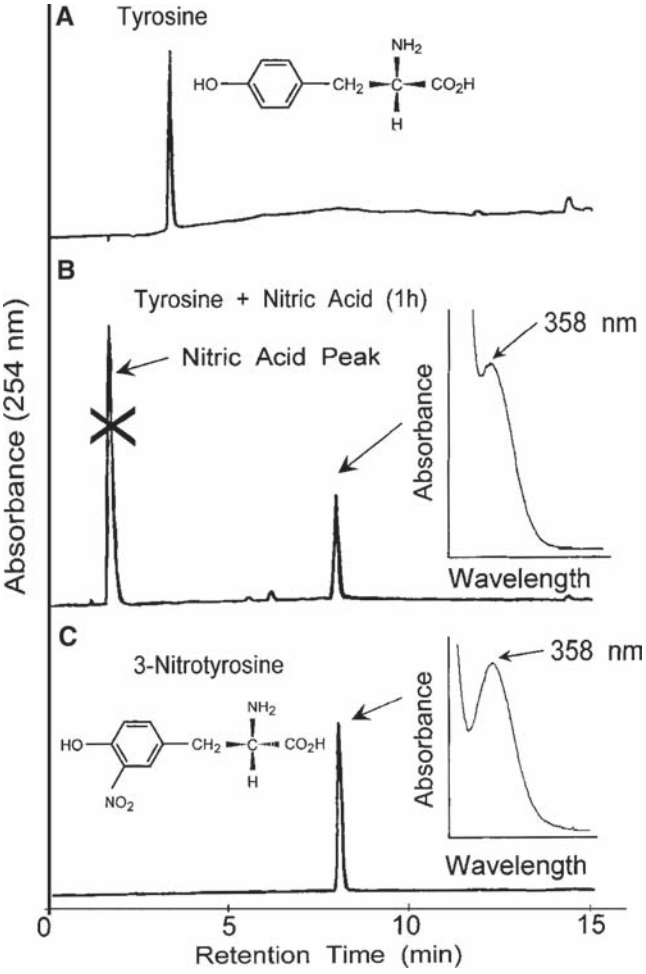

Fig. 2. Nitrotyrosine results from the treatment of L-tyrosine with nitric acid. **(A)** HPLC chromatogram of L-tyrosine. **(B)** HPLC chromatogram of L-tyrosine reacted with nitric acid for 1 h. *Inset*, absorbance spectrum of peak eluting at ~ 8 min. The prominent peak eluting at 2 min corresponds to a contaminant in the nitric acid. **(C)** HPLC chromatogram of 3-nitrotyrosine. *Inset*, absorbance spectrum of peak eluting at ~8 min. HPLC was accomplished using a Beckman Ultrasphere obs column (4.6 × 250 mm, 5 µm) as previously described ***(15)***.

the 3-nitrotyrosine peak and appearance of additional peaks that are thought to reflect nitration at additional sites as well as oxidation (data not shown). As a consequence, the absorbance at 358 nm reached a peak between 1 and 6 h, and then subsequently declined.

To determine whether these observations could be utilized to devise a method for quantitating protein, bovine serum albumin (BSA) was solubilized in nitric acid and incubated for varying lengths of time. As indicated in **Fig. 3A**, absorbance at 358 nm measured after incubation for 0.5–70 h was a linear function of protein content. Examination of these data revealed that production of the chromophore in response to nitric acid treatment at room temperature was approximately 88% complete within 30 min, reached a maximum at approximately 24 h, and remained relatively stable thereafter (**Fig. 3A**, inset). We hypothesize that the relative stability of the 358 nm peak in proteins treated for prolonged periods with nitric acid (in contrast to the disappearance of the same peak when L-tyrosine is subjected to prolonged nitric acid treatment) results from diminished susceptibility of tyrosyl residues in protein to react beyond 3-nitration.

To determine whether this approach could be utilized to quantitate protein under conditions compatible with SDS-PAGE, aliquots of BSA in SDS sample buffer containing Tris, SDS, urea, and β-mercaptoethanol were treated with nitric acid. As indicated in **Fig. 3B**, the presence of increasing amounts of protein resulted in increasing absorbance at 358 nm, which was again a linear function of protein content. To confirm that the present assay was useful for measuring polypeptides other than BSA, we assessed absorbance after reaction of five other polypeptides with nitric acid including bovine insulin, human fibrinogen, human fibronectin, chicken ovalbumin, and rat albumin. Each of these polypeptides reacted with nitric acid to produce species with absorbance maxima at 358 nm. In each case, there was a strong correlation ($r > 0.99$) between protein content and absorbance (data not shown).

1.2.2. Interfering Substances

Urea, SDS, β-mercaptoethanol, 20% glycerol, and 50% saturated ammonium sulfate did not interfere with protein determination by the nitric acid method. In addition, the neutral detergents Tween 20 (1%), Brij 97 (1%), *n*-octyl α-D-glucopyranoside, and digitonin (10 μ*M*) did not interfere with this method. In contrast, the presence of 1% Triton X-100 (a phenol derivative) or trace amounts of phenol produced strong absorbance at 358 nm that interfered with the assay. Although 1% 3-([3-cholamidopro-pyl]dimethylammonio)-1-propanesulfonate (CHAPS) increased absorbance at 358 nm, it did not interfere with the assay - as long as the protein samples used to generate standard curves were also solubilized in CHAPS.

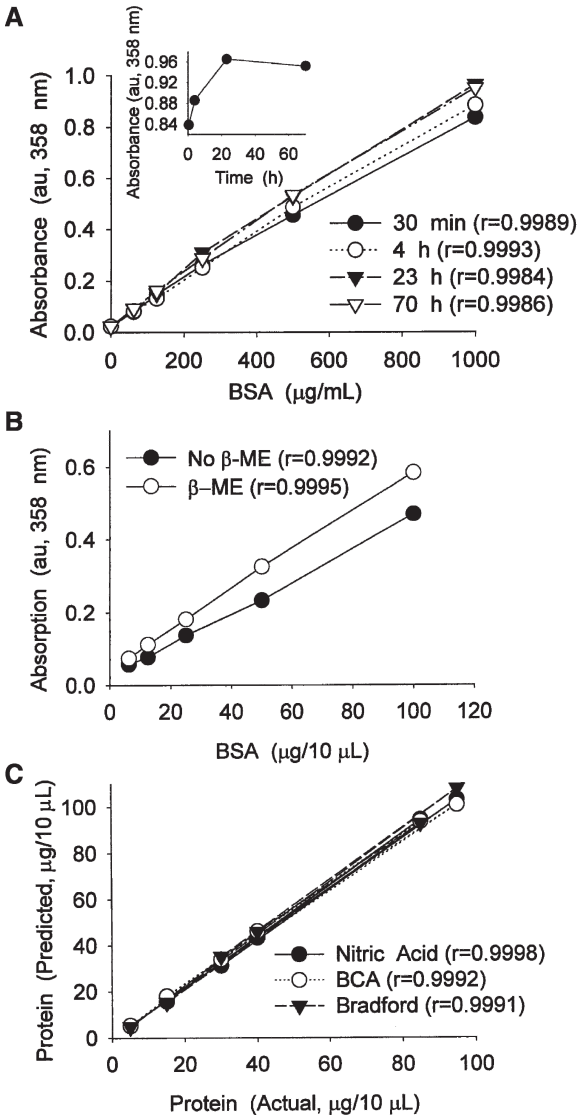

Fig. 3. Measurement of absorbance at 358 nm can be used to quantitate protein levels in samples treated with nitric acid. **(A)** Absorbance (at 358 nm) of varying concentrations of BSA incubated in nitric acid for 30 min, 4 h, 23 h, and 70 h. Inset, time-dependent increase of absorbance at 358 nm for a 1000 μg/mL solution of BSA dissolved in nitric acid. **(B)** Relationship between BSA concentration and absorbance at 358 nm for samples dissolved in SDS-PAGE sample buffer with or without 5% (v/v) β-mercaptoethanol. **(C)** Relationship between actual and measured BSA concentration in six blindly submitted BSA samples assessed by the nitric acid, BCA, and Bradford protein assays. Results in **B** and **C** represent the means of results from the assay of triplicate samples. Error bars (hidden by data points) represent ± 1 sample standard deviation.

1.2.3. Comparison of the Nitric Acid Method to Bradford and BCA Protein Assays

To assess the reliability of this technique, protein content was blindly measured in six unknown samples using the Bradford assay (Coomassie Blue binding), BCA assay, and the nitric acid method. Results of these experiments indicated that the three methods produce comparable results in assessing protein content in unknown samples (**Fig. 3C**). The correlation between actual and predicted protein content was slightly higher for the nitric acid method (r = 0.9998) than for the BCA assay (r = 0.9992) or Bradford assay (r = 0.9991). We also examined whether the nitric acid method is suited to comparing protein levels between different cell lines. To assess this possibility, we ran SDS-PAGE gels with extracts from five different human cancer cell lines loaded in accord with the amounts of protein in the extracts indicated by either the BCA or the nitric acid method. When we compared Western blots for a number of different proteins, we found that both protein assays facilitated similar gel loading (**Fig. 4**). It should be noted, however, that the nitric acid method uniformly resulted in proportionately higher protein values (and hence proportionately less cell extract loaded per gel lane) in comparison to the BCA method.

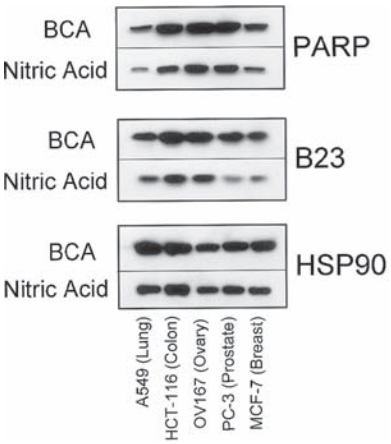

Fig. 4. BCA and nitric acid protein assays produce equivalent results when used as the basis for loading SDS-PAGE gels with extracts from different cell lines. Extracts from five human cancer cell lines (each containing 50 µg of total cellular proteins, as assessed by the BCA or the nitric acid method) were subjected to SDS-PAGE and probed for PARP, B23, and HSP90 via Western blotting. All shown pairs of BCA/nitric acid immunoblots were derived from the same gel and have been aligned to facilitate comparison.

2. Materials

1. 70% Nitric acid, store in acid cabinet at room temperature; CAUTION: toxic, use in fume hood and avoid inhalation of fumes and skin contact.
2. Bovine serum albumin (BSA), storage at 4°C.
3. UV-vis spectrophotometer.
4. (Optional) SDS sample buffer for cell lysis: 2% (w/v) SDS, 4 M urea (deionized with Bio-Rad AG501-X8 mixed bead resin prior to use), 62.5 mM Tris-HCl, pH6.8, 1mM EDTA, and 5% (v/v) β-mercaptoethanol.

3. Methods

3.1. Nitric Acid Protein Determination Method: Cell Lysates

The following is the recommended procedure for determining protein content in samples solubilized in SDS sample buffer or other detergent-based cell lysis buffers without bromophenol blue added ***(21–22)***.

1. Prior to assay for protein, cells must be washed in serum-free medium or 1X PBS to remove exogenous protein and cross-reacting substances contained in culture media.
2. Lyse cells directly in SDS sample buffer or desired detergent-based cell lysis buffer.
3. Remove an aliquot of cell lysate expected to contain 5–100 µg of protein. Bring sample volume to 10 µL using same buffer samples were lysed in (*see* **Note 1**).
4. In a fume hood, add 140 µL 70% nitric acid to bring total volume to 150 µL (*see* **Note 2**).
5. Incubate at room temperature for 2 h (*see* **Note 3**).
6. Utilizing glass or quartz microcuvettes, or a 96-well plate (*see* **Note 2**), measure absorbance at 358 nm with H_2O as a blank (*see* **Note 4**).
7. Compare results to a standard curve constructed in parallel using varying amounts of BSA in 10 µL SDS sample buffer subjected to the same conditions (*see* **Notes 6** and **7**).

3.2. Nitric Acid Protein Determination Method: Whole Cells

Simple modifications allow this procedure to be applied to other settings. This variation is especially helpful when protein content in whole cells is to be determined in conjunction with assessment of cellular drug accumulation ***(17–20)***.

1. Wash cells thoroughly with serum-free buffer to remove exogenous proteins contained in culture media.
2. Solubilize cells directly in 70% nitric acid.
3. Incubate at room temperature for 24 h (*see* **Note 5**).
4. Remove an aliquot for determination of absorbance at 358 nm (dilution in 70% nitric acid may be necessary to assure that all results fall within the linear range of assay, *see* **Note 2**) with H_2O as a blank (*see* **Note 4**).

5. Compare results to a standard curve constructed in parallel using varying amounts of BSA subjected to the same assay conditions (*see* **Notes 6** and **7**).

3.3. Nitric Acid Protein Determination Method: Perchloric or Trichloroacetic Acid Precipitates

When perchloric acid or trichloroacetic acid precipitates are assayed for protein content:

1. Solubilize precipitates directly in nitric acid.
2. Incubate for 2 h at room temperature (*see* **Note 3**).
3. Determine absorbance at 358 nm (dilution in 70% nitric acid may be necessary, *see* **Note 2**) with H_2O as a blank (*see* **Note 4**).
4. Compare results to a standard curve constructed in parallel using varying amounts of BSA subjected to the same assay conditions (*see* **Notes 6** and **7**).

4. Notes

1. One advantage of the nitric acid method is that protein content can be assessed using samples solubilized in SDS sample buffer immediately prior to loading samples for electrophoresis. It is possible to solubilize samples directly in SDS sample buffer, remove an aliquot for protein determination, and then adjust the sample volume based on the result of the assay. Bromophenol blue for gel visualization should only be added to the samples after removing an aliquot to determine protein concentration, as it is not compatible with the assay.
2. 150 µL volumes are suggested for measuring in a microcuvette. If desired, volumes of sample and nitric acid may be adjusted up proportionately to be read in a larger cuvette. Also, the assay may be adapted to a microplate format using a quartz or glass 96-well plate using a UV-visible microplate reader at 358 nm.
3. Incubations are routinely performed between 20–22°C. Incubation at 37°C revealed that the reaction was not appreciably altered (data not shown) and is therefore relatively temperature insensitive.
4. Our experience indicates that H_2O, rather than 70% nitric acid, should be used for a blank for all spectrophotometric determinations.
5. The assay of protein content in detergent-solubilized cells by the nitric acid method requires an incubation period of only 2 h at 22°C. In contrast, similar determinations on nitric acid-solubilized cells require incubation periods of at least 24 h for optimal detection of differences between different cell lines. Longer incubations may be required for nitric acid-solubilized cells because longer times may be required to complete protein nitration under these conditions.

6. Proteins with differing tyrosine/amino acid content would be expected to yield different slopes when utilized as standards for this assay. Although this can present a problem in experiments that require the precise quantitation of a single polypeptide species, it does not appear to be a limitation when this method is used to compare relative protein content in complex biological mixtures. Moreover, when the nitric acid assay was applied to a variety of polypeptides (including BSA, rat albumin, chicken ovalbumin, bovine insulin, human fibrinogen, and human fibronectin), the resulting slopes did not correlate with either tyrosine or tryptophan content of the polypeptides (data not shown), suggesting that tertiary structure or other factors might also influence the extent of nitration during nitric acid treatment. Similar differences in reactivity of various purified polypeptides have been previously observed with other protein estimation methods as well ***(5***, ***6)***.
7. The nitric acid method has a sensitivity limit of approximately 5 μg when performed using 100 μL cuvettes. This sensitivity is slightly lower than the methods of Lowry et al. ***(3)***, Smith et al. ***(5)*** and Bradford ***(6)*** performed under similar semimicro conditions.

Quantitation of Tryptophan in Proteins

Alastair Aitken and Michèle P. Learmonth

1. Introduction

1.1 Hydrolysis Followed by Amino Acid Analysis

Accurate measurement of the amount of tryptophan in a sample is problematic, as it is completely destroyed under normal conditions employed for the complete hydrolysis of proteins. Strong acid is ordinarily the method of choice, and constant boiling 6 *M* hydrochloric acid is most frequently used. The reaction is usually carried out in evacuated sealed tubes or under nitrogen at 110°C for 18–96 h. Under these conditions, peptide bonds are quantitatively hydrolyzed (although relatively long periods are required for the complete hydrolysis of valine, leucine, and isoleucine). As well as complete destruction of tryptophan, small losses of serine and threonine occur, for which corrections are made. The advantages of amino acid analysis include the measurement of absolute amounts of protein, provided that the sample is not contaminated by other proteins. However, it may be a disadvantage if an automated amino acid analyzer is not readily available.

Acid hydrolysis in the presence of 6 *N* HCl, containing 0.5–6% (v/v) thioglycolic acid at 110°C for 24–72 h *in vacuo* will result in greatly improved tryptophan yields ***(1)***, although most commonly, hydrolysis in the presence of the acids described in **Subheading 3.1** may result in almost quantitative recovery of tryptophan.

Alkaline hydrolysis followed by amino acid analysis is also used for the estimation of tryptophan. The complete hydrolysis of proteins is achieved with 2–4 *M* sodium hydroxide at 100°C for 4–8 h. This is of limited application for routine analysis, because cysteine, serine, threonine, and arginine are destroyed in

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

the process and partial destruction by deamination of asparagine and glutamine to aspartic and glutamic acids occurs.

The complete enzymatic hydrolysis of proteins (where tryptophan would be quantitatively recovered) is difficult, because most enzymes attack only specific peptide bonds rapidly. Often a combination of enzymes is employed (such as Pronase), and extended time periods are required (*see* Chapter 106). A further complication of this method is possible contamination resulting from autodigestion of the enzymes. Kuyama and coworkers ***(2)*** have described a method for quantification and sequence identification of tryptophan in individual proteins in complex mixtures. By labeling tryptophan residues with 2-nitrobenzenesulfenyl chloride (NBSCl) in conjunction with tandem mass spectrometry a 6Da mass differential is generated using $^{13}C_6$-labeled NBSCl and $^{12}C_6$-labeled NBSCl in two separate samples. This 6 Da mass difference between the $^{13}C_6$-labeled and the $^{12}C_6$-labeled peptides provides a mass signature to all tryptophan-containing peptides in proteolytic digests for proteomic identification.

1.2. Measurement of Tryptophan Content by UV

The method of Goodwin and Morton ***(3)*** is described in **Subheading 3.3**.

The absorption of protein solutions in the UV is due to tryptophan and tyrosine (and to a very minor, and negligible, extent phenylalanine and cysteine). The absorption maximum will depend on the pH of the solution, and spectrophotometric measurements are usually made in alkaline solutions. Absorption curves for tryptophan and tyrosine show that at the points of intersection, 257 and 294 nm, the extinction values are proportional to the total tryptophan + tyrosine content. Measurements are normally made at 294.4 nm, as this is close to the maximum in the tyrosine curve (where $\Delta\varepsilon/\Delta\varepsilon$, the change in extinction with wavelength, is minimal), and in conjunction with the extinction at 280 nm (where $\Delta\varepsilon/\Delta\lambda$ is minimal for tryptophan) the concentrations of each of the two amino acids may be calculated (*see* **Notes 1** and **2**).

2. Materials

1. 3 *M* *p*-Toluenesulfonic acid.
2. 0.2% 3-(2-Aminoethyl) indole.
3. 3 *M* Mercaptoethanesulfonic acid (Pierce-Warriner).
4. 1 *M* NaOH.

3. Methods

3.1. Quantitation of Tryptophan by Acid Hydrolysis

1. To the protein dried in a Pyrex glass tube (1.2 × 6 cm or similar, in which a constriction has been made by heating in an oxygen/gas flame) is added 1 mL of 3 *M* *p*-toluenesulfonic acid, containing 0.2% tryptamine [0.2% 3-(2-aminoethyl) indole] ***(4)***.

2. The solution is sealed under vacuum and heated in an oven for 24–72h at 110°C, *in vacuo*.
3. Alternatively, the acid used may be 3 *M* mercaptoethanesulfonic acid. The sample is hydrolyzed for a similar time and temperature ***(5)***.
4. The tube is allowed to cool, and cracked open with a heated glass rod held against a horizontal scratch made in the side of the tube.
5. The acid is taken to near neutrality by carefully adding 2 mL of 1 *M* NaOH. An aliquot of the solution (which is still acid) is mixed with the amino acid analyzer loading buffer.
6. Following this hydrolysis, quantitative analysis is carried out for each of the amino acids on a suitable automated instrument.

3.2. Alkaline Hydrolysis

1. To the protein dried in a Pyrex glass tube (as described in **Subheading 3.1., step 1**), 0.5mL of 3 *M* sodium hydroxide is added (*See* **Note 3**).
2. The solution is sealed under vacuum and heated in an oven for 4–8h at 100°C, *in vacuo*.
3. After cooling and cracking open, *while one is wearing safety goggles*, the alkali is neutralized carefully with an equivalent amount of 1 *M* HCl. An aliquot of the solution is mixed with the amino acid analyzer loading buffer and analyzed (as described in **Subheading 3.1., step 6**).

3.3. Measurement of Tryptophan Content by UV

1. The protein is made 0.1 *M* in NaOH.
2. Measure the absorbance at 294.4 nm and 280 nm in cuvettes transparent to this wavelength (i.e. quartz) in a spectrometer (*see* **Note 4**).
3. The amount of tryptophan (*w*) is estimated from the relative absorbances at these wavelengths by the method of Goodwin and Morton ***(3)*** shown in **Eq. 1**., where

x = total mole/L; w = tryptophan mole/L; $(x - w)$ = tyrosine mole/L.

ε_y = Molar extinction of tyrosine in 0.1 M alkali at 280 nm = 1576.

ε_w = Molar extinction of tryptophan in 0.1 M alkali at 280 nm = 5225.

Also, x is measured from $E_{294.4}$ (the molar extinction at this wavelength). This is 2375 for both Tyr and Trp (since their absorption curves intersect at this wavelength). An accurate reading of absorbance at one other wavelength is then sufficient to determine the relative amounts of these amino acids.

$$E_{280} = w\varepsilon_w + (x - \mathrm{w})\varepsilon_y \quad (1)$$

$$\text{Therefore}, w = (E_{280} - x\varepsilon_y) / (\varepsilon_w - \varepsilon_y)$$

4. An alternative method of obtaining the ratios of Tyr and Trp is to use the formulae (**Eq. 2**) derived by Beaven and Holiday ***(6)***.

$$M_{Tyr} = (0.592\,K_{294} - 0.263\,K_{280}) \times 10^{-3} = (0.263\,K_{280} - 0.170\,K_{294}) \times 10^{-3}$$

where M_{Tyr} and M_{Trp} are the moles of tyrosine and tryptophan in 1 g of protein, and K_{294} and K_{280} are the extinction coefficients of the protein in 0.1 *N* alkali at 294 and 280 nm. Extinction values can be substituted for the *K* values to give the molar ratio of tyrosine to tryptophan according to the formula:

$$M_{Tyr} / M_{Trp} = (0.592\ E_{294} - 0.263\ E_{280}) / (0.263\ E_{280} - 0.170\ E_{294}) \quad (2)$$

4. Notes

1. The extinction of nucleic acid in the 280 nm region may be as much as 10 times that of protein at the same wavelength and hence a few percent of nucleic acid can greatly influence the absorption.
2. In this analysis, the tyrosine estimate may be high and that of tryptophan low. If amino acid analysis indicates absence of tyrosine, tryptophan is more accurately determined at its maximum, 280.5 nm.
3. Absorption by most proteins in 0.1 *M* NaOH solution decreases at longer wavelengths into the region 330–450 nm where tyrosine and tryptophan do not absorb. Suitable blanks for 294 and 280 nm are therefore obtained by measuring extinctions at 320 and 360 nm and extrapolating back to 294 and 280 nm.
4. In proteins, in a peptide bond, the maximum of the free amino acids is shifted by 1–3 nm to a longer wavelength and pure peptides containing tyrosine and tryptophan residues are better standards than the free amino acids. A source of error may be due to turbidity in the solution and if a protein shows a tendency to denature, it is advisable to treat with a low amount of proteolytic enzyme to obtain a clear solution.

Kinetic Silver Staining of Proteins

Douglas D. Root and Kuan Wang

1. Introduction

Silver staining methods have long been know to provide highly sensitive detection of proteins and nucleic acids following electrophoresis in agarose and polyacrylamide gels ***(1,2)***. Silver staining technologies can be extended to other media such as blots, thin-layer chromatography (TLC), and microtiter plates. The quantification of proteins adsorbed to microtiter plate wells provides quantitative information for enzyme-linked immunosorbent assay (ELISA) and protein interaction assays. One nonradioactive procedure, copper iodide staining, is described in Chapter 72 ***(3)***. The kinetic silver staining method for measuring the amount of adsorbed protein in a microtiter plate has been developed recently. The microtiter plate assay has a sensitivity similar to copper iodide staining (5–150 ng/well) but higher precision (<5%; ***4***). When quantification is based on the time required for staining to reach a fixed optical density, very little protein-to-protein variation is observed, so a standard protein for calibration can be selected (such as bovine albumin) that is free of interfering substances to which the assay is sensitive ***(4)***. Furthermore, this kinetic silver staining assay is found to be most sensitive for the detection of proteins on cellulose such as is commonly used for TLC (*see* Chapter 72 for a comparison with other solid-phase stains).

2. Materials

1. Polystyrene 96-well microtiter plates (e.g., Titertek 76-381-04, McLean, VA).
2. The kinetic silver staining reagent consists of

   Reagent A: 0.2% (w/v) $AgNO_3$, 0.2% (w/v) NH_4NO_3, 1% (w/v)tungstosilicic acid, and 0.3% (v/v) formaldehyde (from a 37% stock solution in water) in distilled water. Store in the dark at room temperature.

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

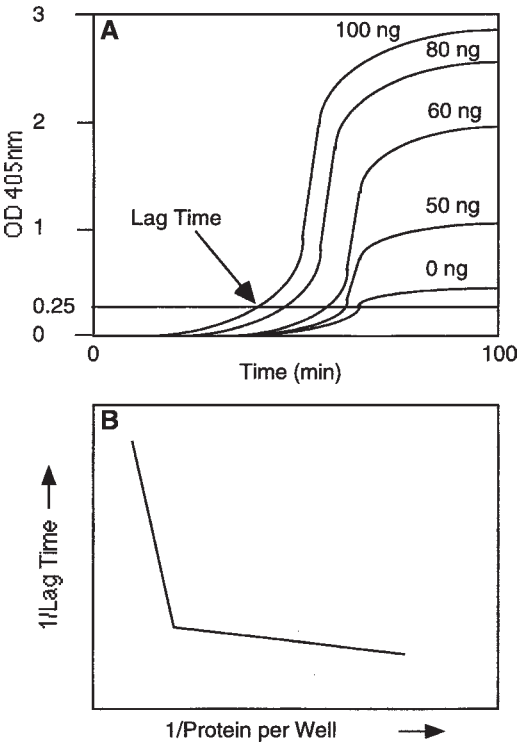

Fig. 1. Representative p\lots of standard curve data. **(A)** Raw data for varying standard protein mass per well. **(B)** Double-reciprocal plot of standard curve.

Reagent B: 5% (w/v) Na_2CO_3 in distilled water.

3. A microtiter plate reader is required (e.g., EIA Autoreader, model EL310, Biotek Instruments, Burlington, VT).
4. Cellulose paper or TLC plates.

3. Methods

3.1. Microtiter Plate Assay

1. Adsorb the protein of interest to duplicate microtiter plates (*see* **Note 1**). Wash the microtiter plate profusely with distilled water after the adsorption (*see* **Note 2**). One of the microtiter plates is used for the kinetic silver staining assay and the other is for quantitative ELISA or binding experiments. The microtiter plate for the kinetic silver staining assay contains protein adsorbed to only a few of the wells (e.g., 4–16 wells).
2. Prepare a known concentration of the standard protein in distilled water (e.g., by dialysis) for use in a standard curve (*see* **Notes 2** and **3**).
3. Apply varying concentrations (e.g., 50–1000 ng/mL) of the standard protein to the blank wells on the microtiter plate at the same volume (50–200 µL) that was used

to adsorb protein in **step 1**. Cover the microtiter plate with a tissue to avoid dust from settling in the wells and allow the protein to air dry for several days (*see* **Note 4**). Do not wash the plate after this step!

4. Mix equal volumes of reagents A and B immediately before use. A fixed volume (e.g., 100 µL) of the mixture is added quickly to the wells on the microtiter plate that were adsorbed with protein in **step 1, step 3,** and to blank control wells. The time for the addition of reagent to each well should be noted as time zero. All wells are filled in less than 10 min from the time of mixing reagents A and B; otherwise, excessive silver development in the reagent may cause a high background.
5. Read optical densities of each well with a microtiter plate reader at 405 nm (*see* **Note 5**). The time elapsed from time zero for each well to reach 0.25 OD (lag time) is noted as the lag time.
6. The lag time is plotted against the mass per well of adsorbed protein in the standard curve (**step 3**), which typically yields an inverse sigmoidal shape curve. Comparison of the lag times of the sample wells to the standard curve allows the determination of the total mass of protein in the sample well. The standard curve may be linearized to a sharply biphasic shape curve by plotting 1/lag time vs 1/protein per well (*see* **Fig. 1**).

3.2. Cellulose Assay

1. Mix equal volumes of reagents A and B immediately before use.
2. Stain cellulose (*see* **Note 6**) with adsorbed proteins by immersion in the mixed reagents for at least 1 h.

4. Notes

1. The wells on the edge of microtiter plates should be avoided for quantitative measurements because they tend to yield less accurate numbers.
2. Washing of microtiter plates is essential, as residual buffer reagents may interfere with silver staining (*see* **Table 1**). The washing is performed by gently dipping in beakers of deionized water. Vigorous washing was avoided for fear of losing adsorbed protein.
3. Kinetic silver staining shows little protein-to-protein variation (<30% over six tested proteins); it is possible to estimate the total amount of adsorbed protein or mixture of proteins using a standard (e.g., bovine albumin) that can be easily dissolved in water and measured for concentration.
4. Kinetic silver staining detects proteins bound to polystyrene and apparently not protein in solution; thus the quantitative adsorption of the standard protein in distilled water (to avoid interference, *see* **Note 2**) to polystyrene by drying is necessary. As the binding capacity of polystyrene is exceeded (typically about 100–200 ng/well, but depends upon both the microtiter plate and the protein of interest), kinetic silver staining does not detect further increases in protein mass per well.

Table 1
Compounds Known to Interfere with Kinetic Silver Staining

Compounds	Concentration in the staining reagent
TCA	>0.01 m*M*
Glucose	>1 m*M*
β-Mercaptoethanol	>0.1 m*M*
DTT	>0.01 m*M*
KOH	>0.01 m*M*
EDTA	>1 m*M*
Phosphate	>0.01 m*M*
SDS	>1 m*M*
Triton X-100	>0.0005%
Ammonium sulfate	>1 m*M*
Urea	>1 m*M*
Imidazole	>0.01 m*M*
Tris	>1 m*M*
NaCl	>0.01 m*M*
KCl	>0.01 m*M*
Guanidine HCl	>0.01 m*M*

5. Kinetic silver staining is based on measurements of light scattering. Thus, other wavelengths may be used, but the corresponding optical density reading will be different and may require optimization.
6. The cellulose may require washing to remove solvents or buffers, if present prior to staining.

Quantitation of Cellular Proteins by Flow Cytometry

Thomas D. Friedrich, F. Andrew Ray, Ralph L. Smith, and John M. Lehman

1. Introduction

Quantitation of specific proteins in complex mixtures is simplified by the use of antibodies directed against the protein of interest. If the specific protein is differentially expressed within a population of cells, quantitation of the protein in cell lysates by immunoblotting will provide an average quantity of the protein per cell. As a result, when lysates of different cell populations are compared, large changes in the amount of a protein in a small percentage of cells cannot be distinguished from small changes in the amount of a protein in a large percentage of cells. Flow cytometric analysis solves this problem by providing a means to measure the amount of a specific protein within each individual cell in a population. A fluorescently labeled probe, usually an antibody, is required for detection of the protein. A single cell suspension is reacted with an antibody and passed through a flow cytometer, which focuses the cell suspension into a stream that intersects a laser beam. As each cell passes through the beam, the fluorescent probe in each cell is excited and photomultiplier tubes register the degree of fluorescence ***(1)***.

Multivariate analysis, the simultaneous measurement of multiple parameters, is a powerful feature of flow cytometry. When determining the quantity of a specific protein in a cell, the quantity of other molecules in the same cell can also be measured by using additional fluors specifically targeted to other molecules. Examples of second molecules measured simultaneously include DNA ***(2–4)*** or additional proteins ***(5)***. In addition, measurement of light scatter can provide information about cell size and granularity. Most flow cytometers are capable of measuring six colors plus light scatter, but specialized flow cytometers that are capable of measuring as many as eighteen colors are now available.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

In this chapter we will describe techniques used to quantitate Simian Virus 40 (SV40) large T antigen (T Ag) in infected cells. By staining infected cells with antibodies against T Ag and with the DNA-binding dye propidium iodide it is possible to measure the amount of T Ag as a function of DNA content.

2. Materials

2.1 Cells and Antibodies

The CV-1 line of African Green monkey kidney cells was obtained from the American Type Culture Collection (ATTC, CCL-70). Confluent cultures of CV-1 were infected with Simian Virus 40 strain RH-911 at 100 plaque forming units per cell.

Pab101 is a monoclonal antibody specific to the carboxy-terminus of SV40 T Ag. Hybridoma cells producing Pab101 were obtained from ATCC (#TIB-117). Alexa conjugated secondary antibodies were obtained from Invitrogen.

2.2 Fixation and Staining

1. Ca^{2+}/Mg^{2+}-free phosphate-buffered saline (PBS): dissolve 8.0g NaCl, 0.2g KCl, 1.2g Na_2HPO_4 and 0.2g KH_2PO_4 in 1 liter of distilled water (dH_2O). Adjust the pH to 7.4, sterilize by passing through a 0.2 µm filter and store at room temperature.
2. Trypsin-EDTA: dilute 10X trypsin/EDTA (Invitrogen) in PBS to give final concentrations of 0.05% trypsin, 0.53 mM EDTA. Filter-sterilize and store at 4°C.
3. Methanol. Store at –20°C.
4. Wash solution (WS): heat inactivate 100 ml of normal goat serum (Invitrogen) at 56°C for 1 hour. Mix with 900 ml PBS, 20 µl Triton X-100 and 1.0g sodium azide. Filter-sterilize and store at 4°C (see **Note 1**).
5. Propidium iodide (PI): dissolve 10.0 mg PI (Calbiochem) in 100 ml PBS. Add 20 µl Triton X-100 and 0.1 g sodium azide. Protect solution from light and store at 4°C.
6. Ribonuclease: dissolve 100 mg of RNAase A (Sigma) in 100 ml PBS. Boil for 1 hour. Add 20 µl Triton X-100 and 0.1g sodium azide. Store at 4°C.

3. Methods

3.1 Fixation

1. Remove the culture medium and rinse the cells with PBS. If floating and/or mitotic cells are of interest, medium and wash fractions should be saved, pelleted and pooled with attached cells after trypsinization.
2. Prewarm trypsin/EDTA to 37°C and add 1 ml per 60 mm dish. (Adjust proportionally for larger culture areas). Tilt the plate to thoroughly distribute solution and then remove.
3. Once the cells have detached (see **Note 2**), add 1 ml of WS to the plate and transfer the cells to a 1.5 ml microcentrifuge tube. Remove a small volume for the determination of cell number (see **Note 3**). Centrifuge remaining cells at 4000 × g for 15 sec.
4. Discard supernatant, resuspend the pellet in 1 ml PBS at 4°C and centrifuge as in **step 3.**

5. Discard the supernatant and thoroughly resuspend cell pellet in 0.1 ml cold PBS.
6. Immediately add 0.9 ml methanol (−20°C) (see **Note 4**), mix and store at −20°C (see **Note 5**).

3.2 Titration of antibodies

It is important that the primary antibody (see **Note 6**) is present in excess to ensure quantitative measurement of the specific protein (see **Note 7**). However, excessive antibody can lead to increased background. In order to determine the appropriate antibody concentration, stain parallel samples of cells with serial dilutions of antibody. If available, similar cells that don't express the protein of interest are used for negative controls. Stain such cells in the same way as the experimental cells.

3.3 Staining

1. Transfer 1.5×10^6 cells to a 1.5 ml microcentrifuge tube and centrifuge at 4000 × g for 15 seconds (see **Note 8**).
2. Discard the supernatant and resuspend the cell pellet in 1 ml PBS at 4°C. Repeat centrifugation step.
3. Discard PBS and add 0.5 ml of diluted primary antibody. Mix gently.
4. Incubate with gentle agitation (see **Note 9**).
5. Pellet at 4000 × g for 15 sec and discard supernatant.
6. Resuspend the pellet in 0.5 ml WS and repeat **step 5.**
7. Resuspend the pellet in 0.5 ml of diluted fluorescently-labeled secondary antibody (see **Note 10**). Mix gently.
8. Incubate at 37°C for 2 h with gentle mixing; minimize exposure to light.
9. Add 0.5 ml RNAase and mix gently.
10. Incubate at 37°C for 30 min.
11. Add 0.5 ml PI, bringing the total volume to 1ml. Mix gently.
12. Filter each sample through a 53 µm mesh nylon grid (Nitex HC3-53, Tetko Inc.) (see **Note 11**).

3.4 Flow Cytometry and analysis

Most commercially available flow cytometers are capable of multiparameter analysis (see **Note 12**). Using 20 mW of power tuned to 488 nm, minimize the coefficient of variation (CV) for the green photomultiplier (see **Note 13**) to <2.0% by aligning the instrument with 2.0 µm fluorescent microspheres (Polysciences Inc.). Minimize the CV for red fluorescence (see **Note 14**) to <6.0% with PI-stained lymphocytes (see **Note 15**).

Set data acquisition to trigger on a photomultiplier collecting unfiltered 90° light scatter. Set gates to collect data representing single cells, and to eliminate data representing cell debris and cell aggregates. Compare red fluorescence to light scatter and set gate 1 to eliminate subcellular debris (low red fluorescence)

and clumped cells (excessive light scatter). Then compare the peak height and area of red fluorescence and eliminate doublets (off axis owing to biphasic peak height). Collect and display red fluorescence vs green fluorescence. Collect data from at least 10,000 cells. Include appropriate control samples, save data and analyze. Representative data are shown in **Fig. 1**. For absolute quantitation (number of molecules of the specific protein per cell) a separate populations of cells with a known absolute quantities of the antigen can be used as standards (see **Note 16**).

4. Notes

1. Sodium azide is highly toxic. Consult the MSDS for proper handling instructions.
2. It is best to monitor cell detachment microscopically. Optimize cell treatment for the generation of a single cell suspension.
3. Each sample should contain 1–1.5 × 10^6 cells, because cells will be lost during fixation and staining. Use polypropylene tubes and minimize tube size to reduce cell loss.
4. The cell concentration can be adjusted at the time of fixation by adding the appropriate amounts of PBS (10%) and then methanol (90%). In some cases methanol fixation may result in loss of the protein antigen. Since the method of fixation can dramatically alter the results it may be necessary to test different fixation protocols. For example, fixation by 0.5% formal-

Fig. 1. Differential T antigen expression in SV40 infected monkey kidney cells. Cells in **A** and **B** were fixed and stained with propidium iodide (PI) and anti-T Ag as described in **Subheading 3.** PI staining (DNA content) is expressed on a linear scale and anti- T Ag fluorescence on a log scale. **(A)** An uninfected culture of confluent CV-1 cells. The cell cycle distribution, as determined by PI staining was: 80% G1 phase, 5% S phase, 12% G2/M phase and 3% >G2 phase. **(B)** Confluent CV-1 cells infected with SV40 at a multiplicity of infection of 100 plaque forming units per cell. Cells were trypsinized and fixed at 48 hours post infection. The *sloped horizontal line* in each panel was set to divide T Ag positive from T Ag negative cells. *Vertical lines* indicate gates that were set on the basis of DNA content to discriminate cells within the different phases of the cell cycle. The cell cycle distribution of the T Ag expressing cells was: 27% G1 phase, 9% S phase, 14% G2/M phase and 50% >G2 phase. Levels of T Ag expression in G1 phase cells cover a 10-fold range, but only cells expressing higher amounts of T Ag enter S phase. >G2 phase represents a virus-regulated override of normal cell cycle events. The cells in >G2 phase are infected cells that are replicating viral DNA and re-replicating cellular DNA **(7).** The G1 phase cells with fluorescence levels similar to the background levels of the uninfected cells are believed to be an uninfected subpopulation that conveniently serves as an internal control in this system. **(C)** The relative quantities of T Ag within each cell cycle gate, as determined by anti T Ag staining. The bar graph shows the average quantity of T Ag per cell in the T Ag expressing population.

dehyde followed by methanol has been used to retain antigens lost with methanol fixation alone ***(6)***.

5. Fixed cells have been stored at −20°C for >1 year with negligible loss of T Ag. However stability during storage must be evaluated for each antigen.
6. Monoclonal antibodies or affinity purified polyclonal antibodies are preferred. Polyclonal antisera may have additional antibodies of unknown specificity that will increase background staining.
7. Antibody binding is actually a quantitative measure of the epitope recognized by the antibody and not necessarily the total amount of the protein antigen. If the epitope is masked through protein conformation/association or as an artifact of fixation, the epitope may not be detected.
8. Use of a swinging bucket microcentrifuge reduces cell loss.
9. Adjust time and temperature to maximize the signal over background. Incubation times generally range from 30 minutes to 2 hours at 37°C or overnight at 4°C. Gentle rocking is recommended.
10. Primary antibodies that are directly conjugated to fluors are commercially available. In addition, kits that allow conjugation of Alexa fluors to antibodies can be obtained from Invitrogen. If particularly weak signals are encountered, the signal can be amplified by additional layers of fluorescently-tagged antibody. For example, cells stained with an FITC-labeled primary or secondary antibody can be reacted with Alexa 488-labeled rabbit anti-fluorescein followed by Alexa 488-labeled goat anti-rabbit IgG.
11. Filtering of samples removes cell aggregates that may clog the tubing in the flow cytometer. If samples are stored and then reanalyzed, filtering should be repeated.
12. We have used a Cytofluorograph Model 50 H-H with an air-cooled argon laser (model 532, Omnichrome). The Cyclops analysis program (Cytomation) was used for data analysis. More recently a BD FACScan has been utilized with similar settings and filters and identical results were obtained.
13. Use a 535 nm band pass filter for this photomultiplier.
14. Use a 640 nm long pass filter for this photomultiplier.
15. PI stained lymphocytes are prepared by first making a stock of spleen cells from a healthy mouse. Spleens are removed and minced with fine surgical scissors in PBS. The cells in the PBS supernatant are removed and placed in a centrifuge tube. Remaining spleen fragments are minced in PBS until few cells are evident in the supernatants. Cells in the pooled supernatants are pelleted by centrifugation and washed 2X with PBS. The pellet is resuspended in 1ml of PBS, mixed with 9ml of −20° C methanol and stored at −20° C. Prior to each run, wash and stain 1×10^6 cells with PI/RNAse only.

16. Values obtained from flow cytometric analysis do not provide an absolute quantitation (numbers per cell) of an epitope, but rather represent relative quantities of the epitope within cells in a population. A common method of determining the number of epitopes per cell is to compare the fluorescent intensity of the cell to standard beads that have a known number of primary antibody molecules per bead. The same fluorescently-labeled antibody that is used to stain cells is also reacted with the standard beads under the same conditions. Alternatively, if the number of fluorochrome molecules per antibody molecule is known, a comparison of a cell's fluorescent intensity to that of standard beads with a known number of bound fluorochrome molecules is possible. Both types of beads are commercially available.

Quantitation of Cellular Proteins by Laser Scanning Cytometry

Thomas D. Friedrich, Ralph L. Smith, and John M. Lehman

1. Introduction

Flow Cytometry (FC) is a popular method for the simultaneous quantitation of multiple specific proteins and other molecules in each cell of a single cell suspension ***(1)***. Laser Scanning Cytometry (LSC) is a closely related technology that provides many of the benefits of FC and offers additional features that allow morphological and biochemical analysis of a cell population ***(2,3)***. In both methods, quantitation of endogenous cellular proteins generally requires antibodies against the protein of interest. These antibodies must be either directly labeled with a fluorochrome or detected by a fluorescently-labeled secondary antibody. Using fluorescently-labeled antibodies in combination with fluorescent dyes that quantitatively bind to DNA, both FC and LSC have been valuable in measuring the quantities of specific proteins in relation to cell cycle position ***(4)***. In contrast to FC, where a single cell suspension is passed through a fixed-position laser beam, LSC analyzes cells fixed to a surface such as a microscope slide or cover slip. Since the position of the cell on the slide is part of the recorded data, it is possible to visualize the cell after the initial recording event or to subsequently stain the cell with another fluorescent probe and make a second measurement. LSC also allows analysis of cells following biochemical treatments that are incompatible with analysis by FC. In this chapter we describe the value of LSC in analyzing chromatin-associated proteins. Specifically, we describe an in situ fractionation procedure that allows measurement of total and chromatin-associated MCM2, a DNA helicase subunit, as a function of cell cycle position.

2. Materials

2.1. Cells and Antibodies

The CV-1 line of African Green monkey kidney cells was obtained from the American Type Culture Collection (ATCC, CL-70). Cells were maintained in MEM/ 5% fetal bovine serum. BM28 (#610701), a monoclonal antibody that specifically recognizes MCM2 was obtained from BD Biosciences. Alexa-488 conjugated goat anti-mouse IgG (#A-11001) was obtained from Invitrogen.

2.2. Fixation and Staining

1. Ca^{2+}/Mg^{2+}-free phosphate-buffered saline (PBS): Dissolve 8.0g NaCl, 0.2g KCl, 1.2g Na_2HPO_4 and 0.2g KH_2PO_4 in 1 liter of distilled water (dH_2O). Adjust the pH to 7.4, sterilize by passing through a 0.2 µm filter and store at room temperature.
2. Wash solution (WS): heat inactivate 100 ml of normal goat serum (Invitrogen) at 56°C for 1 hour. Mix with 900 ml PBS, 20 µl Triton X-100 and 1.0g sodium azide. Filter-sterilize and store at 4°C (see **Note 1**).
3. Propidium iodide (PI): dissolve 10.0 mg PI (Calbiochem) in 100 ml PBS. Add 20 µl Triton X-100 and 0.1 g sodium azide. Protect solution from light and store at 4°C.
4. Ribonuclease: dissolve 100 mg of RNAase A (Sigma) in 100 ml PBS. Boil for 1 hour. Add 20 µl Triton X-100 and 0.1 g sodium azide. Store at 4°C.

2.3. Cell Extraction

1. 2X CSK buffer (200 ml): bring 0.6 g PIPES, 20.5 g sucrose, (see **Note 2**), 4 ml 5 M NaCl and 0.6 ml of 1M $MgCl_2$ to total volume of 190 ml with H_2O. The solution will clear, with stirring, while adjusting to pH 7.0 with 10N NaOH. Add H_2O to a final volume of 200 ml. (1X CSK= 10 mM PIPES pH7.0, 100 mM NaCl, 300 mM sucrose, 3 mM M gCl_2).
2. 100X protease inhibitor cocktail: dissolve 2.5 mg leupeptin, 2.5 mg aprotinin, 15.0 mg benzamidine and 1.0 mg trypsin inhibitor (all protease inhibitors were from Sigma) in 1.0 ml H_20. Store in 0.1 ml aliquots at −20° C.
3. CSK/0.5% Triton X-100. For 5 ml, combine 2.5 ml 2X CSK buffer, 2.15 ml H_20, 0.25 ml 10% Triton X-100, 0.05 ml 100 mM PMSF and 0.05 ml 100X protease inhibitor cocktail.

3. Methods

3.1. CSK Extraction and Fixation

This procedure was adapted from reports describing the use of a selective extraction procedure to demonstrate the release of MCM proteins from chromatin in S phase cells ***(6,7,8)***.

1. Cells can be grown in culture slides or on glass cover slips placed in tissue culture plates. For the purpose of this study, CV-1 cells were grown on 12 mm circular glass cover slips in 60 mm plates.
2. At time of harvest, aspirate medium and wash plate with 5 ml PBS.

3. Remove cover slips with fine-tipped forceps and place cell-side up on a parafilm covered glass plate in a humidified chamber. (see **Note 3**)
4. Gently place 150 µl CSK buffer on each cover slip (see **Note 4**).
5. Aspirate CSK and replace with 100-150 µl CSK/0.5% Triton X-100; keep in humidified chamber for 5 min.
6. Aspirate CSK/0.5% Triton X-100 and gently wash 3X with CSK buffer (see **Note 5**).
7. Fix immediately by transferring cover slips to Alumina staining racks (Thomas Scientific) submerged in methanol at −20°C (see **Note 6**).
8. Allow cover slips to air dry; either store at −20°C or continue with antibody staining.

3.2. Titration of Antibodies

Quantitative measurement of a specific protein requires that antibody be present in excess. Yet, the background of nonspecific antibody staining should be kept to a minimum. To determine the appropriate antibody concentration, stain parallel cover slips with serial dilutions of antibody. If similar cells not expressing the protein of interest are available, they can be stained at the same dilutions to determine levels of nonspecific staining. Background staining due to nonspecific binding by the primary antibody can also be measured in cells stained with nonspecific antibody of the same isotype. Background staining due to the fluorescent secondary antibody can be measured in cells stained with the secondary antibody only.

3.3. Protein and DNA Staining

1. Rehydrate dried cover slips by placing cell-side up on a parafilm covered glass plate in a humidified chamber and covering with 150 µl wash solution.
2. Remove WS and layer 20-50 µl of primary antibody diluted in WS onto each cover slip. Incubate 30 min at 37°C (see **Note 7**).
3. Rinse cover slips 3X by gentle addition and aspiration of 150 µl wash solution.
4. Layer 20-50 µl of fluorescently labeled secondary antibody onto each cover slip and incubate 30 min at 37°C (see **Note 8**).
5. Rinse cover slips 5X by gentle addition and aspiration of 150 µl wash solution.
6. Combine equal volumes of PI solution and RNAase solution. Incubate each cover slip with 20-50 µl of the mixture for 30 min at room temperature.
7. Briefly rinse cover slip by dipping in H_20 and drain by touching edge of cover slip to a Kimwipe. Prepare mounting medium by mixing 90% glycerol/ 10% PBS and then diluting 1:1 with PI solution. Apply 5-10 µl of mounting media to a glass microscope slide and mount cover slip cell side down (see **Note 9**).

3.4. Laser Scanning Cytometry and Data Analysis

The data was acquired with an iCys Research Imaging Cytometer manufactured by CompuCyte, Cambridge, MA, which is capable of scanning micro plates, slides, and other carriers. This microscope-based instrument uses three lasers (488 nm argon, 633 nm helium neon, and 405 nm violet diode), dichroic

mirrors, optical filters (650 LP for CY5, 580/30 for PE, 530/30 for FITC, and 463/39 for DAPI), and photomultipliers (PMTs). Software utilized was the iGeneration Cytometric Analysis Software Version 3.2.5. Instrument settings were 5 mW laser power (488nm argon) with the detector voltages set at 35 V green channel with a 530/30 optical filter and 33 V long red channel with a 650 LP optical filter. For reanalysis, the contour primary minimum area of 20 μm^2 was set to exclude cell fragments and a maximum area of 340 μm^2 to allow doublet discrimination. The instrument will acquire the data and record the location of each cell. Therefore, after the data is acquired, stored and analyzed, the cells may be viewed in a gallery for their morphology and surrounding cells. Cells can be restained with other fluorochromes/antibodies if required.

The procedure detailed above was used to examine the expression and nuclear association of the DNA helicase subunit, MCM2, in proliferating monkey kidney cells. **Figure 1A** shows MCM2 (*y* axis) vs DNA staining (*x* axis) of cells directly fixed in methanol. The greatest range in MCM2 expression is observed in G1 phase cells. Cells in S and G2 phases uniformly express higher levels of MCM2. **Panel B** shows cells that were extracted with CSK/0.5% Triton X-100 to remove soluble proteins prior to methanol fixation. A striking characteristic of extracted S phase cells is the decrease in MCM2 as cells increase in DNA content, whereas the directly fixed cells have consistently high levels of MCM2 throughout S phase. The conclusion from this analysis is that although the level of nuclear MCM2 remains constant throughout S phase, the increase in DNA content during S phase directly correlates with release of chromatin-bound MCM2. The release of MCM proteins as a consequence of replication origin firing has been described previously in biochemical and immunofluorescent microscopy studies ***(6-8).*** However, the multiparameter capabilities of LSC provide the advantage of simultaneous quantitation of MCM2 protein and DNA ***(5).***

Another powerful feature of LSC, which is not possible with FC, is the ability to visualize laser scan images of each event assembled in an image gallery. This is particularly useful in further defining specific events and eliminating undesirable events from the scattergrams. An example is seen in panel B where there appear to be subpopulations of extracted cells that retain MCM2 in G2/M phase and higher DNA contents. Examination of an image gallery revealed that these events were not single cells, but doublets and clusters of multiple nuclei. The acquired data (**panels A and B**), were reanalyzed to eliminate doublets and large nuclear clusters based on their area (see **Note 10**). Morphological identification of the cells from image galleries of the G2/M regions of **panels B** and **D** is presented is presented in **panels E** and **F**, respectively. Only nuclei are apparent due to visualization of the PI stain. Cells viewed in **panel E** prior to exclusion of events greater than 340 μm^2 exhibit numerous doublets and multiple clusters, while the cells viewed following exclusion (**panel F**) are single cells. The scattergrams in **panels C** and **D** exclude events greater than 340 μm^2 from **panels A**

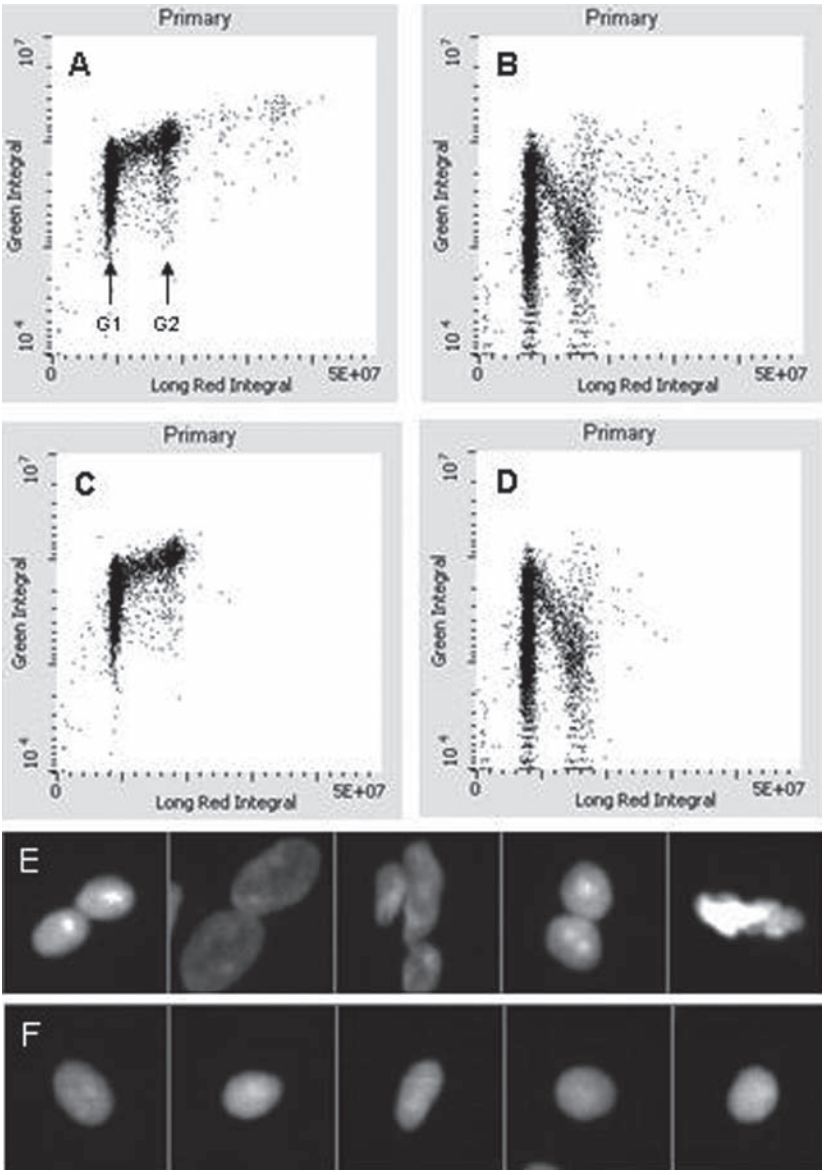

Fig. 1. Growing CV-1 monkey kidney cells stained for MCM2 (*y* axis) and DNA content (*x* axis). **(A)** Cells were directly fixed in methanol and then stained for MCM2 and DNA. **(B)** Parallel cover slips were extracted with CSK/0.5% Triton X-100 prior to fixation and staining. To eliminate doublet and larger nuclear clusters from the scattergrams, PI-stained events with an area greater than 340 μm^2 were subtracted from the scattergrams A and B to generate the distributions in **(C)** directly fixed and **(D)** extracted. **(E)** A gallery of nuclei excluded by elimination of events greater than 340 μm^2 from the G2/M phase region. **(F)** A gallery of nuclei with areas between 20 and 340 μm^2 from the G2/M phase region.

and **B,** respectively, and significantly reduce two artifactual results. First, cells that appear to have DNA contents greater than that of a G2/M phase cell are nearly eliminated. Second, a cell subpopulation that appears to retain MCM2 binding in G2/M and cells of higher DNA content is markedly decreased.

The ability to perform *in situ* extractions brings elements of biochemical fractionation to the field of quantitative cytometry. Additional fractionation procedures or other biochemical manipulations should be feasible as long as primary cell morphology and the epitope being examined are not destroyed. In addition, the capacity of this instrumentation to reanalyze data provides a powerful tool to determine and characterize multiple parameters of the collected data.

4. Notes

1. Sodium azide is highly toxic. Consult the MSDS for proper handling instructions.
2. Use a molecular biology-grade sucrose, such as Sigma S0389.
3. A simple humidified chamber can be made from a plastic or glass 150 mm Petri dish. Filter paper or paper towel is cut to fit inside the lid and moistened with H_20. A glass plate such as an 8 × 10 cm minigel plate is wrapped in parafilm and placed on the moistened paper. The base of the dish is used as the lid.
4. An alternative to individual treatment of cover slips is to leave cover slips in the tissue culture plate and treat with larger volumes of extraction and wash buffers.
5. Cells treated with CSK/0.5% Triton X-100 are more susceptible to detachment from the cover slip. Extra care must be taken in adding and removing buffer from the cover slip.
6. 70% acetone/30% methanol has also been successfully used for fixation of MCM2 (5). Appropriate fixation conditions will need to be optimized for each epitope.
7. Longer periods of incubation (1-2 hours) at room temp may also be used and should be optimized for each epitope.
8. To protect fluorescently labeled antibody from light, use aluminum foil to wrap the base and lid of the humidified chamber, described in **Note 3.**
9. If more permanent mounting is required, the cover slips can be mounted in ProLong (Invitrogen) supplemented with PI.
10. Doublets and clusters of multiple nuclei can be excluded based on the area (measured in square microns) of each event. For example, two G1 phase nuclei in close proximity may be recorded as a single event. Although the DNA content of the two G1 phase nuclei will be recorded as equivalent to a G2 phase nucleus, the area of the two G1 nuclei will be greater than that of the G2 nucleus. In this case, doublets and larger nuclear clusters

were eliminated by excluding events with an area greater than 340 μm^2. The optimal exclusion threshold should be determined empirically for each experimental group.

Protein Solubility in Two-Dimensional Electrophoresis

Basic Principles and Issues

Thierry Rabilloud

1. Introduction

The solubilization process for two-dimensional (2-D) electrophoresis has to achieve four parallel goals:

1. Breaking macromolecular interactions in order to yield separate polypeptide chains. This includes denaturing the proteins to break noncovalent interactions, breaking disulfide bonds, and disrupting noncovalent interactions between proteins and nonproteinaceous compounds such as lipids or nucleic acids.
2. Preventing any artefactual modification of the polypeptides in the solubilization medium. Ideally, the perfect solubilization medium should freeze all the extracted polypeptides in their exact state prior to solubilization, both in terms of amino acid composition and in terms of posttranslational modifications. This means that all the enzymes able to modify the proteins must be quickly and irreversibly inactivated. Such enzymes include of course proteases, which are the most difficult to inactivate, but also phosphatases, glycosidases, and so forth. In parallel, the solubilization protocol should not expose the polypeptides to conditions in which chemical modifications (e.g., deamidation of Asn and Gln, cleavage of Asp-Pro bonds) may occur.
3. Allowing the easy removal of substances that may interfere with 2-D electrophoresis. In 2-D electrophoresis, proteins are the analytes. Thus, anything in the cell but proteins can be considered as an interfering substance. Some cellular compounds (e.g., coenzymes, hormones) are so dilute they go unnoticed. Other compounds (e.g., simple nonreducing sugars) do not interact with proteins or do not interfere with the electrophoretic process. However, many compounds bind to proteins and/or interfere with 2-D electrophoresis and must be eliminated prior to electrophoresis if their amount exceeds a critical interference threshold. Such compounds mainly include salts, lipids, polysaccharides (including cell walls), and nucleic acids.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

4. Keeping proteins in solution during the 2-D electrophoresis process. Although solubilization *stricto sensu* stops at the point where the sample is loaded onto the first dimension gel, its scope can be extended to the 2-D process *per se*, as proteins must be kept soluble till the end of the second dimension. Generally speaking, the second dimension is an SDS gel, and very few problems are encountered once the proteins have entered the SDS-polyacrylamide gel electrophoresis (SDS PAGE) gel. The one main problem is overloading of the major proteins when micropreparative 2-D electrophoresis is carried out, and nothing but scaling-up the SDS gel (its thickness and its other dimensions) can counteract overloading an SDS gel. However, severe problems can be encountered in the isoelectric fusing (IEF) step. They arise from the fact that IEF must be carried out in low ionic strength conditions and with no manipulation of the polypeptide charge. IEF conditions give problems at three stages:
    a. During the initial solubilization of the sample, important interactions between proteins of widely different pI and/or between proteins and interfering compounds (e.g., nucleic acids) may happen. This yields poor solubilization of some components.
    b. During the entry of the sample in the focusing gel, there is a stacking effect due to the transition between a liquid phase and a gel phase with a higher friction coefficient. This stacking increases the concentration of proteins and may give rise to precipitation events.
    c. At, or very close to, the isoelectric point, the solubility of the proteins comes to a minimum. This can be explained by the fact that the net charge comes close to zero, with a concomitant reduction of the electrostatic repulsion between polypeptides. This can also result in protein precipitation or adsorption to the IEF matrix.

Apart from breaking molecular interactions and solubility in the 2-D gel, which are common to all samples, the solubilization problems encountered will greatly vary from a sample type to another because of wide differences in the amount and nature of interfering substances and/or spurious activities (e.g., proteases). The aim of this outline chapter is not to give detailed protocols for various sample types, and the reader should refer to the chapters of this book dedicated to the type of sample of interest. I would rather like to concentrate on the solubilization rationale and to describe nonstandard approaches to solubilization problems. More detailed review on solubilization of proteins for electrophoretic analyses can be found elsewhere ***(1,2)***.

2. Rationale of Solubilization-Breaking Molecular Interactions

Apart from disulfide bridges, the main forces holding proteins together and allowing binding to other compounds are noncovalent interactions. Covalent bonds are encountered mainly between proteins and some coenzymes. The

noncovalent interactions are mainly ionic bonds, hydrogen bonds, and "hydrophobic interactions." The basis for "hydrophobic interactions" is, in fact, the presence of water. In this very peculiar (hydrogen-bonded, highly polar) solvent, the exposure of nonpolar groups to the solvent is thermodynamically not favored compared to the grouping of these apolar groups together. Indeed, although the van der Waals forces give an equivalent contribution in both configurations, the other forces (mainly hydrogen bonds) are maximized in the latter configuration and disturbed in the former (solvent destruction). Thus, the energy balance in clearly in favor of the collapse of the apolar groups together ***(3)***. This explains why hexane and water are not miscible, and also that the lateral chain of apolar amino acids (L, V, I, F, W, Y) pack together and form the hydrophobic cores of the proteins ***(4)***. These hydrophobic interactions are also responsible for some protein-protein interactions and for the binding of lipids and other small apolar molecules to proteins.

The constraints for a good solubilization medium for 2-D electrophoresis are therefore to be able to break ionic bonds, hydrogen bonds, hydrophobic interactions, and disulfide bridges under conditions compatible with IEF (i.e., with very low amounts of salt or other charged compounds) (e.g., ionic detergents).

2.1. Disruption of Disulfide Bridges

Breaking of disulfide bridges is usually achieved by adding to the solubilization medium an excess of a thiol compound. Mercaptoethanol was used in the first 2-D protocols ***(5)***, but its use does have drawbacks. Indeed, a portion of the mercaptoethanol will ionize at basic pH, enter the basic part of the IEF gel, and ruin the pH gradient in its alkaline part because of its buffering power ***(6)***. Although its pK is approximately 8, dithiothreitol is much less prone to this drawback, as it is used at much lower concentrations (usually 50 m*M* instead of the 700 m*M* present in 5% mercaptoethanol). However, DTT is still not the perfect reducing agent. Some proteins of very high cysteine content or with cysteines of very high reactivity are not fully reduced by DTT. In these cases, phosphines are very often an effective answer. First, the reaction is stoichiometric, which allows in turn to use very low concentration of the reducing agent (a few m*M*). Second, these reagents are not as sensitive as thiols to dissolved oxygen. The most powerful compound is tributylphosphine, which was the first phosphine used for disulfide reduction in biochemistry ***(7)***. However, the reagent is volatile, toxic, has a rather unpleasant odor, and needs an organic solvent to make it water-miscible. In the first uses of the reagent, propanol was used as a carrier solvent at rather high concentrations (50%) ***(7)***. It was however found that DMSO or DMF are suitable carrier solvents, which enable the reduction of proteins by 2 m*M* tributylphosphine ***(8)***. All these drawbacks have disappeared with the introduction of a water-soluble phospine, tris (carboxyethyl) phosphine

(available from Pierce), for which 1M aqueous stock solutions can be easily prepared and stored frozen in aliquots. The successful use of tributylphosphine in two-dimensional electrophoresis has been reported ***(9)***. However, the benefits over DTT do not seem obvious in many cases ***(10)***, although th use of phosphines allows in turn to use thiol-blocking agents (e.g., dithiodiethanol), resulting in iproved resolution of the basic proteins ***(11,12)***.

2.2. Disruption of Noncovalent Interactions

The perfect way to disrupt all types of noncovalent interactions would be the use of a charged compound that disrupts hydrophobic interactions by providing a hydrophobic environment. The hydrophobic residues of the proteins would be dispersed in that environment and not clustered together. This is just the description of SDS, and this explains why SDS has been often used in the first stages of solubilization ***(13–16)***. However, SDS is not compatible with IEF, and must be removed from the proteins during IEF.

The other way of breaking most noncovalent interactions is the use of a chaotrope. It must be kept in mind that all the noncovalent forces keeping molecules together must be taken into account with a comparative view on the solvent. This means that the final energy of interaction depends on the interaction *per se* and on its effects on the solvent. If the solvent parameters are changed (dielectric constant, hydrogen bond formation, polarizability, etc.), all the resulting energies of interaction will change. Chaotropes, which alter all the solvent parameters, exert profound effects on all types of interactions. For example, by changing the hydrogen bond structure of the solvent, chaotropes disrupt hydrogen bonds but also decrease the energy penalty for exposure of apolar groups and therefore favor the dispersion of hydrophobic molecules and the unfolding of the hydrophobic cores of a protein ***(1,17)***. Unfolding the proteins will also greatly decrease ionic bonds between proteins, which are very often not very numerous and highly dependent of the correct positioning of the residues. As the gross structure of proteins is driven by hydrogen bonds and hydrophobic interactions, chaotropes decrease dramatically ionic interactions both by altering the dielectric constant of the solvent and by denaturing the proteins, so that the residues will no longer positioned correctly.

Nonionic chaotropes, as those used in 2-D electrophoresis, however, are unable to disrupt ionic bonds when high charge densities are present (e.g., histones, nucleic acids) ***(18)***. In this case, it is often quite advantageous to modify the pH and to take advantage of the fact that the ionizable groups in proteins are weak acids and bases. For example, increasing the pH to 10 or 11 will induce most proteins to behave as anions, so that ionic interactions present at pH 7 or lower turn into electrostatic repulsion between the molecules, thereby promoting solubilization. The use of a high pH results therefore in dramatically improved

solubilizations, with yields very close to what is obtained with SDS ***(19)***. The alkaline pH can be obtained either by addition of a few m*M* of potassium carbonate to the urea-detergent-ampholytes solution ***(19)***, or by the use of alkaline ampholytes ***(16)***, or by the use of a spermine-DTT buffer which allows better extraction of nuclear proteins ***(20)***.

For 2-D electrophoresis, the chaotrope of choice is urea. Although urea is less efficient than substituted ureas in breaking hydrophobic interactions ***(17)***, it is more efficient in breaking hydrogen bonds, so that its overall solubilization power is greater. It has been found that thiourea in addition to urea results in superior solubilization of proteins ***(21)*** and also in improved protein focusing. This may be explained by the fact that thiourea is a superior to urea for protein denaturation, being overwhelmed only by guanidine ***(22)***. However, the solubility of thiourea in water is not sufficient to draw full benefits from its denaturing power, so that it must be used in admixture with urea. However, denaturation by chaotropes induces the exposure of the totality of the proteins hydrophobic residues to the solvent. This increases in turn the potential for hydrophobic interactions, so that chaotropes alone are often not sufficient to quench completely the hydrophobic interactions, especially when lipids are present in the sample. This explains why detergents, which can be viewed as specialized agents for hydrophobic interactions, are almost always included in the urea-based solubilization mixtures for 2-D electrophoresis. Detergents act on hydrophobic interactions by providing a stable dispersion of a hydrophobic medium in the aqueous medium, through the presence of micelles for example. Therefore, the hydrophobic molecules (e.g., lipids) are no longer collapsed in the aqueous solvent but will disaggregate in the micelles, provided the amount of detergent is sufficient to ensure maximal dispersion of the hydrophobic molecules. Detergents have polar heads that are able to contract other types of noncovalent bonds (hydrogen bonds, salt bonds for charged heads, etc.). The action of detergents is the sum of the dispersive effect of the micelles on hydrophobic part of the molecules and the effect of their polar heads on the other types of bonds. This explains why various detergents show very variable effects varying from a weak and often incomplete delipidation (e.g., Tweens) to a very aggressive action where the exposure of the hydrophobic core in the detergent-containing solvent is no longer energetically unfavored and leads to denaturation (e.g., SDS).

Of course, detergents used for IEF must bear no net electrical charge, and only nonionic and zwitterionic detergents may be used. However, ionic detergents such as SDS may be used for the initial solubilization prior to isoelectric focusing to increase solubilization and facilitate the removal of interfering compounds. Low amounts of SDS can be tolerated in the subsequent IEF ***(13)*** provided that high concentrations of urea ***(23)*** and nonionic ***(13)*** or zwitterionic detergents ***(24)*** are present to ensure complete removal of the SDS from the

proteins during IEF. Higher amounts of SDS must be removed prior to IEF, by precipitation ***(13)*** for example. It must therefore be kept in mind that SDS will only be useful for solubilization and for sample entry, but will not cure isoelectric precipitation problems.

The use of nonionic or zwitterionic detergents in the presence of urea presents some problems due to the presence of urea itself. In concentrated urea solutions, urea is not freely dispersed in water but can form organized channels (see ***[20]***). These channels can bind linear alkyl chains, but not branched or cyclic molecules, to form complexes of undefined stoichiometry called inclusion compounds. These complexes are much less soluble than the free solute, so that precipitation is often induced upon formation of the inclusion compounds, precipitation being stronger with increasing alkyl chain length and higher urea concentrations. Consequently, many nonionic or zwitterionic detergents with linear hydrophobic tails ***(24,25)*** and some ionic ones ***(28)*** cannot be used in the presence of high concentrations of urea. This limits the choice of detergents mainly to those with nonlinear alkyl tails (e.g., Tritons, Nonidet P40, CHAPS) or with short alkyl tails (e.g., octyl glucoside), which are unfortunately less efficient in quenching hydrophobic interactions. However, sulfobetaine detergents with long linear alkyl tails have received limited applications, as they require low concentrations of urea. However, good results have been obtained in certain cases for sparingly soluble proteins ***(27–29)***, although this type of protocol seems rather delicate owing to the need for a precise control of all parameters to prevent precipitation. Thus, protocols using detergents with a good urea compatibility are generally preferred, both because of their simpler use and because synergistic effects between the urea-thiourea chaotrope mixture and some detergents have been observed ***(32)***.

Apart from the problem of inclusion compounds, the most important problem linked with the use of urea is carbamylation. Urea in water exists in equilibrium with ammonium cyanate, the level of which increases with increasing temperature and pH ***(33)***. Cyanate can react with amines to yield substituted urea. In the case of proteins, this reaction takes place with the α-amino group of the N-terminus and the ε-amino groups of lysines. This reaction leads to artefactual charge heterogeneity, N-terminus blocking and adduct formation detectable in mass spectrometry. Carbamylation should therefore be completely avoided. This can be easily made with some simple precautions. The use of a pure grade of urea (p.a.) decreases the amount of cyanate present in the starting material. Avoidance of high temperatures (never heat urea-containing solutions above 37°C) considerably decreases cyanate formation. In the same trend, urea-containing solutions should be stored frozen (–20°C) to limit cyanate accumulation. Last, but not least, a cyanate scavenger (primary amine) should be added to urea-containing solutions. In the case of isoelectric focusing, carrier ampholytes are perfectly

suited for this task. If these precautions are correctly taken, proteins seem to withstand long exposures to urea without carbamylation ***(34)***.

3. Methods

3.1 Solubility During IEF

Additional solubility problems often arise during the IEF at sample entry and solubility at the isoelectric point.

3.1.1 Solubility During Sample Entry

Sample entry is often quite critical. In most 2-D systems, sample entry in the IEF gel corresponds to a transition between a liquid phase (the sample) and a gel phase of higher friction coefficient. This induces a stacking of the proteins at the sample-gel boundary, which results in very high concentration of proteins at the application point. These concentrations may exceed the solubility threshold of some proteins, thereby inducing precipitation and sometimes clogging of the gel, with poor penetration of the bulk of proteins. Such a phenomenon is of course more prominent when high amounts of proteins are loaded onto the IEF gel. The sole simple but highly efficient remedy to this problem is to include the sample in the IEF gel. This process abolishes the liquid-gel transition and decreases the overall protein concentration, as the volume of the IEF gel is generally much higher than the one of the sample.

This process is however rather difficult for tube gels in carrier ampholyte-based IEF. The main difficulty arises from the fact that the thiol compounds used to reduce disulfide bonds during sample preparation are strong inhibitors of acrylamide polymerization, so that conventional samples cannot be used as such. Alkylation of cysteines and of the thiol reagent after reduction could be an answer, but many neutral alkylating agents (e.g., iodoacetamide, ethyl maleimide) also inhibit acrylamide polymerization. Owing to this situation, most workers describing inclusion of the sample within the IEF gel have worked with nonreduced samples ***(35,36)***. Although this presence of disulfide bridges is not optimal, inclusion of the sample within the gel has proven of great, but neglected, interest ***(35,36)***. It must however be pointed out that it is now possible to carry out acrylamide polymerization in an environment where disulfide bridges are reduced. The key is to use 2 m*M* tributylphosphine as the reducing agent in the sample and using tetramethylurea as a carrier solvent. This ensures total reduction of disulfides and is totally compatible with acrylamide polymerization with the standard Temed/persulfate initiator (T. Rabilloud, unpublished results). This modification should help the experimentators trying sample inclusion within the IEF gel when high amounts of proteins are to be separated by 2D.

The process of sample inclusion within the IEF gel is however much simpler for IPG gels. In this case, rehydration of the dried IPG gel in a solution containing the protein sample is quite convenient and efficient, provided that the gel has a sufficiently open structure to be able to absorb proteins efficiently ***(20)***. Coupled with the intrinsic high capacity of IPG gels, this procedure enables to easily separate milligram amounts of protein ***(20,37)***.

3.1.2. Solubility at the Isoelectric Point

This is usually the second critical point for IEF. The isoelectric point is the pH of minimal solubility, mainly because the protein molecules have no net electrical charge. This abolishes the electrostatic repulsion between protein molecules, which maximizes in turn protein aggregation and precipitation.

The horizontal comet shapes frequently encountered for major proteins and for sparingly soluble proteins often arise from such a near-isoelectric precipitation. Such isoelectric precipitates are usually easily dissolved by the SDS solution used for the transfer of the IEF gel onto the SDS gel, so that the problem is limited to a loss of resolution, which however precludes the separation of high amounts of proteins.

The problem is however more severe for hydrophobic proteins when an IPG is used. In this case, a strong adsorption of the isoelectric protein to the IPG matrix seems to occur, which is not reversed by incubation of the IPG gel in the SDS solution. The result is severe quantitative losses, which seem to increase with the hydrophobicity of the protein and the amount loaded ***(38)***. The sole solution to this serious problem is to increase the chaotropicity of the medium used for IEF, by using both urea and thiourea as chaotropes ***(21)***.

The benefits of using thiourea-urea mixtures to increase protein solubility can be transposed to conventional, carrier ampholyte-based focusing in tube gels with minor adaptations. Thiourea strongly inhibits acrylamide polymerization with the standard temed/persulfate system. However, photopolymerization with methylene blue, sodium toluene sulfinate and diphenyl iodonium chloride ***(39)*** enables acrylamide polymerization in the presence of 2M thiourea without any deleterious effect in the subsequent 2D ***(40)*** so that higher amounts of proteins can be loaded without loss of resolution ***(40)***.

3.1.3 The Epitome in Solubilization Problems: Membrane Proteins

Biological membranes represent a prototype of difficult samples for 2-D electrophoresis. They contain high amounts of lipids, which are troublesome compounds for 2-D electrophoresis. In addition, many membrane proteins are highly hydrophobic, and therefore very difficult to keep in aqueous solution, even with the help of chaotropes and detergents. Thus, membrane proteins

have often been reluctant to 2-D electrophoretic analysis ***(41)***. In fact, it has been shown that typical membrane proteins with multiple transmembrane helices are resistant to solubilization by chaotrope-detergent mixtures, even using thiourea ***(42)***. For such proteins, the development of new detergents proved necessary ***(42,43)***. Even if some successes have been obtained ***(42–45)***, it is still obvious that many membrane proteins are not properly solubilized and focused with the chemicals described up to now ***(46)***. Therefore, further development is still needed to improve the representation of membrane proteins in 2-D maps. However, the problem of isoelectric precipiation may prevent definitively proper solubilization of membrane proteins in IEF-based 2-D electrophoretic systems

4. Concluding Remarks

Although this outline chapter has mainly dealt with the general aspects of solubilization, the main concluding remark is that there is no universal solubilization protocol. Standard urea-reducer-detergent mixtures usually achieve disruption of disulfide bonds and noncovalent interactions. Consequently, the key issues for a correct solubilization is the removal of interfering compounds, blocking of protease action, and disruption of infrequent interactions (e.g., severe ionic bonds). These problems will strongly depend on the type of sample used, the proteins of interest and the amount to be separated, so that the optimal solubilization protocol can vary greatly from a sample to another.

However, the most frequent bottleneck for the efficient 2-D separation of as many and as much proteins as possible does not lie only in the initial solubilization but also in keeping the solubility along the IEF step. In both fields, the key feature is the disruption of hydrophobic interactions, which are responsible for most, if not all, of the precipitation phenomena encountered during IEF. This means improving solubility during denaturing IEF will focus on the quest of ever more powerful chaotropes and detergents. In this respect, the use of thiourea has proven to be one of the keys to increase the solubility of proteins in 2-D electrophoresis. It would be nice to have other, even more powerful chaotropes. However, testing of the chatropes previously described as powerful ***(22)*** has not led yet to improvement in protein solubilization (T. Rabilloud, unpublished results). One of the other keys for improving protein solubilization is the use of as powerful detergent or detergent mixtures as possible. Among a complex sample, some proteins may be well denatured and solubilized by a given detergent or chaotrope, while other proteins will require another detergent or chaotrope (e.g., in ***[42]***). Consequently, the future of solubilization may still be to find mixtures of detergents and chaotropes able to cope with the diversity of proteins encountered in the complex samples separated by 2-D electrophoresis.

Mouse and Human Tissue Sample Preparation for 2-D Electrophoresis

Claus Zabel and Joachim Klose

1. Introduction

The protocol for extracting proteins from mouse and human tissues (organs) described in this chapter adheres to a strategy that is based on a rationale to include all protein species of a particular tissue in a set of samples which are suitable for two dimensional electrophoresis (2-DE), particularly for large gel 2-DE described in Chapter 32 ***(1)***. The extraction procedure is one of the most important steps to maintain reproducibility in 2-D gel based proteomics ***(2)***. The ultimate goal is resolution and visualization of all these protein species in 2-DE gels. This aim determines some features of our tissue extraction procedure for retrieving proteins. Since the last publication of our comprehensive protein extraction protocol ***(3)*** we found that an extraction protocol for total cell or tissue proteins may be sufficient for many more users than a protocol for fractionated extraction ***(4)***. Still, fractionated extraction has also a number of applications, especially when only certain classes of proteins such as cytoplasmic, membrane or nuclear proteins are of interest.

1.1. Total Extraction of all Cellular Proteins

Extraction of total proteins at once insures that no distribution artefacts occur as may be seen when proteins are fractionated into different subcellular fractions. Therefore the total amount of a given protein is determined within each protein sample investigated. In addition, the total extraction procedure is much simpler, takes less time and is highly compatible with new protein visualization techniques such as differential in gel electrophoresis (DIGE). This extraction procedure can be applied to almost any tissue, cell culture or subcellular components. No ultracentrifugation steps are involved which avoids protein precipitation and

elimination during sample preparation. The total extraction procedure is based on adding protease inhibitors, detergent (CHAPS), urea/thiourea in very close succession to solubilze proteins in a tissue/cell as much as possible and keep them from degradation. Grinding the deep frozen tissue and sonication are the second instrumental part in the solubilization process. DNA-bound proteins are recovered by DNAse treatment. In this way all proteins are solubilized in one fraction without precipitation and fractionation steps.

1.2. Fractionated Extraction of Cellular Proteins

On the other hand, using the fractionation procedure the many different protein species of a tissue can be distributed over several 2-DE gels and this certainly increases resolution. However, a postulate is that fractionation of tissue proteins results in fraction-specific proteins. Usually, cell fractionation is performed with the aim of isolating special cell organelles (nuclei, mitochondria) or cell structures (membranes). Proteins are then extracted from these subcellular fractions. This procedure, however, includes washing steps to purify cell fractions and eliminate cell components which are not of interest and cell residues which are rejected. Using fractionation this way, an *uncontrolled* loss of proteins is unavoidable.

The tissue fractionation procedure described in this chapter renounces the isolation of defined cell components using washing and precipitation steps. This allows us to avoid any selective loss of proteins which is of utmost importance for all protein extraction protocols. Mouse (human) tissues (liver, brain, heart) are fractionated into three fractions: (1) The "supernatant I+II" (SI+II) containing the proteins soluble in buffer (cytoplasmic and nucleoplasmic proteins), (2) the "pellet extract" (PE) containing the proteins soluble in the presence of urea and CHAPS (proteins from membranes and other structures of the cells and cell organelles), and (3) the "pellet suspension" (PS) containing proteins released by DNA digestion (histones and other chromosomal proteins). The SI+II fraction is obtained by homogenization, sonication and centrifugation of tissue and reextraction of pellet (I) and the combination of the two supernatants gained in this way. The solution thus obtained is the first protein sample. The pellet (II) that remained is extracted with urea and CHAPS and the homogenate is centrifuged. The supernatant is the PE fraction and constitutes the second protein sample. The final pellet (III) is suspended into buffer containing benzonase, a DNA digesting enzyme. The pellet suspension (PS fraction) is the third protein sample. It is applied to 2-DE without further centrifugation.

Care is taken during the whole procedure to avoid any loss of material. In spite of this caution, some material may be lost, for example by transfer of the pulverized, frozen tissue from the mortar to a tube or by removing the glass

beads from the sonicated homogenate. However, this does not lead to a preferential loss of certain protein species or protein classes.

1.3. Important Considerations When Using Protein Extraction Procedures

Generally, it is evident that the best conditions for keeping proteins stable and soluble are present in living cells ***(1,2)***. Therefore, an important principle of our tissue extraction procedure is to extract proteins, using conditions as close to the natural environment in the cell as possible. That means keeping ionic strength of the tissue homogenate at 150-200 m*M*, the pH in a range of 7.0-7.5, protein concentration high, and protecting the proteins against water by adding glycerol to the buffer. Generally, the best conditions for the first tissue extraction step would be if an addition of diluent that disturbs the natural protein concentrations and milieu of the cell were avoided. We prepared a pure cell sap from a tissue by homogenizing it without additives (except for protease inhibitor solutions added in small volumes) followed by high speed centrifugation and extracted the pellet that resulted successively in increasing amounts (0.5, 1 or 2 parts) of buffer. The series of protein samples obtained were separated by 2-DE and the patterns compared. The results showed that by increasing the dilution of proteins the number of spots and their intensities decreased in the lower part of the 2-DE patterns and increased in the upper part. The same phenomenon, but less pronounced, was observed even when the cell sap was diluted successively. Apparently, low molecular weight proteins are best dissolved in the pure cell sap and, presumably, tend to precipitate in more diluted extracts. In contrast, high molecular weight proteins dissolve better in more diluted samples. This effect was most pronounced in protein patterns from liver and not obvious in patterns from heart muscle. This is probably due to the high protein concentration in the liver cell sap that is not reached in extracts of other organs.

The dependence of protein solubility on the molecular weight of proteins is obscured in 2-DE patterns by another effect that causes a similar phenomenon. An increasing protein concentration of the first tissue extract leads to a higher activity of proteases released by breaking cellular structure by homogenization. Protein patterns from pure liver cell sap, extracted without protease inhibitors (but even with inhibitors) showed an enormous number of spots in the lower part of the gel and a rather depleted pattern in the upper part. In the pH range around pH 6 protein spots disappeared almost completely, in the upper as well as in the lower part, suggesting that these proteins are most sensitive to degradation by proteases. By extracting tissue or the first pellet with increasing amounts of buffer, the 2-DE pattern (spot number and intensity) shifted from the lower part to the upper part of the gel. Again, this observation was made particularly in liver.

The consequence of these observations for our total as well as our fractionated protein extraction procedure was to maintain the total extract or to obtain the supernatant I and II at concentrations that keep all the soluble proteins in solution but do not reach a level where proteases cannot be inhibited effectively anymore. As a consequence, we introduced buffer factors which adjust the concentration of the different extracts of each organ. The optimum protein concentrations in the extracts and therefore the buffer factors were determined experimentally. An optimum was reached when a maximum number of spots was present in the upper as well as in the lower part of a 2-DE protein pattern. In addition, the region close to pH 6 should not be depleted of spots, a process starting from the top.The methods described in the following sections were developed with mouse tissues but were found to be applicable to corresponding human tissues, cell culture cells and subcellular fractions as well.

2. Materials

2.1. Equipment

1. A small apparatus is preferred for performing sonication in a water-bath (Transsonic 310, FAUST, Singen, Germany).
2. Glass beads added to tissue samples for sonication: Size (diameter) of glass beads should be 2.0- 2.5 mm. A factor 0.034 was calculated for this bead size (*see* **Note 1**).
3. Mortar and pestle: Build and size of this equipment are shown in **Fig. 1**. Mortar and pestle are manufactured of agate or glass (WITA GmbH, Teltow, Germany). Glass

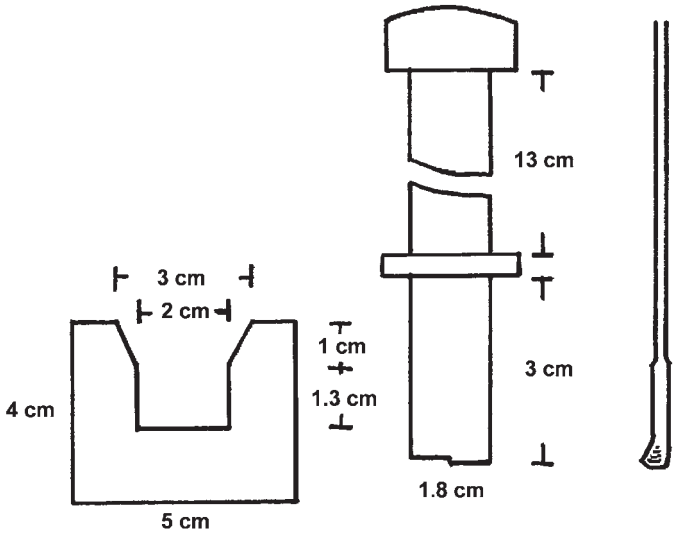

Fig. 1. Special equipment for pulverization of frozen tissue. **(A)** Glass mortar and plastic pestle. **(B)** Spatula used to transfer frozen tissue from a mortar to the test tube. A regular spatula was moulded into a small shovel.

was found to be more stable in liquid nitrogen. Alternatively an electronic mortar grinder can be used (Mortar Grinder RM 200; RETSCH, Haan, Germany).

4. A small spatula is formed into a shovel by wrought-iron work (**Fig. 1**) and used to transfer tissue powder from a mortar to tubes.

2.2. Reagents

1. Buffer A: 20% glycerol, 100 m*M* KCl, 50 m*M* Tris-HCl, pH 7.1, filtered and aliquoted into 1,000 µL portions, and stored at −70°C.
2. Phosphate buffer, pH 7.1: Add 67 mL 200 m*M* Na_2HPO_4 to 33 mL 200 m*M* NaH_2PO_4.
3. Buffer B: 20 % glycerol, 200 m*M* KCl, 100 m*M* phosphate buffer, pH 7.1, filtered, aliquoted *precisely* into 900 µL portions and stored at −70°C. When used, 100 µL of an aqueous CHAPS solution is added. The CHAPS concentration in this aqueous solution is calculated (*see* **Table 1**) so that the pellet II/buffer homogenate (*see* **Table 1**) contains 4.5% CHAPS. This concentration was found to be best when 2-DE patterns are compared. The concentration was determined empirically using protein samples containing different amounts of CHAPS.
4. Buffer C: 1 m*M* $MgSO_4$, 50 m*M* Tris-HCl, pH 8.0 (I mg of pellet III homogenised in 1 mL of this buffer gives a concentration of 1 mM $MgSO_4$. The final solution is filtered, aliquoted into 1 ml portions, and stored at −70°C.
5. Buffer P: 7.7 % glycerol (final concentration in sample if buffer factor is 1.6), 50 m*M* KCl, 50 m*M* Tris-HCl, pH 7.5. The final solution is filtered and aliquoted into 900 µL units and stored at −70°C.
6. Buffer P-$MgCl_2$: 5 m*M* $MgCl_2$ in buffer P. Final solution is aliquoted into 20 µL units and stored at −70°C.
7. Protease inhibitor 1A: One tablet of Complete™ (ROCHE, Mannheim, Germany) is dissolved in 2 ml buffer A (according to the manufacturer's instructions) and the resulting solution aliquoted into 50, 80 and 100 µL units. Inhibitor 1B was prepared in the same way but using buffer B (900 µL buffer + 100 µL H_20) and aliquoted into 30 and 50 µL units. Inhibitor 1C was prepared in the same way as Inhibitor 1A but using buffer P. Inhibitor 2 (pepstatin A): Prepared as a stock solution (9.603mg/100mL ethanol) and aliquoted into 100 µL portions. All inhibitor solutions are stored at −70°C.
8. DTT-solution: 2.16 g DTT is dissolved in 10 mL bidistilled water. The solution is aliquoted into 100 µL portions and stored at −70°C.
9. Sample diluent: Buffer P-$MgCl_2$. The solution is aliquoted into 250 µL units and stored at −70°C.

3. Methods

3.1. Extraction of Total Proteins

3.1.1. Dissection of Mouse Tissue

To obtain good results with protein extraction harvest organs rapidly and remove all contaminating material such as hair and blood.

Table 1
Total Tissue Protein Extraction Protocol

Liver	Brain	Heart
Homogenization		
– Liver tissue (25–50 mg)	– Brain tissue (25–150 mg)	– Heart tissue (25–150 mg)
– Buffer P-CHAPS	– Buffer P-CHAPS	– Buffer P-CHAPS

3.1.1.1. Dissection of Mouse Liver

1. Kill the mouse by decapitation. Thereby, the body is allowed to bleed. The following steps are performed in a cold room:
2. Cut open the abdomen and through the *vena femoralis* on both sides and perfuse the liver with 5 ml saline (0.9% NaCl solution).
3. Dissect the complete liver from the body, remove the gall bladder without injuring it and separate the liver into its different lobes. The central part of each lobe, i.e. the region where blood vessels enter the liver lobe, is cut off as are the remainders of other tissues (diaphragm, fascia).
4. Cut the liver lobes into 2-4 pieces, rinse in ice-cold saline and briefly immerse it there. Immediately after this step the next organ (e.g. brain) is prepared from the same animal, if desirable, and processed to the same stage of preparation as liver.
5. Cut the liver pieces into smaller pieces (about 5 × 5 mm) and transfer each piece to filter paper, immerse into liquid nitrogen, and put into a screw-cap tube where all pieces are collected. During preparation time, tubes are kept in a liquid nitrogen containing box and afterwards stored at −70°C.

3.1.1.2. Dissection of Mouse Brain

1. Kill mouse by decapitation. The following steps are performed in a cold room. If several organs have to be taken from the same animal, start with the brain.
2. Cut off the skin of the head and open the cranium starting from the spinal canal proceeding in a frontal direction. Break the cranial bones apart to expose the brain. Remove the brain including both *bulbi olfactorii* and a small part of the spinal cord. Transfer the brain into a petri dish containing ice-cold saline. Remove any blood vessels and blood from the outside of the brain.
3. As desired, cut the brain to retrieve the desired brain regions or in half along the *corpus callosum*, place the pieces on filter paper and then individually immerse into liquid nitrogen and collect in a screw-capped tube. Keep the tubes in liquid nitrogen during tissue harvest and finally store at −70°C.

3.1.1.3. Dissection of Mouse Heart

1. Kill mouse by decapitation. The following steps are performed in a cold room.
2. Open the thorax and remove the heart. Place the heart into a petri dish containing ice-cold saline. Cut off both atria and open the *ventriculi* to remove any blood and blood clots.
3. Dry the heart on filter paper, freeze in liquid nitrogen and store in a screw-capped tube at −70°C.

3.1.2. Total Extraction of Liver Proteins

1. Fill frozen liver pieces into a small plastic tube of known weight and weigh quickly without thawing. The amount of liver tissues used for extraction should be between 50 and 150 mg.

2. Place a mortar, pestle and a small metal spoon into a styrofoam box that contains liquid nitrogen to a level not exceeding the height of the mortar. The mortar should be pre-cooled for at least 3–4 min. Pre-cool pestle and spatula.
3. Put frozen liver pieces into the mortar, and add buffer P, inhibitor 1C and 2. The required volumes of each of the solutions are calculated as indicated in **Table 1**. The precise amount of each solution is pipetted as a droplet onto a small spoon-like spatula that was kept in the N_2-box before use. The solution is immediately frozen into an ice bead that can easily be transferred into the mortar.
4. Slowly grind all frozen components in the mortar to powder. Care should be taken that small pieces of material do not jump out of the mortar when starting to break up the solid frozen material with a pestle.
5. Transfer the powder into a pre-frozen 2 ml Eppendorf tube using a special spatula (**Fig. 1**). Forceps are used to freeze the tube briefly in N_2 and then to hold the tube close to the mortar in the N_2-box. Care is taken that no powder is left in the mortar or on the pestle. For collection of this powder always use the same type of plastic tube. This contributes to reproducibility of the subsequent sonication step. Compress the powder collected in the tube by gently knocking the tube against the mortar. The powder can be stored at −70°C or immediately subjected to sonication.
6. For sonication a predetermined number of glass beads (*see* **Table 1** and **Note 1**) is added to the sample and the powder is then thawed and kept immersed in ice. Sonication is performed in an ice-cold water-bath. The fill-height of the water is critical for the sonication effect and should always be at the level indicated in the instruction manual of the manufacturer. Furthermore, when dipping the sample tube into the water, it is important to do this at the "sonication center" visible by a concentric water surface motion which appear when holding the tube into the water. We prefer a small sonication apparatus that forms only one sonication center (*see* **Subheading 2.1**). Sonication is performed for 10 sec. Immediately afterwards the sample is stirred with a thin wire for 50 sec with the tube still remaining in the ice water. The tube is then kept immersed in ice for 1 min. Now the next sonication circle is started, until a total of 6 two-minute steps (*see* **Note 1**). After sonication, the tubes are turned upside down and punctured with a steel needle to generate a 2 mm diameter opening. The holes should not be larger than that to keep the glass beads from crossing over. A second tube is attached to the bottom of the first. Both tubes are transferred into a centrifuge using other samples or dummy tubes for balancing. Tubes are quickly centrifuged at 2,000 *g* for 1 min. The sample is thereby transferred in to the lower tube whereas the glass beads remain in the upper.
7. Add a small bar magnet and slowly stir homogenate at 4°C for 15 min.
8. Add benzonase (Merck, Darmstadt, Germany) and P-$MgCl_2$. Slowly stir the homogenate for 15 min at 4°C (DNA digestion).
9. Determine control factor (**Table 1** and **Note 2**).
10. Remove aliquot for determination of protein concentration. (***Note***: When sample volume is very low, remove aliquot only after addition of urea/thiourea.)
11. Add urea and thiourea to the homogenate. The amounts indicated in **Table 1** are transferred into a capped 1.5 mL tube. The tube is sealed and turned up side down. Now the bottom of the tube is cut away by scissors and the tube is put on top of

the 2 mL tube containing the homogenate. A quick-spin transfers the urea/thiourea completely into the homogenate (1 min, 1,000g). The homogenate is stirred for about 30 min until the urea/thiourea is dissolved. Now the aliquot for DIGE can be sampled (**Table 1** and **Note 3**).

12. Add DTT and stir homogenate for at least 5 min then add Ampholin 2-4. Now, carefully remove the small bar magnet. Now aliquot samples to omit freeze and rethaw cycles. Usually samples need to be diluted (most commonly 1:2) by sample dilution solution (Buffer P-$MgCl_2$) before application to isoelectric focusing (IEF).
13. Samples are quick-frozen and stored at −70°C.

3.1.3. Extraction of Total Proteins from Other Tissues

In general, the total extraction protocol differs only in buffer factors and the repeats of sonication (**Table 1**). Only very special tissue such as lens would show deviations. In our experience lens does not require DNAse treatment.

3.2. Fractionated Extraction of Proteins

3.2.1. Fractionated Extraction of Liver Proteins

3.2.1.1. Extraction of Liver Proteins Soluble in Buffer (Supernatant I + II)

1. Fill frozen liver pieces into a small plastic tube of known weight and weigh quickly without thawing. The weight of the liver tissues should be between 25 and 260 mg (for lower amounts *see* **Note 4**).
2. Place a mortar, pestle and a small metal spoon into a styrofoam box that contains liquid nitrogen to a level not exceeding the height of the mortar.
3. Put frozen liver pieces into the mortar, and add buffer A, inhibitor 1A and 2. The required volumes of each of the solutions are calculated as indicated in **Table 2.** The precise amount of each solution is pipetted as a droplet onto the spoon that was kept in the N_2-box before use. The solution immediately is immediately frozen into an ice bead that can easily be transferred into the mortar.
4. Grind all frozen components in the mortar to powder. Care should be taken that small pieces of material do not jump out of the mortar when starting to break up the hard frozen material with the pestle.
5. Transfer the powder into a 2 mL Eppendorf tube using a special spatula (**Fig. 1**). Forceps are used to freeze the tube briefly in N_2 and then to hold the tube close to the mortar in the N_2-box. Care is taken that no powder is left in the mortar or on the pestle. For collection of this powder always use the same type of plastic tube. This contributes to reproducibility of the subsequent sonication step. Compress the powder collected in the tube by gently knocking the tube against the mortar. The powder can be stored at −70°C or immediately subjected to sonication.
6. For sonication a predetermined number of glass beads (*see* **Table 2** and **Note 1**) is added to the sample and the powder is then thawed and kept immersed in ice. Sonication is performed in an ice-cold water-bath. The fill-height of the water is critical

Table 2
Fractionated Tissue Protein Extraction Protocol

SI+II fraction: Liver		Brain	Heart
– Liver pieces	250 mg[2] (A)[3]	– 25-250 mg fine pieces	– 100-130 mg (total heart)

[1] All factors used in this table are explained in **Note 8**.

[2] This figure is given as an example. The amount of starting material may vary from 25 to 250 mg (*see* **Note 4**).

[3] B ÷ A = control value; D ÷ C = control value (*see* **Note 2**).

[4] This figure is provided as an example and is not the result of a calculation. The pellet weight varies because slight losses of material are unavoidable, even during very precise work.

[5] *See* **Footnote 4** for pellets; this also holds true for supernatants.

[6] Buffer B/CHAPS volume.

[7] Buffer C.

for the sonication effect and should always be at the level indicated in the instruction manual of the manufacturer. Furthermore, when dipping the sample tube into the water, it is important to do this at a "sonication center" visible by a concentric water surface motion which appear when holding the tube into the water. We prefer a small sonication apparatus that forms only one sonication center (*see* **Subheading 2.1**). The water must be kept ice-cold. Sonication is performed for 10 sec. Immediately afterwards the sample is stirred with a thin wire for 50 sec with the tube still remaining in the ice water. The tube is then kept immersed in ice for 1 min. Now the next sonication circle is started, until a total of 6 two-minute steps (*see* **Note 1**). After sonication, the tubes are turned upside down and punctured with a steel needle to generate a 2 mm diameter opening. The holes should not be larger than that to keep the glass beads from crossing. A second tube is attached to the bottom of the first. Both tubes are transferred into a centrifuge using other samples or dummy tubes for balancing. Tubes are quickly centrifuged at 2,000 *g* for 1 min. The sample is thereby transferred into the lower tube whereas the glass beads remain in the upper. The homogenate is then frozen in liquid nitrogen and can be stored at −70°C. Be careful to hold the tube at an angle of about 45° to decrease the difficulty of retrieving the frozen homogenate.

7. Detach the frozen homogenate in the tube from the wall by quickly knocking at the tube with a large screw driver. Transfer the frozen piece of sample into a preweighed centrifuge tube and briefly thaw the homogenate. Centrifuge for a maximum of 226,000 *g* for 30 min at 4°C.
8. Completely withdraw the supernatant (I) with a pasteur pipette and fill into a preweighed small test tube. The centrifuge tube is kept on ice and the pipette is put back into the tube again with the tip at the center of its bottom (***Note***: the pellet sticks to the wall if a fixed-angle rotor was used). In this position, remainders of the supernatant accumulate at the bottom of the tube and inside the pipette. Withdraw residual supernatant with the pipette and transfer it to the test tube. Now the supernatant is frozen in liquid nitrogen and stored at −70°C.
9. Weigh the pellet (I) left in the centrifuge tube on ice and add buffer A at an amount calculated as indicated in **Table 2**. Mix the pellet and buffer by vortexing, collect the homogenate at the bottom by a short spin, freeze in liquid nitrogen and store at −70°C, or process further immediately.
10. Transfer the homogenate from the centrifuge tube to the mortar after detaching the frozen homogenate from the wall by knocking onto the bottom of the tube. Grind the homogenate together with inhibitors 1A and 2 to powder as described above for the liver pieces. Transfer the powder back into the used centrifuge tube, taking care that no powder remains in the mortar.
11. Thaw the powder and slowly stir the homogenate for 45 min in a cold room.
12. Centrifuge the homogenate as described in **step 7** above.
13. Completely withdraw the supernatant (II) from the pellet. This is done in such a way that a white layer which partially covers the surface of the supernatant sinks unaffected onto the pellet. Collect the remainder of the supernatant as mentioned in **step 8.** Add supernatant II to supernatant I and thoroughly mix both solutions. Determine the weight of the total supernatant.

14. Take a 50 µL-aliquot from the total supernatant and mix with urea, DTT-solution and ampholyte pH 2-4, as indicated in **Table 2**. The final concentrations of these components are: 9 *M* urea, 70 m*M* DTT and 2% ampholytes. These three components should be added to the supernatant in the order indicated here and each component should be mixed and dissolved in the supernatant before adding the next. The final volume of this supernatant mixture is 100 µL. Add 100 µL sample diluent (*see* **Table 3**) and mix before IEF run.
15. The resulting solution is the final sample ("supernatant I + II", SI + II). Divide the sample into several portions, freeze each portion in liquid nitrogen and store at −70°C. Usually 8 µL of sample are applied to an IEF gel, if the large gel 2-D electrophoresis technique described in Chapter 11 is used (*see* **Note 5**). Freeze the remaining portion of the pure supernatant and store at at −70°C.
16. Determine the weight of the pellet (II). Collect the pellet at the bottom of the tube by a short spin, then freeze in liquid nitrogen and store at −70°C.

3.2.1.2. Extraction of the Pellet Proteins Soluble in the Presence of Urea and CHAPS (Pellet Extract)

1. Grind pellet II, buffer B/CHAPS and inhibitor 1B to powder in a mortar placed in liquid nitrogen (*see* **Subheading 3.2.1.1., steps 2-4**). The calculations for buffer and inhibitor volumes are provided in **Table 2**. Transfer the powder back to the centrifuge tube, avoid leaving any remainders in the mortar or on the pestle.
2. Thaw the powder mix and stir slowly for 60 min in a cold room (CHAPS solubilizes structural proteins).
3. Add urea (for the amount see **Table 2**) to the homogenate and stir the mixture for 45 min at room temperature (urea reaction). Some minutes after adding urea a large part of it is already dissolved. At this point add DTT solution (for the amount see **Table 2**).
4. Remove the magnet rod from the homogenate. At this step, also avoid any loss of homogenate. Centrifuge the homogenate at 17°C for 30 min at 50,000 rpm.
5. Completely withdraw the supernatant (III) with a Pasteur pipette and fill it into a small pre-weighed test tube. Collect the remainders of the supernatant as mentioned in **Subheading 3.2.1.1.**, step 8. Determine the weight of the supernatant.
6. Add ampholytes pH 2-4 (for amount *see* **Table 2**) to the supernatant and immediately mix solution.

Table 3
Sample Diluent

Component	Mixture	Final concentration	
Urea	1.08	g (=0.80 ml)	9.000 M
DTT-solution [a]	0.10	ml	0.070 M
Servalyt pH 2 – 4 (Serva)	0.10	ml	2.000 %
Bidistilled water	1.00	ml	50.000 %
Sample diluent	2.00	ml	

[a] *See* **Subheading 2.2,** item 5.

7. The resulting solution is the final sample (”pellet extract”, PE). Divide the sample into several portions, freeze each portion in liquid nitrogen and store at −70°C. Usually the volume of sample applied per IEF gel is 8 µL, if large gel 2-D electrophoresis (*see* Chapter 18) is used (*see* **Note 5**).
8. Determine the weight of the pellet (III). Collect the pellet on the bottom of the tube by a short spin, then freeze in liquid nitrogen and store at −70°C.

3.2.1.3. Suspension of the Remaining Pellet (Pellet Suspension)

1. Grind pellet III and buffer C to powder in a mortar as described in **Subheading 3.2.1.1.**, **steps 2-4.** The buffer volume is calculated as indicated in **Table 2**. The powder is transferred into a test tube, avoiding any loss of material.
2. Thaw powder and add benzonase (Merck, Darmstadt, Germany; for the amount *see* **Table 2**). Slowly stir the homogenate for 30 min in a cold room (DNA digestion).
3. Add urea (for amount *see* **Table 2**) and stir the homogenate at room temperature for another 30 min. During this time add DTT solution (for amount *see* **Table 2**) once the largest part of urea is dissolved. At the end of this period add ampholytes pH 2-4 (for amount *see* **Table 2**) and quickly mix with the homogenate.
4. The resulting solution is the final sample (”pellet suspension,” PS). It is frozen in liquid nitrogen and stored at −70°C. Usually 9 µL of sample is applied per IEF gel (if large gel 2-D electrophoresis is used; *see* Chapter 11 and **Note 6**). The sample still contains some fine undisolved material and is therefore transferred to the gel with a thin Pasteur pipette instead of a microliter syringe.

3.2.2. Fractionated Extraction of Brain Proteins

Frozen brain tissue is transferred into a mortar that was placed into a box containing liquid nitrogen, and crushed with the pestle to fine pieces. The crushed material is transferred completely back into test tubes so that one tube contains 25-250 mg of frozen tissue (weigh the tube without thawing the tissue).

This material is used to prepare the supernatant I + II, the pellet extract and the pellet suspension. The procedure follows that of liver extraction with some differences indicated in **Table 2**. One exception is that the tissue powder is produced without buffer and subjected to centrifugation without sonication so that a rather small amount of supernatant I results. Sonication is only performed with pellet I homogenate.

3.2.3. Fractionated Extraction of Heart Proteins

The supernatant I + II, the pellet extract and the pellet suspension are prepared from a single heart. The procedure is as described for liver with some modifications which are indicated in **Table 2**.

4. Notes

1. Sonication: Conditions for sonicating mouse tissue homogenates (liver, brain, heart) were optimized to break membranes of all cells and cell nuclei

of a tissue. Three parameters were varied in the experiments: the time of sonication, the number of sonication repeats and the number of glass beads added per volume of homogenate. The effect of the various parameters was determined by inspection of sonicated material under the microscope. Sonication for 10 sec increases the temperature of the homogenate from 0°C to 11-12°C. Therefore, sonication was not performed for more than 10 sec. Glass beads are essential for breaking cellular structures (membranes). Since most of the homogenates are rather viscuous fluids, the beads cannot flow freely and their addition is limited. For a given homogenate volume a certain number of glass beads is necessary to expose it evenly to the disrupting power of sonication. Due to viscosity, an increase in this number has not much effect. This number can be calculated. By standardization experiments we determined that a factor 0.034 is a good approximation for the optimal number of glass beads for a given volume of homogenate. It can be concluded from the above-mentioned that the only parameter which can be varied without harming the sample while still increasing the effect of sonication, was the number of repeats of the 10 sec sonication period. Under the conditions described in the Methods section the membranes of all cells were broken and no longer visible under the microscope. However, a certain number of intact nuclei were still detectable. Still, this shortcoming was not compensated for by increasing the number of sonication repeats because we assume that homogenization, stirring and high-speed centrifugation may eventually extract all nucleoplasm proteins. A more aggressive sonication procedure using a metal tip cannot be recommended. We observed heavily disturbed 2-DE patterns as a result of employing this technique: many protein spots disappeared depending on the extent of sonication and new spot series occurred in the upper part of the gel, apparently as a result of aggregation of protein fragments.

2. Control values: Control values were calculated for each sample prepared by the fractionated extraction procedure to monitor correctness and reproducibility of the preparation. The calculation of control values is shown in **Tables 1 and 2**. To visualize the calculation procedure an example from a real experiment is provided: From a series of 73 individual mouse hearts the SI+II fractions were prepared and the control values B÷A (*see* **Table 2**) were calculated: 60 samples yielded values between 1.97-2.10, three samples between 1.94-1.96, and six samples between 2.11-2.13. Four samples with largest deviations (1.90, 1.91, 2.16 and 2.24) were excluded from the investigation. The range 1.97-2.10 (mean 2.04 ± 0.04) was taken as reference value for preparation of mouse heart SI+II samples.
3. The extraction procedure was adapted for labeling with CyDyes. It is important that only urea and thiourea should be present in the sample for

labeling. DTT and ampholines are added only afterwards since both bind CyDyes. In addition, determination of the protein concentration is now mandatory since the amount of CyDyes for labeling is calculated based on the protein concentration. Therefore a 5 µL aliquot of the sample is specifically used for this purpose (**Table 1**, protein concentration). 50 µg protein labeled by 400 pMol CyDye works well for brain samples.

4. The tissue amount indicated (25 mg – 150 mg) yields enough sample to run a large number of 2-DE gels so that less rather than more material may be used. In cases in which only a very small amount of tissue is available (e.g. 2-5 mg heart biopsy samples, 10-12 mg of two mouse eye lenses, early mouse embryos) a total protein extract should be prepared instead of SI+II, PE and PS fractions. Small plastic tubes and a glass rod with a rough surface at the well fitting tip may serve as mortar and pestle.
5. Amount of protein applied per gel: The protein amount applied to IEF gels (*see* **Tables 1** and **2**), contains about 100 µg protein. There is, however, no need to determine the protein concentration of each sample prepared in order to get protein patterns of reproducible intensities. The concept of the procedure described here for extracting tissues was to keep the volume of the extracts in strong correlation to the amount of the starting material (tissue or pellet) which was extracted. Therefore, by working precisely, the final sample should always contain nearly the same protein concentration. This was confirmed by determining the protein concentrations of a large number of protein samples. Accordingly, the reproducibility of the pattern intensity depends on the precise sample volume applied to the gel – and, of course, on the protein staining procedure. The sample volumes per gel given in **Table 2** are adapted for silver staining protocols. As a general guideline one should take into account: decreasing the protein amount per gel and increasing the staining period is better than the vice versa; diluted samples using reasonable volumes are better than concentrated protein samples at a small volume since in the first case clogging is avoided.
6. Maximum resolution of tissue protein fractions by 2-D electrophoresis: **Fig. 2** shows 2-DE patterns of three protein fractions SI+II, PE and PS of mouse liver. The SI+II fraction reveals the highest number of protein spots.

Fig. 2. (continued) pattern and vice versa. Pellet-specific spots occur predominantly in the basic half, supernatant-specific spots more on the acid half of the pattern. The pellet suspension pattern reveals very basic proteins of a tissue extracts. Since IEF gels do not cover the entire basic pH range, these proteins cannot reach their isoelectric points. To prevent these proteins from accumulating at the basic end of a gel, the IEF run was shortened by 2 h at the 1000 V level. Consequently, the very basic proteins form streaks instead of focused spots. For evaluation of patterns in terms of spot number *see* **Notes 6** and **7**.

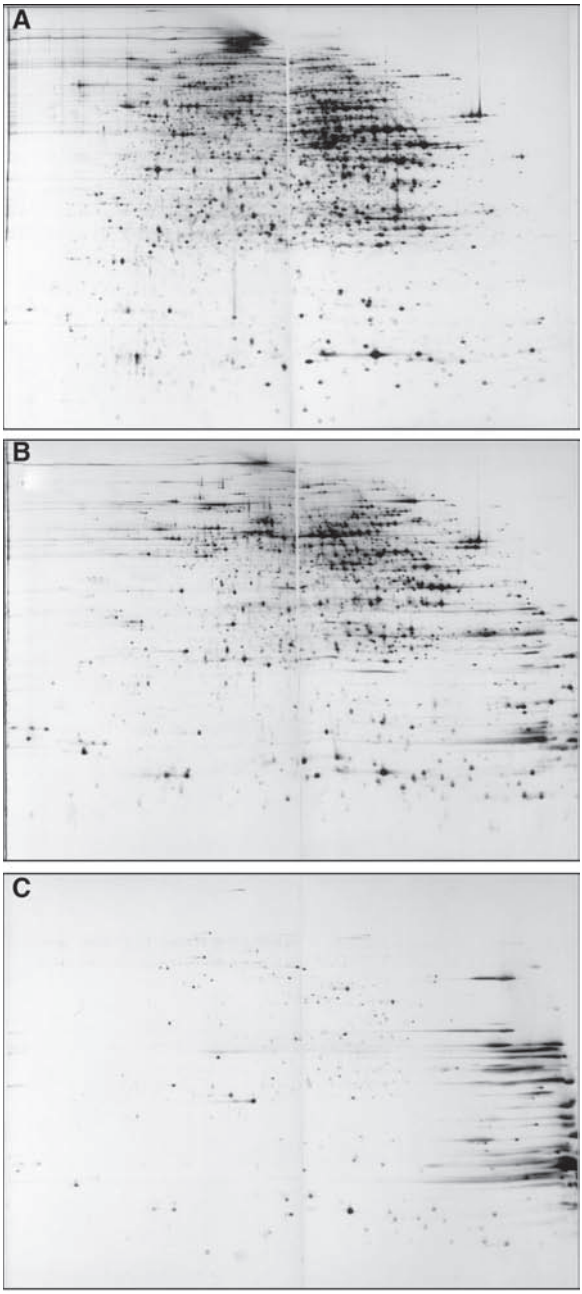

Fig. 2. 2-DE protein patterns from mouse liver. Tissue was fractionated into supernatant I + II (a), pellet extract (b), and pellet suspension (c) as described in **Subheading 3.1**. Three fractions were subjected to large gel 2-D electrophoresis (see Chapter 11). In the pellet extract pattern many protein spots were visible which are not present in the supernatant

When spots were counted visually, i.e. by placing a 2-DE gel on a light box and dotting each spot with a pencil **(3),** about 9200 proteins were detected in this fraction. The SI+II pattern of the brain revealed about 7700 proteins, that of the heart about 4800 protein spots. The high spot numbers reflect the high resolution of the large gel 2-DE (see Chapter 11), which reveals many weak spots between major spots. All these spots were counted with high precision and great care.

7. Effect of fractionated extraction of tissue proteins: The purpose of fractionating the proteins of a tissue was to increase the number of proteins detectable by 2-DE. This goal, however, would only be achievable if each fraction contained a notable number of proteins which are strongly fraction-specific, so that the total tissue proteins can be distributed over several gels. Comparison of the 2-DE patterns from the SI+II and PE fractions of the liver **(Fig. 2)** showed that the PE pattern revealed about 2000 protein spots not detectable among the 9200 spots of the SI+II pattern. The PS pattern revealed only about 70 additional spots. The PS protein spots represent classes of the most basic proteins (**Fig. 2**) and belong mainly to the chromosomal proteins (e.g. histones). Therefore, the PS fraction is only of interest when a class of very basic proteins is subject of the investigation. Considering the 2-DE patterns of the SI+II and PE fraction in more detail (**Fig. 3**), quite a number of very prominent spots can be observed which are visible in one pattern but do not occur, not even in trace amounts, in the others. At the same time, other spots revealing only low intensities are present in both patterns. This suggests that the phenomenon where many protein spots of the SN I+II pattern also occur in the PE pattern is not due to impurities of the pellet fraction by supernatant proteins caused by technical problems. We found, using centrifugation at different speeds and samples prepared with different degrees of viscosity, that an overlap in 2-DE patterns is due to the fact that most proteins exist solitarily as well as in protein-complexes. Apparently, protein complexes sink to the pellet at high speed and are later resolved again by detergent and urea extraction in the PE fraction. Taking into account all three fractions, the total liver proteins could be resolved into about 11,270 different proteins (polypeptide spots). This, however, does not mean that the protein sample preparation procedure described here – in combination with the 2-DE technique in Chapter 32 – revealed all proteins of the liver. Many proteins may exist in a tissue in undetectable amounts, and special fractionation procedures with subsequent protein concentration steps would be required to detect these proteins. We isolated liver and brain cell nuclei and extracted the nuclear pellet in a similar way as was done for the tissues. The 2-DE patterns showed that the nuclear extracts add a large number of new proteins

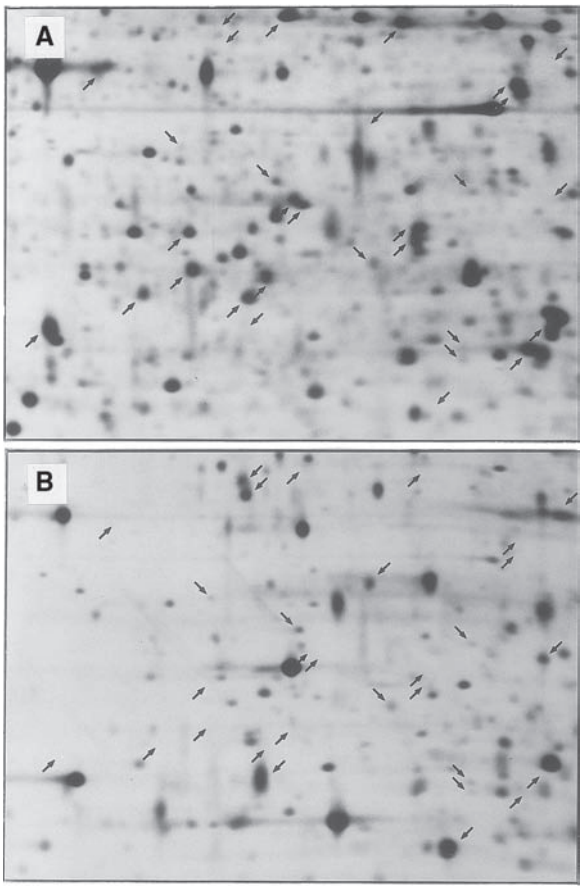

Fig. 3. Sections from 2-DE patterns shown in **Fig. 2.** The supernatant I + II (a) and the pellet extract (b) of liver are compared. (i) Some of the prominent protein spots present in the supernatant pattern (↗) but completely absent in the pellet extract pattern(↗), (ii) the reverse situation(↙), and (iii) some spots of low intensity present in both patterns(↘) are indicated. Other spots show a high intensity in one pattern but low intensity in the other. These spots may reflect naturally occurring unequal distributions of proteins between the two different fractions due to a formation of protein complexes rather than contaminations of one fraction by the other (*see* **Note 7**).

to those already known from the tissue extract patterns. However, protein spots present in both the nuclear and the tissue extracts occur as well, particularly in the acidic halves of the supernatant patterns. In general, the proteins represented by the SI+II, PE, and PS patterns can be considered as the main population of protein species of a tissue to which further species may be added by analyzing purified and concentrated subfractions. There-

fore, the amount of spots detectable with fractionated extraction is larger than by total extracts but the effort involved is also exceptionally higher.

8. Explanation of correction factors used in **Table 2**: Factors were calculated to determine the amounts of urea, DTT-solution and ampholytes necessary to transmute any volume of a solution (theoretically water) into a mixture containing 9 *M* urea, 70 m*M* DTT and 2% ampholytes. Calculations of factors: 500 µL water (aqueous protein extract) + 540 mg urea (displaces 400 µL) + 50 µL DTT-solution (*see* **Subheading 2.2** item 5) + 50 µL ampholyte solution (commercial solutions which usually contain 40% ampholytes) = 1000 µL. If the volume of a protein solution to be mixed with urea, DTT and ampholytes is *n* µL, the amounts of the components to be added are: (540 ÷ 500) × *n* = 1.08 × *n* mg urea, (500 ÷ 50) × *n* = 0.1 × *n* µL DTT solution and 0.1 × *n* µL ampholyte solution. If the protein solution already contains urea and DTT (*see* **Table 2**: PE preparation), the factor 0.0526 is used to calculate the ampholyte volume for this solution. Calculation of this factor: (500 µL extract + 400 µL urea + 50 µL DTT solution) ÷ 50 µL ampholyte solution = 0.0526. If a protein solution of *n* µL includes a cell pellet, i.e. insoluble material, *n* µL volume should be reduced by the volume of insoluble material (theoretically by the volume of the dry mass of this material). For this reason a pellet factor (e. g. 0.3) was introduced. This factor was determined experimentally using urea as an indicator. The factor reduces the volume *n* µL of a protein solution (containing a pellet) to volume *n* µL; *n* µL × 1.08 yields an amount of urea that is added to the *n* µL of the solution, at the border of solubility, i.e. about 9 *M*. Note that pellet III contains urea and DTT by the foregoing steps. Therefore, in this case the pellet volume was not taken into account when calculating the amounts for urea and DTT to be added to the final pellet suspension. In all these calculations no distinction was made between values measured in volumes (µL) and values measured in weights (mg). This makes the calculation somewhat incorrect but more practicable and reproducible. The inhibitor 2 solution was prepared as concentrated as possible to keep the volume of this solution small (1/50th of the homogenate volume, i.e. factor 0.01). This allows for ignoring the volume determination error that results when this inhibitor solution is added instead of including it to the total volume of the homogenate. The factor 0.08 for all inhibitor 1 (A, B and C) solutions was derived from the dilution requirements according to manufacturers instruction (CompleteTM tablets, ROCHE, Mannheim, Germany): 1 tablet should be dissolved in 2 mL buffer and this volume added to 25 mL of the homogenate, i.e. the volume of the inhibitor 1 solution to be added to *n* µL homogenate is (2 ÷ 25) × *n* = 0.08 *n* µL. The volume of benzonase solution (ready-made solution from MERCK, Darmstadt, Germany) necessary to

digest DNA in the pellet III suspension was determined experimentally: a chromatin pellet was prepared from isolated liver cell nuclei and found to change from a gelatinous clot to a fluid if treated as follows: 1 g chromatin pellet + 1 mL buffer + 0.050 mL benzonase solution (= 0.025 mL Benzonase / mL homogenate), stirred for 30 min at 4°C. If benzonase from other sources is used the amount added has to be adjusted. Buffer factors used to calculate the volumes of buffer added to tissues or pellets are explained in the Introduction. Note that tissue to be homogenized must be free of any wash solutions otherwise the calculated buffer volumes will be too high.

Plant Protein Sample Preparation for 2-DE

Sebastien Christian Carpentier, Rony Swennen, and Bart Panis

1. Introduction

Most plant tissues are not a ready source for protein extraction and need specific precautions. The cell wall and the vacuole make up the majority of the cell mass, with the cytosol representing only 1 to 2 % of the total cell volume. Subsequently, plant tissues have a relatively low protein content compared to bacterial or animal tissues. The cell wall and the vacuole are associated with numerous substances responsible for irreproducible results such as proteolytic breakdown, streaking and charge heterogeneity. Most common interfering substances are phenolic compounds, proteolytic and oxidative enzymes, terpenes, pigments, organic acids, inhibitory ions, and carbohydrates.

Some species contain extremely high levels of interfering compounds. Banana (*Musa* spp.), for example, contains extremely high levels of oxidative enzymes (polyphenol oxidase) ***(1–3)*** and phenol compounds (simple phenols [dopa], flavonoids, condensed tannins, and lignin). Moreover, it contains high amounts of latex and carbohydrates ***(4)***. Phenolic compounds reversibly combine with proteins by hydrogen bonding and irreversibly by oxidation followed by covalent condensations ***(5)***, leading to charge heterogeneity and streaks in the gels. It is known that carbohydrates can block gel pores causing precipitation and extended focusing times, resulting in streaking and loss.

In the 1980s, much effort had been invested in the establishment of two-dimensional (2-D) gel electrophoresis sample preparation methods for plant tissue ***(6–8)***. The original 2-DE protocol consists of only one step, i.e., denaturing extraction in a lysis buffer ***(9)***. This one step protocol is restricted to "clean" samples and is rarely used for plant material. The majority of the plant protocols introduce a precipitation step to concentrate the proteins and to separate them from the interfering compounds. Proteins are usually precipitated by the addition

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

of high concentrations of salts ***(10)***, extreme pH ***(11)***, organic solvents ***(12–14)*** or a combination of organic solvents and ions ***(15,16)***. Typical ions used for precipitation are ammonium sulfate and ammonium acetate. Ions effectively compete with water molecules on the protein surface, favoring protein-protein interactions over protein-solvent interactions and causing protein aggregation and precipitation. Organic solvents also decrease protein solubility by dehydrating the protein surface. They lower the solution dielectric constant, promoting charge-charge interactions between proteins. Typical organic solvents used for precipitation are methanol, ethanol, and acetone. Organic solvent precipitation is generally performed at low temperatures, since proteins are then less "soluble" ***(17)***. The protein precipitation step can be preceded by a denaturing or non-denaturing extraction step and is combined with one or two washing steps to remove introduced salt ions and other remaining interfering substances. The most commonly used method for extraction of plant proteins is the TCA/acetone precipitation method ***(15)***. Proteins are very sensitive to denaturation at low pH. Trichloroacetic acid (TCA) is a strong acid (pK_a 0.7) that is soluble in organic solvents. The extreme pH and negative charges of TCA together with the addition of acetone realizes an immediate denaturation of the protein along with precipitation, thereby arresting instantly the action of proteolytic enzymes ***(18)***. However, a disadvantage of TCA precipitated proteins is that they are difficult to redissolve ***(19)*** and the extreme low pH might create problems with basic chemical labeling methods. The development of succinimidyl ester derivatives of different cyanine fluorescent dyes that modify free amino groups of proteins prior to separation ***(20)*** was a major achievement for 2-DE in terms of reproducibility and throughput. The difference gel electrophoresis (DIGE) minimal labeling approach uses fluorophores that have a different absorption optimum, making it possible to run multiple samples simultaneously in the same gel. The different dyes were designed to assure that a protein acquires the same relative mobility irrespective of the dye used to tag them. The difference in MW introduced by the different length linkers is compensated by the different alkyl moieties opposite the linker moiety. Succinimidyl ester derivatives react with the nucleophilic primary amines, subsequently releasing the N-hydroxysuccinimide group. At a specific pH (8.5), these reagents react almost exclusively with the ε-amino group of lysine to form stable amide linkages that are highly resistant to hydrolysis. The pH of the protein solution is hence of utmost importance.

We have tested in the past different protocols to extract proteins from plant samples (***21***). In our hands, the phenol extraction protocol proved to be the most powerful. The protein precipitation step is in this method achieved by ammonium acetate and methanol and is preceded by a denaturing phenol extraction. We optimized this method for small amounts of banana fresh weight (***21***) and lyophilized tissues (***22***). This "micro" phenol protocol is applicable for a wide

variety of plant species since we successfully applied it to apple, banana, pear ***(23)***, potato and stevia. We describe here in detail this successful "micro" phenol extraction protocol.

2. Materials

1. All the materials that were used were clean and the chemicals are of the highest purity in order to not interfere with the electrophoresis process and with the mass spectrometry.
2. DTT (dithiothreitol) has a limited shelf life and should not be added to the different stock solutions. Make always a fresh 10% (w/v) solution and add prior to use.
3. All consumables were purchased from Acros Organics (Geel, BE) unless stated otherwise.

2.1. Protein Extraction

1. Liquid nitrogen.
2. Pestle and mortar (washed and baked in an oven at 180°C overnight prior to use).
3. Phenol, acetone and methanol compatible tubes and pipettes.
4. 10 % (w/v) DTT (GE Healthcare, Diegem, BE). Make freshly in MQ H_2O.
5. Extraction buffer: 50 mM Tris-HCl pH 8.5, 5 mM EDTA, 100 mM KCl, 1% (w/v) DTT, 30% (w/v) sucrose and complete protease inhibitor cocktail (according to the manufacturer, Roche Applied Science) in MQ H_2O. Prepare freshly (*see* **Note 1**).
6. Tris buffered phenol (pH 8.0) (*see* **Notes 2** and **3**).
7. Precipitation buffer: 100 mM ammonium acetate in methanol. Store at −20°C.
8. Cold acetone. Store at −20°C.
9. Lysis buffer: 7 M urea (GE Healthcare, Diegem, BE), 2 M thiourea (Fluka, Bornem, BE), 4% (w/v) CHAPS (GE Healthcare), 0.8% (v/v) IPG-buffer (GE Healthcare), 1% (v/v) DTT (GE Healthcare) and 30mM Tris in MQ H_2O. Store aliquots at −80°C (*see* **Notes 4** and **5**).
10. Protein Quantification kit 2D Quant (GE Healthcare).

2.2. Protein Separation

1. 1% (w/v) bromophenol blue: bromophenol blue (GE Healthcare) and 50 m*M* Tris-base in MQ H_2O.
2. Rehydration buffer: 6 M urea, 2 M thiourea, 0.5% (w/v) CHAPS, 10% (v/v) glycerol, 0.002% (v/v) bromophenol blue, 0.5% (v/v) IPG-buffer and 0.28% (v/v) DTT in MQ H_2O (*see* **Note 6**).
3. 24 cm IPG-strips pI 4-7 (GE Healthcare) (*see* **Note 7**).
4. Reswelling tray (GE Healthcare).
5. Isoelectric focusing apparatus IPGphor II (GE Healthcare).
6. Sample cups (GE Healthcare).
7. Ceramic 12-strip sample tray (GE Healthcare).
8. Filter paper electrode pads (GE Healthcare).
9. Mineral cover oil (GE Healthcare).

10. Gel casting chamber (GE Healthcare).
11. SDS-PAGE apparatus Ettan Dalt 6 (GE Healthcare).
12. Cooling bath type 1140S (VWR international, Leuven, BE).
13. Power supply Power PAC 3000 (Bio-Rad, Nazareth, BE).
14. Equilibration buffer I: 6 M urea, 30% (v/v) glycerol, 2% (v/v) SDS, 0.002% (v/v) bromophenol blue, 50 mM Tris-HCl pH 8.8 and 1% (w/v) DTT in MQ H_2O. Store aliquots at −20°C.
15. Equilibration buffer II: 6 M urea, 30% (v/v) glycerol, 2% (v/v) SDS, 0.002% (v/v) bromophenol blue, 50 mM Tris-HCl pH 8.8 and 4.5% (w/v) iodoacetamide in MQ H_2O. Store aliquots at −20°C (*see* **Note 8**).
16. SDS 10%. Store at room temperature (*see* **Note 9**).
17. Laemmli running buffer: 25mM Tris, 0.1% (v/v) SDS, 192 mM glycine in demineralized water. Do not adjust the pH. Store a 10x buffer at room temperature.
18. Agarose sealing solution: 0.5% (w/v) agarose (ultra pure, GibcoBRL, Merelbeke, BE) 0.002% (v/v) bromophenol blue in Laemmli running buffer.
19. 10% (w/v) Ammonium persulfate. Make freshl in MQ H_2O.
20. Thirty percent acrylamide/bis solution (37.5:1 with 2.6% C) (Bio-Rad). Store at 4°C (*see* **Note 10**).
21. N,N,N,N -Tetramethyl-ethylenediamine (TEMED) (Bio-Rad). Store at room temperature (*see* **Note 11**).
22. Tris 1.5M pH 8.8 in MQ H_2O. Store at 4°C.
23. Water-saturated isobutanol. Shake equal volumes of MQ H_2O and isobutanol and allow separation. Use the top layer. Store at room temperature.

2.3. Protein Labeling and Scanning

1. 10m*M* lysine.
2. CyDye DIGE fluors (Cy2, Cy3 and Cy5) (GE Healthcare). Store at −20°C.
3. N,N-dimethylformide (DMF). Store at room temperature (*see* **Note 12**).
4. Typhoon™ imager (GE Healthcare).
5. Low fluorescent glass plates (GE Healthcare).

3. Methods

3.1. Protein Extraction

1. Transfer fresh plant tissue to a liquid nitrogen pre-cooled mortar and grind in liquid nitrogen (*see* **Note 13**).
2. Transfer 50 to 100 mg of frozen tissue powder to an extraction tube (2 mL), add 500 µL extraction buffer and vortex 30 sec (*see* **Note 14**).
3. Add 500 µL of buffered phenol and vortex 10 min at 4°C.
4. Centrifuge for 3 min, 6000 g at 4°C, collect the upper phase, i.e., the phenolic phase, transfer to a new tube and discard the lower phase (*see* **Note 15**).
5. Re-extract by adding 500 µL of new extraction buffer.
6. Centrifuge for 3 min, 6000 g at 4°C.
7. Transfer the phenolic phase into a new 2 mL tube and precipitate the proteins overnight (or at least 2.5 h) with 5 volumes 100 m*M* ammonium acetate in methanol at −20°C.

8. Centrifuge 60 min, 16 000 g, at 4°C.
9. Remove the supernatant and rinse the pellet twice (do not resuspend) in 2 mL rinsing solution (cold acetone/0.2 % DTT). After the first rinse leave in rinsing solution for 1 hour at –20° C. After rinsing, centrifuge 30 min, 13 000 rpm, at 4°C.
10. Dry the pellet (*see* **Note 16**).
11. Suspend the pellet in 100 mL lysis buffer (optimum concentration is 1–5 µg/µL) (*see* **Note 17**).
12. Clear samples by centrifugation (16 000 g, 2 × 30 min at 18° C) (*see* **Notes 18** and **19**).
13. Quantify the samples (*see* **Note 20**).

3.2. Protein Labeling

1. Briefly spin the fluor stock solutions.
2. To 4.2 µL DMF add 2.8 µL DMF reconstituted fluor stock solution (1 nmol/ µL) in a microfuge tube (200 µL). Ensure all fluor is removed from the pipette tip by pipetting up and down. This is the working fluor sample solution.
3. Add 50 µg of protein sample (without DTT and IPG buffer) to a microfuge tube (200 µL) and add 1 µL of working fluor sample solution.
4. Mix fluor and protein sample thoroughly and leave on ice for 30 min in the dark.
5. Repeat this for all samples (*see* **Note 21**).
6. Add 1 µL of 10 mM lysine to stop the reaction. Mix and leave for 10 min on ice in the dark. The labeled samples can be stored for at least 3 months at –80°C.
7. Dilute the samples with an equal volume of Lysis Buffer (with 2x DTT and 2x IPG buffer) and leave at room temperature for 10 min.

3.3. Protein Separation: First Dimension

1. Rehydrate IPG dry strips with rehydration buffer in a reswelling tray for at least 8 h and cover with mineral oil.
2. Apply the rehydrated IPG gel strips onto the cup-loading tray, gel side upward and acidic ends facing toward the anode.
3. Moisten two filter paper electrode pads with demi water and apply the moistened filter paper pads on the surface IPG gel covering the anodic and cathodic ends of the IPG strip.
4. Position the movable electrodes at the extremes of the electrode filter paper pads.
5. Overlay the IPG strips (and empty lanes) with several mL of cover fluid (120 mL) (*see* **Note 22**).
6. Position the movable sample cup either near the anode, and gently press the sample cup onto the surface of the IPG gel strip (*see* **Notes 23** and **24**).
7. Dilute your sample in rehydration buffer (final volume 150 µL) and pipette the sample into the cup.
8. Program the instrument (desired volthours, voltage gradient, temperature, etc.) and run IEF according to the settings recommended in **Table 1**. Current and power settings should be limited to 0.05 mA and 0.2 W per IPG gel strip, respectively. Optimum focusing temperature is 20°C.
9. After IEF, IPG gel strips can be stored between two sheets of plastic film at –78°C up to 3 months.

Table 1
Program for Cup Loading IPGphorII

Step	Mode	Voltage	
1	Step and hold	300	3h
2	Gradient	1000	6h
3	Gradient	8000	3h
4	Step and hold	8000	32 kVh

3.4. Protein Separation: Second Dimension

1. Cast the polyacrylamide gels. For 600 mL (6 gels) 12.5% acrylamide gels: add 250 mL 30% acryl/bisacryl, 150 mL Tris buffer pH8.8, (1.5 M), 187 mL MQ H_2O, 300 µL TEMED, 6 mL 10 % SDS and 2.4 mL 10% APS, under continuous stirring (*see* **Note 25**).
2. Cover with water saturated isobutanol and cover to prevent drying out.
3. Allow polymerization overnight (*see* **Note 26**).
4. Remove the isobutanol prior to use by rinsing with MQ (*see* **Note 27**).
5. Place the IPG strips in an individual tube and add 7 mL of equilibration buffer I. Shake for 15 min.
6. Remove the first equilibration solution and replace by 7 mL of equilibration buffer II. Shake for 15 min.
7. Prepare the running buffers for upper (2x) and lower chamber (1x) and fill the lower chamber.
8. Rinse the strips with running buffer.
9. Place the gel cassettes in an upright position and apply the strips and fill with 2–3 mL of hot (60°C) 0.5 % agarose solution. Make sure that the strip is in close contact with the second dimension gel without air bubbles.
10. Place the cassettes in the running tank, place the upper buffer chamber and fill it further with running buffer.
11. Run the gels at 2 W per gel overnight.

3.5. Scanning

1. Prescan the gels at the 3 wavelengths at a low resolution and adjust the PMT (photomultiplier tube) to ensure a maximum pixel intensity between 70,000 and 100,000 pixels using a Typhoon™ imager (GE Healthcare).
2. Scan the gels at the optimal pixel intensity. See **Fig. 1** for a representative DIGE gel. A protein spot map realized in ***(24)*** containing MS/MS identified spots can be found at http://www.pdata.ua.ac.be/musa/

4. Notes

1. Our extraction buffer has been designed to minimize enzymatic reactions and to remove as much interfering compounds as possible. Sucrose is added to the buffer to create a phase inversion. The buffer forms the aqueous

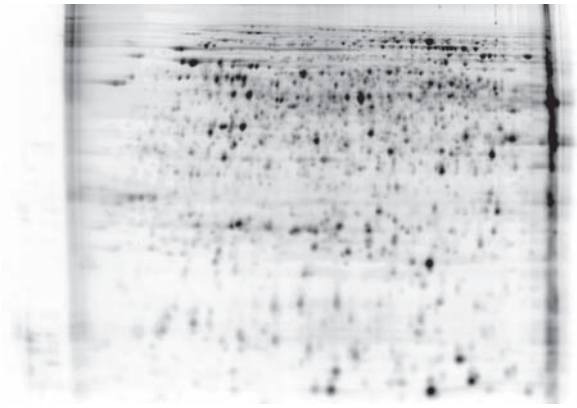

Fig. 1. Representative gel of the banana meristem proteome labelled with Cy3. 24 cm IPG strips pI 4–7.

lower phase containing carbohydrates, nucleic acids and cell debris and the upper phenol rich phase contains cytosolic and membrane proteins, lipids, and pigments. The high pH of the buffer inhibits most common proteases, assures that the abundant phenolic compounds are mainly ionized (inhibiting H bonding with the proteins) and neutralizes acids that are released by disrupted vacuoles. KCl facilitates the extraction of proteins (salting in effect) and EDTA inhibits metalloproteases and polyphenol oxidase by chelating the metal ions. DTT is a powerful reducing agent that does not actually prevent the oxidation of plant (poly)-phenols (quinones) but reduces them to form thio-ethers. The protease inhibitor cocktail is added to inhibit proteases that are released upon cell rupture.

2. The pH of the phenol is important. We opted to buffer the phenol to pH 8.0 instead of water buffered phenol ***(25–27)*** to assure that the interfering nucleic acids are partitioned to the buffer phase and not to the phenol rich phase.
3. Phenol is toxic and needs to be handled with great care. Wear gloves and work in a dedicated room. Use only under the hood and make sure that the waste (tips, pipettes, tubes) is disposed safely.
4. Tris is added to the lysis buffer to get the pH stable between 8 and 9 to assure proper labeling and to avoid pH adjusting with other salts afterward since salts affect the electrophoresis process. If the proteins are visualized with a post staining procedure the Tris can be omitted.
5. DTT and IPG-buffer are added freshly prior to use. For the DIGE labeling they must be added after labeling since they are subject to labeling.
6. Glycerol is added to the buffer in order to obtain an even reswelling of the strips and to minimize electro-osmotic flow (counter flow of water ions).

7. The size of the strips plays an important role in the resolution of the gel. The longer the strip, the better the resolution.
8. As for the DTT, the iodoacetamide is not added to the stock solution but prior to use.
9. SDS is irritating. The powder should be handled with care since it can be inhaled very easily and should always be weighted under a hood. Make always a stock solution of 10% (w/v).
10. Acrylamide is a neurotoxin when unpolymerized and so care should be taken not to receive exposure. Wear gloves, work under a hood in a dedicated room.
11. TEMED has a limited shelf life. Buy therefore small amounts. The quality is important for a good polymerization.
12. The DMF must be high quality anhydrous (specification: 0.005% H_2O, ≥99.8% pure) and every effort should be taken to ensure it is not contaminated with water. DMF, once opened will start to degrade to produce amine compounds. Those amines will react with the succinimidyl ester derivatives of the cyanine dyes, reducing the concentration of dye available for protein labeling. DMF is toxic and any contact should be avoided. Wear gloves.
13. The grinding process is very important. Do not stop grinding until the power is very fine and homogeneous.
14. It is important to keep this period as short as possible in order to keep enzymatic reactions like oxidation of polyphenols and protease activity to the strict minimum. All enzymes are considered to be irreversibly inactivated after adding phenol as is the case with TCA precipitation.
15. Take care to avoid transferring parts of the lower phase and the inter phase since they contain a lot of interfering compounds.
16. The drying of the pellet is very important. Take care that the pellet is dry enough (indicated by a slight color change) but not over dry. A pellet that is too dry will often be very difficult to resuspend. It is recommended to dry the pellet under a hood and to follow up the drying process.
17. A recalcitrant (difficult-to-redissolve) pellet can elegantly be forced to redissolve by freezing the solution at −20°C. The formed crystals will break the pellet upon vortexing. Repeated freezing and thawing of the sample must be avoided!
18. A lower temperature of the centrifuge can result in crystallization of urea.
19. Storage in a freezer at −78°C is preferred. Repeated freezing and thawing of the sample must be avoided. Make aliquots of the desired quantity and thaw only once!
20. The quantification of the proteins is very important but challenging. Each quantification method has its limitations since the concentration of a complicated protein mixture is estimated based on the quantification of one

reference protein usually BSA. It is therefore important to have sufficient replications and to stay within the optimal linear range of the reference protein. Each sample has to be equally labeled and loaded.

21. The power of the DIGE approach arises from the use of an internal standard, which is a common representative mixture of all analyzed samples. The internal standard is a mixture of an equal amount of all analyzed samples and is labeled with Cy2. This internal standard is used to calculate a standardized abundance of each spot and to match the spots across the gels. In order to anticipate any dye specific effect, the samples should be labeled at random with Cy3 and Cy5. All pre-culture sample points should be randomized over the gels to anticipate gel-specific effects.
22. It is very important that all the strips are covered. Uncovered strips will dry out and urea will start to crystallize. If less than 12 strips are used also the remaining lanes should be filled to prevent crystallization. The oil can move from one lane to the other.
23. Cup loading involves applying the samples at a specific experimentally determined zone of a rehydrated strip. All proteins approach their pI only from the same side. However, the application point of the cup should be carefully chosen. Proteins tend to precipitate at their pI and can lead to aggregation at the sample entry point. Therefore, the placement of the cup is sample specific and depends on the pI range of the IEF-strip. The cup is placed at the cathodal side in case of an acidic zoom strip and at the anodal side in case of a basic zoom strip.
24. It is very important that the cups do not leak. Leakage can be checked by adding a small volume of rehydration buffer if desired.
25. In order to better control the start of the polymerization reaction use acrylamide, water and Tris that is stored at 4°C.
26. Although the gels look polymerized after a few hours, there is still silent polymerization going on. For reproducible gels, it is therefore very important to perform the polymerization overnight and always at the same room temperature.
27. The shelf life of the Laemmli buffered gels is limited and the quality is guaranteed only for a few days.

Preparation of Bacterial Samples for 2-D PAGE

Brian B. Vandahl, Gunna Christiansen, and Svend Birkelund

1. Introduction

Sample preparation is a very crucial step in two-dimensional (2-D) gel electrophoresis in which the proteins of the sample are brought into a state where they can be separated by isoelectric focusing in the first dimension. The proteins must be denatured, reduced, and solubilized, and they must be kept so during electrophoresis without changing their pI. The buffer for this purpose is traditionally called the lysis buffer.

Most bacterial studies aim to solubilize as many proteins as possible to obtain the best possible representation of the total protein content or protein expression under the investigated biological circumstances. However, prefractionation, or the successive application of different chemical reagents, can be used to investigate proteins with certain characteristics. Note that the gels will reflect the proteome of the bacteria at the time the proteins are solubilized and that preceding centrifugations or other manipulations may stress the bacteria, thereby influencing the protein profile.

The solubilization procedure is highly dependent on the nature of the sample. Some bacteria are readily lysed by the constituents of the lysis buffer. Others must be disrupted mechanically and, for some, it may be necessary to remove the cell wall by enzymatic digestion prior to mechanical disruption. **Subheading 3.1** provides a general protocol for solubilization. All reagents are described in the notes together with common alternatives.

Some samples may contain nonprotein substances in amounts that are incompatible with especially first dimensional electrophoresis and, thus, have to be removed from the sample. Salts and most other compounds can be removed by protein precipitation, as described in **Subheading 3.2.1**. If nucleic acids are present in high amounts, these may have to be removed by enzymatic digestion, which is described in **Subheading 3.2.2**.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

In addition, highly abundant proteins may cause problems for 2-D PAGE by preventing optimum focusing in the first dimension or by masking large areas of the gel. In such cases, it may be necessary to carry out prefractionations or to specifically remove the abundant proteins by immunoprecipitation. A novel method of enrichment as a result of low abundant proteins is the ProteoMiner technology from BioRad. By the use of a peptide labrary coupled to column material, the amount of highly abundant proteins is decreased because of binding site saturation and, by passing large volumes of sample over the column, the relative amount of low abundant proteins is simultaneously increased. Prefractionation can be obtained by various means such as chemical extractions or chromatographic or electrophoretic techniques ***(1)***, but these methods fall beyond the scope of this chapter.

All procedures should be kept as simple as possible to ensure reproducibility and because proteolytic degradation must be considered a risk. When bacteria are disrupted, proteases will be released and degrade the proteins of the sample, if not inhibited. As folded proteins are less susceptible to proteolysis than denatured proteins and as proteases are often more resistant to denaturation than most other proteins, solubilization in urea will often make the problem worse. However, most proteases will be inactivated by disruption in lysis buffer containing thiourea, in 2% SDS or in precipitation solution containing 10% TCA. Still, all handling of the sample after disruption of the bacteria should be carried out as quickly as possible and on ice to minimize proteolytic degradation. It may also be necessary to add protease inhibitors.

Several reagents used for the sample preparation are toxic and/or carcinogenic. For safety reasons use protective gloves and glasses and work in a fume hood.

2. Materials

1. Lysis buffer (*see* **Note 1**): 7 M Urea (2.10 g) (*see* **Note 2**), 2 M thiourea (0.76 g) (*see* **Note 3**), 65 mM DTE (650 µL of a 0.5 M stock) (*see* **Note 4**), 4% (W/V) CHAPS (0.2 g) (*see* **Note 5**), 2% (v/v) Pharmalyte pH 3–10 (*see* **Note 6**), 40 mM Tris base (*see* **Note 7**), a trace of bromphenol blue (*see* **Note 8**).
2. Presolubilization solution: 2% SDS, 65 mM DTE.
3. Precipitation solution: 10% Trichloracetic acid (TCA) in acetone, 20 m*M* DTE.
4. DNase/RNase solution: 1 mg/mL DNase I, 0.25 mg/mL RNase A, 50 m*M* $MgCl_2$.

3. Methods

3.1. General Solubilization Protocol

It is crucial that all bacteria are disrupted so that the lysis buffer gains access to all proteins. In studies where multiple extractions with different chemical reagents are employed sequentially, it will mask the result if more and more bacteria are disrupted during the procedure. The best method for disruption is dependent on the type of bacteria. In most cases, disruption by sonication will do, but it may

be necessary to add lysosyme to break down cell walls. It is advantageous to perform the disruption in SDS or in lysis buffer containing thiourea in which most proteases are denatured ***(2)***. If prolonged manipulation, such as fractionation by different steps of centrifugation, must be performed, protease inhibitors should be added (*see* **Note 9**). In the procedure described below, the bacteria are sonicated in 2% SDS, 65 mM DTE and boiled to enhance the protein solubilization in general ***(3)***. It has been suggested ***(4)*** that SDS used for presolubilization does not interfere with first dimensional electrophoretic separation because it forms micelles with the nonionic detergent of the lysis buffer and migrates out of the strip. Still, the amount of SDS should be kept low compared to the amount of detergent in the lysis buffer ***(5)*** (*see* **Note 10**). **Figure 1** shows a silver stained gel loaded with 100 µg of *Chlamydia pneumoniae* protein that was presolubilized by boiling in

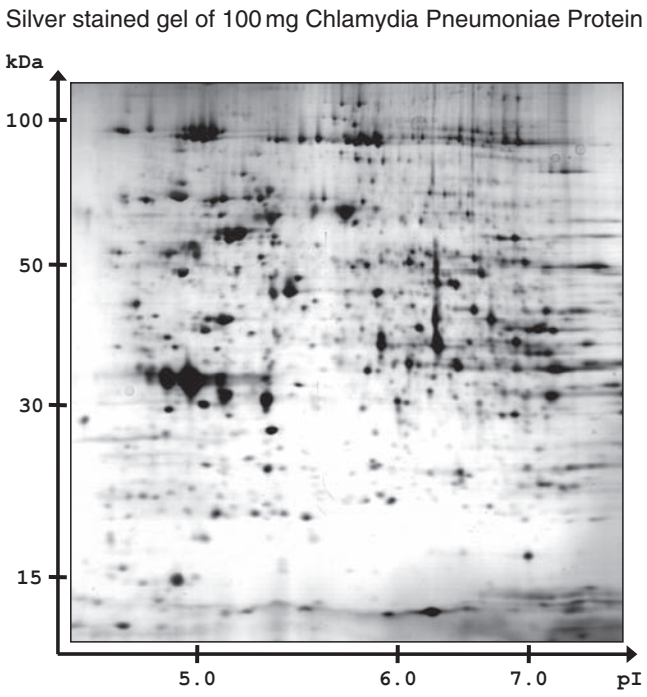

Fig. 1. A pellet of purified *Chlamydia pneumoniae* elementary bodies (12) was resuspended in 1% SDS, 50mM Tris-HCl pH 7.0, sonicated and boiled for 5 min. Cooled sample was diluted 1:10 in lysis buffer, sonicated briefly, left at room temperature for one hour and centrifuged at 20.000 x g for 15 minutes. 350 µL of the supernatant containing 100 µg protein was loaded onto a pH 3–10 non-linear immobilized pH gradient strip (Amersham Biosciences) and focused for 120.000 Volt hours. Second dimension was 9–16% linear gradient SDS PAGE. The gel was silver stained.

1% SDS and 50mM Tris-HCl and then diluting it in the described lysis buffer to a final concentration of 0.1% SDS (*see* **Note 11**).

The protocol below describes the solubilization of proteins from pelleted bacteria. If proteins have been precipitated, for example, for desalting, the lysis buffer should be added directly **(step 8)** in the highest possible amount (*see* **Note 12**).

1. Start out with an appropriate amount of bacteria as pellet (*see* **Note 13**).
2. Add four times the pellet volume of 2% SDS, 65m*M* DTE (*see* **Note 14**).
3. Sonicate three times for 2–20 sec depending on sample size (*see* **Note 15**).
4. Spin shortly to collect the sample (*see* **Note 16**).
5. Resuspend any pellet that may have formed.
6. Boil for five min (*see* **Note 17**).
7. Allow the sample to cool
8. Add 8 volumes of lysis buffer to one volume of extract (*see* **Note 18**).
9. Sonicate three times for 5 sec, cool between sonications (*see* **Note 19**).
10. Leave the sample on a rocking table for 30 min.
11. Spin at 20,000 × g for 15 min and collect the supernatant (*see* **Note 20**).
12. Asses the protein concentration (*see* **Note 21**).
13. Run first dimension immediately or store the sample at −70°C for several months (*see* **Note 22**).

3.2. Sample Purification

Common contaminants in 2-D PAGE studies are salts, small ionic compounds, polysaccharides, nucleic acids and lipids. Salt is the most likely reason if bad first dimensional focusing is observed. Enhanced conductivity and water migration in the strip due to high concentrations of salts will cause horizontal streaks. The concentration of salt should preferably be below 10 m*M* when samples are loaded by strip rehydration. Small charged substances may likewise disturb the isoelectric focusing, especially at the acidic end, as such are often negatively charged. Polysaccharides may clog the gel of the strip and may complex proteins by electrostatic interactions. Lipids may also clog the gel but are mainly a problem due to complexing of hydrophobic proteins and binding of detergent. Nucleic acids may clog the gel, bind proteins through electrostatic interactions, and cause streaking in itself, especially in silver staining.

Buffer shift using spin of drip columns, dialysis, and precipitation **(Subheading 3.2.1)** are straightforward and effective ways to reduce the concentration of salt and small ionic compounds to an acceptable level. Dialysis causes a minimal loss of sample, but requires relative large volumes of solute and is rather time consuming. Spin dialysis using, for instance, Amicon Ultra from Millipore is faster and requires no extra volume of solute, but protein may be lost by adsorption onto the dialysis membrane. Similar issues exist for buffer shifting. Precipitation may also be used to remove polysaccharides and, to some

extent, lipids. Large polysaccharides can be removed by ultracentrifugation. If lipids are causing major problems, the amount and nature of detergent must be optimized for the particular sample. High amounts of nucleic acids may require treatment with DNase/RNase (**Subheading 3.2.2**).

The presence of proteases is likely to be a problem during sample purification and in such case protease inhibitors must be added (*see* **Note 9**). It must be stressed that sample purification preceding addition of lysis buffer should only be carried out if necessary and not as a standard part of the sample preparation.

3.2.1. Precipitation

Precipitation is very efficient for removal of most contaminants including salts, but no precipitant will precipitate all proteins, and some proteins will be difficult to resuspend following precipitation. This is a particular problem when a picture of the total protein content is desired.

A combination of TCA and acetone is the most common precipitant in 2-D PAGE studies, as it is more effective than either of these reagents alone. Besides, very few proteases are active in 10% TCA. Resolubilization is easier after precipitation with acetone alone (75% final concentration), but precipitation wil not be as efficient as with TCA. The TCA/acetone precipitation described here is essentially as in ***(6)***.

1. Add 10% TCA in ice-cold acetone with 20mM DTE to the sample (*see* **Note 23**).
2. Leave at –20°C for two hours (*see* **Note 24**).
3. Centrifuge at 10.000 × g for 10 min.
4. Wash with cold acetone containing 20m*M* DTE.
5. Repeat wash.
6. Let the pellet dry to remove residual acetone.
7. Resuspend pellet in lysis buffer (*see* **Subheading 3.1**).

3.2.2. DNase/RNase Treatment

If nucleic acids are present in high amounts, the sample will appear viscous and a smear will be seen after silver staining. If ultracentrifugation does not solve the problem, enzymatic digestion will.

1. Add 1/10 of the sample volume of a solution containing 1 mg/mL DNase I, 0.25 mg/mL RNase A and 50 mM $MgCl_2$ (*see* **Note 25**).
2. Incubate on ice for 20 min.

4. Notes

1. Absolute amounts are to make 5 mL. All reagents must be analytical grade. Use doubly distilled water. The solution is best mixed in a 10 mL tube on a rotating device. The solution should be made fresh before use or alterna-

tively frozen in aliquots at –70°C and only thawed once. The solution must not be heated above 37°C.

The composition of the lysis buffer is essential for the final result of 2-D PAGE and different lysis buffers may be optimum for different samples and for different proteins in one sample. The function of the lysis buffer described here is to bring as many proteins in the sample as possible into solution and keep them in solution during electrophoresis. As isoelectric focusing is best carried out under denaturing and reducing conditions, the lysis buffer should solubilize, denature, and reduce the proteins of the sample. At the same time, the lysis buffer must not change the pI of the proteins, and it must not be highly conductive. Thus, uncharged components are preferred. Most lysis buffers are still based on that introduced by O'Farrel in 1975 ***(4)*** containing urea as denaturing agent, a detergent, a reducing agent and carrier ampholytes. The standard lysis buffer described here is based on ***(3)*** and the characteristics of each reagent are described in the following notes.

2. Urea, $(NH_2)_2CO$, is a non-charged chaotrope that disrupts non-covalent bonds and thereby denatures proteins. It is the main denaturant in all lysis buffers used in 2-D PAGE and it can be brought into solution in concentrations up to 9.8 M if no thiourea is added. Urea in solution is in equilibrium with ammonium cyanate, which in the form of isocyanic acid will react with amino groups of lysine and arginine residues and the amino terminus of proteins causing carbamylation. The carbamylation of an amine group removes a positive charge from the protein causing a shift toward the acidic side in the gel. Furthermore, it prevents N-terminal sequencing and some enzymatic digests. To avoid carbamylation use only freshly prepared urea solutions. A urea solution should not be left at room temperature for longer periods and should never be heated above 37°C ***(7)***.
3. Thiourea, $(NH_2)_2CS$, improves the solubilization of especially hydrophobic proteins during first dimension ***(8)*** and, in combination with urea, it can be used in concentration up to 2.5 M. The addition of thiourea reduces the solubility of urea and combinations of 7 M urea and 2 M thiourea or 8 M urea and 0.5 M thiourea are most common. The addition of thiourea to the lysis buffer has a pronounced inhibitory effect on proteases, which may still be active in high concentrations of urea alone ***(2)***. As thiourea can hinder the binding of SDS to proteins, it should not be included in the buffers used to equilibrate strips prior to second dimension ***(8)***.
4. DTE, dithioerythritol, MW: 154.3, make a 0.5 M stock solution and store at –20°C. DTE has the same strong reducing power as dithiothreitol (DTT) and both can be used in concentrations from 10–100 m*M*. At alkaline pH both DTE and DTT are charged and migrate toward the anode during first dimen-

sion, which may leave the basic end of the strip without reducing agent and thus cause streaking as a result of reoxidation and precipitation. An alternative and very strong reducing agent is tributyl phosphine (TBP). It can be used in concentrations as low as 2 m*M* and is noncharged, which means that it keeps all proteins reduced throughout the first dimension thereby enhancing the resolution ***(9)***. TBP is stable, but spontaneously inflammable in air. Make a 200m*M* stock in anhydrous isopropanol and store under nitrogen at 4°C ***(9)***. Other alternatives are to alkylate the cysteines prior to first dimension or to oxidize the disulfides by performing the isoelectric focusing in the presence of excess hydroxyethyldisulphide (HED), which is commercially available as DeStreak (GE Healthcare) and includes detailed protocols for its use.

5. CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate, is a zwitterionic detergent that is used in many 2-D PAGE studies. Zwitterionic or nonionic detergents are preferred to anionic detergents like SDS that interferes with the isoelectric focusing in first dimension (*see* **Note 1**). The efficiency of many zwitterionic detergents has been investigated and sulfobetaines with a hydrophobic tail of 12-16 alkyl carbons and an empirically determined linker in between have been found to be good alternatives to CHAPS and superior for some samples ***(10)***. Which detergent is best for a given sample can still not be predicted. The zwitterionic agent ASB-14 ($C_{22}H_{46}N_2O_4S$, Calbiochem) with a 14-carbon alkyl tail, the nonionic Triton X-100 ($C_{14}H_{22}O(C_2H_4O)_n$ with an average number (n) of ethylene oxide of 9 to 10) or the maltoside n-Dodecyl β-D-maltoside ($C_{24}H_{46}O_{11}$, Sigma-Aldrich) would be good first-choice alternatives if CHAPS does not give satisfactory results ***(11)***.
6. Pharmalyte 3–10 can be used for most immobilized pH gradient strips, but if narrow strips or very basic strips are used, carrier ampholytes that match the pH range of the strip should be chosen. Ask the strip supplier if in doubt. Pharmalyte 3–10 is a mixture of carrier ampholytes with pI between 3 and 10. These are small amphoteric compounds with a molecular weight below 1 kDa that have a high buffering capacity at their pI but do not bind proteins due to their high hydrophilicity. When we use 2% v/v of Pharmalyte 3–10 (Amersham Pharmacia) it gives a final concentration of carrier ampholytes of 0.72% in the lysis buffer since "Pharmalyte 3-10" is 36% (w/v). Carrier ampholytes help keep proteins in solution during first dimension and especially prevent hydrophobic interactions between proteins and the IPG in the basic end of the strip. Furthermore, the precipitation of nucleic acids is improved by carrier ampholytes.
7. Tris base is added to raise pH of the lysis buffer to 8.5. Without the addition of base, pH of the lysis buffer would be about 5.5. At alkaline pH more proteins will be anionic and thus not bind to DNA. However, the pH for

optimal solubilization will vary among samples, and Tris base is left out in many studies. Note that if the sample is to be labbeled before electrophoresis, pH may be improtant for the labelling reaction, which for instance is the case for CyDye labelling in the DIGE (GE Healtcare) approach.

8. Bromphenol blue should be added in a small amount to color the solution lightly blue. The color will move toward the anode during first dimension, which can be used to check that the isoelectric focusing is ongoing. However, the color will disappear before the first dimension is finished and cannot be used as an indicative of when to stop.
9. Protease inhibitor cocktails are available from several commercial laboratory reagent suppliers but most proteases will be inhibited by adding 2 m*M* EDTA, 1 mM PMSF, 1 μM Pepstatin A, and 13 μM Bestatin. EDTA chelates free metal ions, thereby inhibiting metalloproteases, make a 0.5 M stock solution in water, pH 8.0. PMSF (phenylmethylsulfonyl fluoride), inhibits serine proteases and some cysteine proteases, make a 100 mM stock solution in methanol. Pepstatin A inhibits aspartic proteases, make a 1 mM stock stock solution in methanol. Bestatin inhibits aminopeptidases, make a 13 mM stock solution in water.
10. When NP-40 is used as detergent in the lysis buffer it has been reported ***(5)*** that the ratio of NP-40 to SDS should be at least 8 to avoid streaking. NP-40 (Nonidet P-40) is a nonionic detergent that is very similar to Triton X-100 and the properties are often reported as being identical. NP-40 (Roche) is $C_{15}H_{24}O(C_2H_4O)n$, where $n = 9–10$ on average.
11. No reducing agent was added during presolubilization.
12. If the sample is applied by strip rehydration of 18 cm strips, the maximum amount is 350 μL per strip.
13. For most bacteria 25–100 μg of protein is appropriate for silver staining, 100–150 μg for Western blotting, and 0.5–2 mg for preparative gels, when 18 cm immobilized pH gradient strips in the pH range of 3–10 or similar broad range intervals are used.
14. Be sure not to add more SDS than it can be diluted to 0.25% in lysis buffer. If all the sample is to be used for one gel using 350 μL lysis buffer to rehydrate an immobilized pH gradient strip, this means that no more than 40 μL of 2% SDS should be added. However, if streaking is observed, try lowering the amount of SDS used for presolubilization. For some samples pH must be buffered to optimize solubilization. Use for instance 50–100 m*M* Tris-HCl, pH 7.0. The optimal pH may vary from sample to sample. Be aware that the final concentration of salt should not exceed 10 m*M* when samples are loaded by strip rehydration (*see* **Subheading 3.2**).
15. Adjust the amplitude of the sonicator so that microbubbles are formed, and keep the tip of the probe deep in the sample to avoid too much foam formation. The sample should be cooled between sonications.

16. It cannot be avoided that some foam is formed during sonication and this should be spun down before the sample is boiled, in order to avoid protein coagulation in drying bubbles.
17. DTE develops toxic gas upon heating. Boil in a fume hood.
18. Dilute the sample as much as possible in lysis buffer (*see* **Notes 13** and **14**).
19. When the sample is in lysis buffer containing urea it is important to keep the temperature below 37°C in order to avoid carbamylation of proteins. If boiling in SDS is left out, the sonication may have to be extended.
20. The centrifugation step is important to remove cell debris and precipitated DNA and it should not be left out.
21. Several constituents of the lysis buffer may cause problems for assessment of protein concentration. Carrier ampholytes, CHAPS, and other detergents will bind most dyes and reduction of cupric ion cannot be employed in the presence of thiourea and DTE. Thus, the protein must be selectively precipitated and then measured. This may be done with the 2-D Quant Kit form Amersham Pharmacia. Alternatively, the protein may be estimated in a parallel sample which is not solubilized in lysis buffer. This may not give the actual protein concentration in the lysis buffer but will in most cases provide adequate information to determine the load.
22. Repeated freeze thaw cycles should be avoided due to the risk of carbamylation and because the solubility of some proteins may be changed by the process.
23. The bacteria must be disrupted beforehand by an appropriate method (*see* **Subheading 3.1**). If the bacteria are disrupted directly in the precipitation buffer most proteases will be inactivated by the TCA.
24. The precipitation time should not be longer than the minimal time required for satisfactory precipitation. For some samples 15 min will do while others must be incubated overnight. Be aware that prolonged exposure to the very acidic solution may cause protein degradation.
25. The bacteria must be disrupted beforehand by an appropriate method (*see* **Subheading 3.1**). If active proteases are present it may be necessary to add protease inhibitors (*see* **Note 9**) even if the DNase/RNase treatment is carried out on ice.

Preparation of Bodily Fluids for 2-D PAGE

Anthony G. Sullivan, Henry Brzeski, Jeban Ganesalingam, and Manuel Mayr

1. Introduction

The importance of bodily fluids as a source of clinically relevant biomarkers/surrogate markers of human disease has increased significantly over the last decade ***(1,2)***, and modern proteomic methods have evolved and been adapted to meet the demand. The specific challenges facing serum analysis include the wide dynamic range in the concentration of individual components and the tremendous number of potential variants of glycosylated proteins ***(3)***. The most dominant plasma proteins, albumin and immunoglobulin (Ig)G, typically comprise up to 70% of the plasma proteome in abundance. To enable the majority of the remaining, far less abundant proteins to be better visualized by two-dimensional gel electrophoresis (2-DE), these two proteins must first be removed or, at least, depleted in relative concentration. There are a number of currently available commercial products from a range of suppliers that enable albumin depletion by chemical affinity, exploiting the remarkable albumin-binding ability of structures closely related to the reactive dye molecule Cibacron blue 3GA ***(4)***, and the IgG binding properties of protein G ***(5)***. The blue dye has been shown to have a special affinity for proteins containing the dinucleotide fold, a structural feature that is common to several classes of proteins ***(4)***. Albumin can be separated from other plasma proteins using lectin affinity, as it is not normally glycosylated, while the majority of classical plasma proteins are. This approach allows both enrichment of lower-abundance proteins, and the study of differences in glycoprotein profiles ***(6)***. Highly effective depletion of albumin using monoclonal antibody selection has also been demonstrated, and coupled with protein G/IgG depletion ***(7)***.Recent research has identified 325 distinct proteins from 1800 2-D gel protein features following multi-component immunoaffinity extraction and further comprehensive chromatographic fractionation ***(8)***. Depletion of IgG by

a protein G resin can also be coupled with NaCl/Ethanol precipitation to deplete albumin ***(9)***. However, depletion can cause problems in itself. The concentration of the high abundant proteins varies considerably within bodily fluids. Therefore once the samples are depleted, there is a significant change in the relative concentration of the protein constituents from the original sample. As an example in our own studies the percentage protein remaining after depletion in cerebrospinal fluid has an average of 17.9% with a standard deviation of 6.6%. This could be overcome by loading according to sample volumes rather than protein loading, which is often the norm in proteomic experiments ***(10)***. A major drawback is that the depletion not only adds further steps in sample processing, but undoubtedly alters the protein constituents within the sample as high abundant proteins bind other proteins. Consequently, the depletion may complicate quantitative comparisons and result in the loss of potential biomarkers ***(11)***.

2. Materials

1. Blue dye affinity resin: Affi-gel, (Biorad), Mimetic Blue SA (Prometic).
2. 20 m*M* Na_2HPO_4, pH adjusted to 7.0 with HCl.
3. Lysis buffer: 7 *M* urea, 2 *M* thiourea, 30 m*M* Tris, 5 m*M* magnesium acetate, 4% CHAPS, 1% NP-40.
4. Trichloroacetic acid (TCA)/acetone protein precipitation: 2-D Cleanup Kit (Amersham Biosciences, Piscataway, NJ).
5. Biomax 10K NMWL membrane centrifugal filter (Millipore, Bedford, MA).
6. WGA-agglutinin lectin (Sigma, St. Louis, MO).
7. Handee Mini Spin Columns (Pierce Biotechnology, Inc., Rockford, IL) or Macro Spin Columns (NEST Group, Southborough, MA).
8. Phosphate buffer: 50 m*M* Na_2HPO_4, 0.2 *M* NaCl, pH adjusted to 7.0 with HCl.
9. Phosphate buffer with SDS: 50 m*M* Na_2HPO_4, 0.2 *M* NaCl, 0.05% SDS, pH adjusted to 7.0 with HCl.
10. Sugar solution: 0.3 *M N*-acetyl glucosamine or neuraminic acid (Sigma, St. Louis, MO), in phosphate buffer.
11. Resin slurry: Albumin and IgG Removal Kit (Amersham Biosciences, Piscataway, NJ).
12. POROS Affinity depletion cartridges (Applied Biosystems, Framingham, MA).
13. AccuGENE 10X PBS solution (Cambrex, East Rutherford, NJ).

3. Methods

3.1. Affinity Depletion of Serum Albumin

3.1.1. Batch Use of Dye-Agarose Affinity Resins

Here we describe a generic method, based on manufacturer's instructions, adaptable for the majority of available dye resin slurries. The steps involved are equilibration, binding, washing, and stripping.

1. Add 250 µL of resin (*see* **Note 1**) to a 1.5-mL microcentrifuge tube (*see* **Note 2**), centrifuge for 2 min at 0.2 *g*, and remove liquid using a gel-loading pipet tip.
2. Add 200 µL of 20 m*M* sodium phosphate, pH 7.0, and shake gently for 10 min. Centrifuge at 1000 rpm for 2 min and remove liquid. Repeat the equilibration twice.
3. Take 25 µL of clarified plasma/serum, dilute it with 175 µL of the 20 m*M* sodium phosphate, pH 7.0 buffer, and mix thoroughly.
4. Add the diluted plasma to the conditioned resin, vortex briefly, and shake gently for 10 min to allow serum albumin to bind to the dye resin. Centrifuge for 2 min at 1000 rpm and remove supernatant using a gel-loading pipet tip. Transfer solution, containing unbound albumin-depleted proteins, to a clean 1.5-mL microcentrifuge tube.
5. Wash the resin three times with 150 µL 20 m*M* sodium phosphate, pH 7.0 buffer, shake for 10 min, centrifuge for 2 min at 1000 rpm, remove the supernatant, and combine with the previous solution.
6. Elute the proteins bound to the resin by washing three times with lysis buffer (*see* **Note 3**). Combine stripped fractions into a separate 1.5-mL tube.
7. Concentrate the albumin-depleted fraction (approx vol 650 µL) to a final vol of approx 100 µL using a 10,000 MWCO (molecular weight cut-off) membrane filter. Desalt and prepare for 2-DE by TCA/acetone precipitation (*see* **Note 4**). For the albumin-rich fraction, remove a 150-µL aliquot from the stock solution and perform TCA/acetone precipitation directly.

3.1.2. Lectin Affinity Serum Albumin Removal Using WGA/Agarose

1. Prepare the Handee Mini Spin column for use by ensuring the frit at the bottom of the main chamber is firmly in place by pushing down with a paper clip. Resuspend the lectin in the buffer supplied by the manufacturer to give a homogeneous lectin slurry, then pipet 200 µL into the chamber, centrifuge briefly, and remove liquid.
2. Add 500 µL of phosphate buffer and shake gently for 10 min. Centrifuge at 1000 rpm for 2 min, remove liquid, and repeat twice.
3. Prepare plasma by diluting 50 µL of plasma with 750 µL of phosphate buffer containing 0.05% SDS. This amount will typically yield 50 µg of albumin-free protein.
4. Transfer diluted plasma to the column containing the beads. Shake gently using a rotary mixer, ensuring good mixing, for 5 min. Centrifuge briefly and collect eluent. Wash beads three times with 200 µL of phosphate buffer. Combine wash eluents (albumin-rich fraction).
5. Elute the glycosylated proteins with 200 µL sugar solution *see* **Note 6**), shaking for 5 min on a rotary shaker. Wash three times with 150 µL of sugar solution and combine, total volume approx 650 µL.
6. Reduce the albumin-depleted fraction to a final vol of approx 100 µL using a 10,000 MWCO membrane filter. Desalt and prepare for 2-DE by TCA/acetone

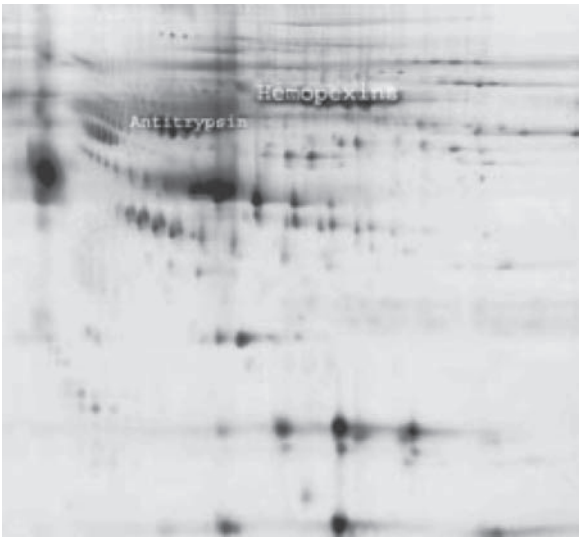

Fig. 1. An example of a two-dimensional gel showing serum prepared using the method outlined in **Subheading 3.1.2**.

precipitation (*see* **Note 4**). An example of a 2-D gel showing serum prepared by the method in **Subheading 3.1.2**. is shown in **Fig. 1**.

3.1.3 Antibody Serum Albumin/Immunoglobulin G Removal

3.1.3.1. Use of Antibody/Protein G Resin

1. Pipet 20 µL of plasma/serum into a 1.5-mL microcentrifuge tube and add 750 µL of resin slurry. Close cap and mix on a rotary shaker, ensuring strong mixing is taking place, for 30 min at room temperature.
2. Transfer entire slurry to the upper chamber of a microspin column and insert column into a suitable microcentrifuge tube. Centrifuge at 1000 rpm for 5 min. Remove liquid (approx 500 µL) and desalt/concentrate as described in **Subheading 3.1.1.**, **step 7**.

3.1.3.2. Use of Antibody/Protein G Cartridges (see Note 7)

1. Connect a syringe to the anti-SA cartridge using a needle-port adapter and equilibrate packing material with at least five cartridge volumes of PBS solution, pH 7.4.
2. Dilute the serum/plasma 10-fold with PBS solution and inject an amount less than the maximum binding capacity into the cartridge at a steady flow rate (*see* **Note 8**).
3. Collect the flowthrough in a clean 0.5-mL microcentrifuge tube. Wash cartridge with three column vols of PBS solution and combine wash fractions in a separate tube.

4. Connect the needle-port adapter to the protein G cartridge and condition the packing material with at least five cartridge vols of PBS solution, pH 7.4.
5. Inject the albumin-depleted fraction from **step 3** at a steady flow rate and collect the flowthrough in a fresh 1.5-mL tube.
6. Inject the combined wash fractions from **step 3** at a steady flow rate and combine with liquid from **step 6**.
7. Concentrate the albumin-IgG-depleted fraction to a final volume of approx 100 µL using a 10,000 MWCO membrane filter. Desalt and prepare for 2-DE by TCA/acetone precipitation (*see* **Note 4**).

3.2. Use of Commercial Depletion Kits

3.2.1 Commercial Kits Available

There are many different commercial depletion kits available which include Aurum Serum Protein Minikit (Bio-Rad, Hercules, CA), Multiple Affinity Removal Column (Agilent Technologies, San Diego, CA), POROS Affinity depletion Cartridges (Applied Biosystems, Framingham, MA) and Albumin and IgG Removal kit (Amersham Biosciences, Uppsala, Sweden). The relative performance of these columns has been compared by Bjorhall *et al*. ***(12)***.

3.2.2 Protocol Using the Agilent Multiaffinity Depletion Column

1. Add an appropriate volume of bodily fluid to a 4 ml spin column.
2. Centrifuge sample at 4000 rpm for 30 min..
3. Add 1 ml of buffer A (Agilent Technologies).
4. Centrifuge sample at 4000 rpm for 30 min.
5. Repeat **steps 3** and **4** a further two times.
6. Filter CSF solution through a 0.22 micron spin filter.
7. Centrifuge sample through the column at 100 g for 1.5 min and collect elute.
8. Add 400 mcl Buffer A and centrifuge through column at 100 g for 2.5 min and collect elute.
9. Repeat **step 8**.
10. Keep total elute (1 ml) which contains the depleted sample.
11. Elute bound fraction by passing 2 ml Buffer B, (Agilent Techonologies) slowly through column.
12. Buffer exchange samples into an appropriate buffer for downstream analysis. Representative 2-D gel images of cerebrospinal fluid, before and after depletion with the above described column, are shown in **Fig. 2**.

4. Notes

1. The amount of resin used here ensures that the total albumin loaded to the resin is less than its albumin-binding capacity (typically approx 11 mg/mL).
2. As an alternative to the procedure listed here, the resin may be applied to the upper chamber of a spin column, and the removal of liquid facilitated

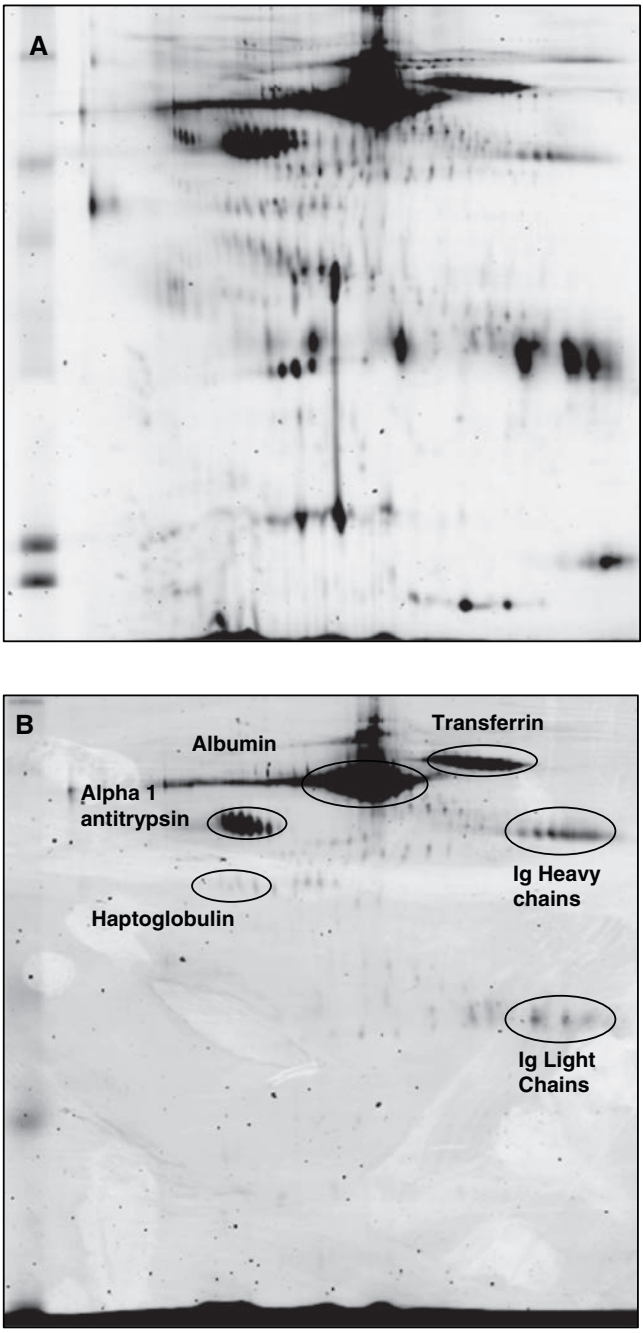

Fig. 2. (continued)

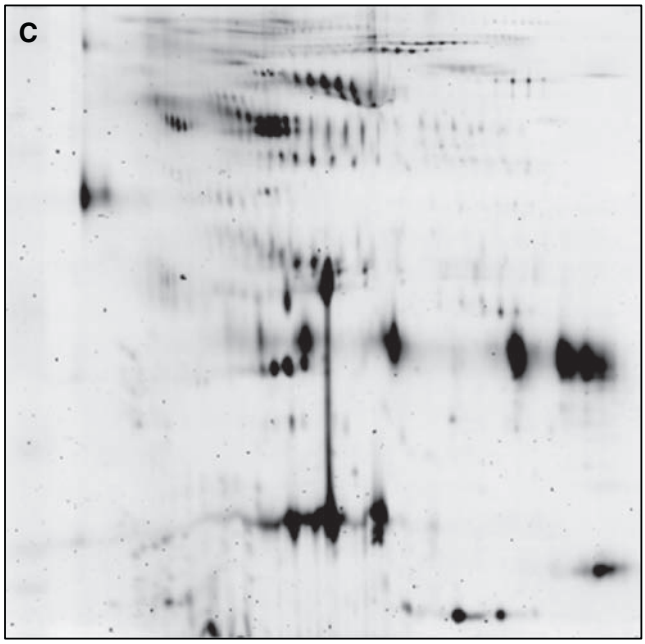

Fig. 2. 2-D gel images of cerebrospinal fluid before and after antibody depletion. Depletion was carried out using commerical depletion columns (Agilent Technologies). Representative images of the original sample **(A)**, the bound fraction **(B)**, and the depleted fraction **(C)**.

by centrifugation. In our hands, this variation led to less efficient albumin removal due to inconsistent residence times.

3. Alternatives to lysis buffer include solutions of sodium chloride or guandinium chloride (5–6 *M*).
4. Desalting/concentrating is absolutely required for the isoelectric focusing step. The use of MWCO membrane filters followed by protein precipitation was found in our hands to be the most effective method combination. The initial preconcentration to volumes of 100 µL depletes salt levels and reduces the amount of protein precipitation solutions required.
5. Columns are available in several sizes and therefore total protein loading capacities.
6. *N*-acetyl glucosamine can be replaced by *N*-acetyl neuraminic acid depending on the type of glycosylation under investigation.
7. These cartridges can be used separately as outlined here, or in series, either manually with the aid of a syringe, or automatically using a solvent delivery system on a liquid chromatograph.

8. The albumin-binding capacity depends on the column size and will be supplied by the manufacturer. The albumin content of the plasma can only be estimated, unless specific albumin assay methods are available.

Immunoaffinity Depletion of High Abundance Plasma and Serum Proteins

Lynn A. Echan and David W. Speicher

1. Introduction

Analysis of human serum and plasma has been a major focus of many recent proteomics studies because blood is a promising, routinely collected biological fluid that is likely to contain multiple novel biomarkers for many human diseases, such as cancers and cardiovascular disease (***1***). Most cells in the body are thought to secrete or shed proteins into the blood, and therefore plasma is very likely to contain information concerning the physiological status of all tissues and organs in the body ***(2–4)***. While serum and plasma hold great potential as sources of new disease biomarkers, systematic discovery of novel biomarkers in patient cohorts is greatly complicated by the presence of a small number of highly abundant (mg/ml range) proteins in blood ***(2–6)***. In particular, serum albumin constitutes about 65% of total serum protein, while immunoglobulins contribute an additional 15%. Most of the remaining 20% of total protein content is comprised of a modest number of additional high- and medium-abundance (μg/ml range) proteins, which tend to obstruct discovery of novel, specific disease biomarkers present at ng/ml to pg/ml levels.

Until approximately 2003, the only available technology for depletion of major proteins was represented by commercial kits that combined Cibacron blue dye for removal of albumin with Protein A or G for removal of immunoglobulins. Unfortunately, these columns incompletely removed albumin and removed many non-targeted proteins, including potential biomarkers ***(7)***. Recently, several companies have produced immunoaffinity depletion resins that are more effective and more specific than the blue dye approach for depleting multiple blood proteins. Depletion of at least six or more abundant proteins has become standard practice as the first step in multidimensional

plasma or serum proteome analyses. Early research studies explored use of monoclonal or polyclonal antibodies to attempt to remove one or multiple abundant proteins. The development *(8)* and commercial production of the Multiple Affinity Removal System (Agilent) in 2003 was particularly noteworthy as it was the first widely available product that removed more than one or two proteins. Specifically, it removed six abundant proteins and reduced the protein content by 85%. This improves protein profiling capacities substantially, but the next level of abundant proteins continue to limit volumes of plasma that can be analyzed. Hence, ideally additional abundant proteins should be depleted so that at least 98–99% of total protein is removed *(4,7)*.

More recently, several manufacturers have produced antibody columns against 7, 12, 14, or 20 abundant blood proteins in both HPLC/FPLC and spin column formats. In addition, most manufacturers will produce custom larger scale FPLC or spin column formats to fit the needs of individual laboratories. The choice of FPLC or spin column format depends upon several factors. First, FPLC columns require relatively expensive instrumentation not available in every laboratory, and antibody LC columns are usually larger and more expensive than spin columns. However, the FPLC columns are highly robust, more completely remove the targeted proteins, and are more time efficient because they usually deplete larger volumes of plasma or serum in a single pass.

In our experience, the available commercial multiprotein immunodepletion columns (**Table 1**) perform similarly. That is, they are highly efficient at depleting the targeted proteins, typically >98–99.5% removal of most targets, while simultaneously not removing significant amounts of untargeted minor proteins *(7)*. Of course, if serum albumin is present at 40 mg/ml and 99% is removed, the residual 0.4 mg/ml of albumin is still a major protein. Hence, for the most critical experiments, it is necessary to optimize removal to greater than 99%, at least for the most abundant proteins. In this regard, it is not surprising that polyclonal antibodies are usually used for these depletion matrices rather than monoclonal antibodies. Monoclonal antibodies are sometimes more specific; each antibody has a single binding affinity, and it is easier to consistently produce a uniform product. But because they have single epitopes, they will usually be less effective than polyclonal antibodies in removing proteolytic fragments, some posttranslationally modified forms of the target protein, oxidized forms of the protein, etc. An unknown challenge is whether these commercial products can be consistently produced over the long term, since polyclonal antibody properties can vary from batch-to-batch due to variations in host immune response to injected antigens.

Factors that may influence decisions concerning the type of column to use include: FPLC or spin format, column size and capacity options, moderate

Table 1
Commercially Available Multiprotein Immunoaffinity Depletion Columns[a]

Manufacturer/Product	# Proteins Depleted	Format	Capacity	# Runs[b]
Sigma				
ProteoPrep 20 (Human)	20	10 ml LC Spin Column	100 µl 8 µl	100
Agilent	14	4.6 × 50 mm LC	20–40 µl	200
MARS Human-14		4.6 × 100 mm LC	20–40 µl	
		10 × 100 mm LC	160 µl	
		Std. Spin Column	8–10 µl	
MARS Human-7	7	4.6 × 50 mm LC	30–70 µl	200
		4.6 × 100 mm LC	30–70 µl	
		10 × 100 mm LC	250–300 µl	
		Std. Spin Column	12–14 µl	
MARS Human-6	6	4.6 × 50 mm LC	15–80 µl	200
		4.6 × 100 mm LC	15–80 µl	
		10 × 100 mm LC	340 µl	
		Std. Spin Column	7–10 µl	
		HC[c] Spin Column	14–16 µl	
MARS Mouse-3	3	4.6 × 50 mm LC	37–100 µl	200
		4.6 × 100 mm LC	37–100 µl	
		Std. Spin Column	25–30 µl	
Beckman	12	2 ml LC	50 µl	100
IgY- 12 (Human)		10 ml LC	250 µl	
		Spin Column	20 µl	
IgY-R7	7	2 ml LC	20–40 µl	100
(Mouse/Rat)		10 ml LC	100–200 µl	
		Spin Column	10–15 µl	

[a] Only products that deplete at least six abundant human proteins and the only available mouse columns are summarized here. Some columns only deplete one or two proteins.
[b] Stated maximum lifetime as reported by manufacturer.
[c] High capacity

price-to-capacity differences, whether buffers are defined or proprietary, and most importantly, the proportion of the total plasma protein removed by the column. As a general rule, it is beneficial to deplete as many abundant proteins as possible, because the greater the reduction in total protein content per volume of original plasma, the greater the improvement in detection of lower abundance proteins. The following protocols describe common HPLC/FPLC and spin

column immunoaffinity depletion using ProteoPrep 20 columns, which currently remove the largest number of proteins and remove approximately 95% of the total plasma protein content. The same methods can be used for either plasma or serum. For simplicity, we will generally refer to plasma only when describing the protocols.

2. Materials

2.1. FPLC Affinity Depletion of Plasma or Serum

1. Human plasma or serum.
2. HPLC or FPLC system capable of operating at low pressure.
3. ProteoPrep 20 LC Plasma Immunodepletion Column Kit (Sigma Catalog No. PROT20LC). Storage: 2–8 °C. Individual components are:
   a. ProteoPrep 20 LC Plasma Immunodepletion Column; 9.4 ml resin, 100 µl plasma (50–70 mg) capacity (Sigma Catalog No. P9874).
   b. ProteoPrep 20 Equilibration Buffer, 10x concentrate; (Sigma Catalog No. P1749).
   c. ProteoPrep 20 Elution Solution, 10x concentrate; (Sigma Catalog No. P9749).
   d. ProteoPrep Preservative Concentrate; (Sigma Catalog No. K3889).
4. Stericup GP Express Plus Membrane, 0.22 µm filter units (500 ml capacity); (Millipore Catalog No. SCGPU05RE).
5. Amicon Ultrafree-MC 0.22 µm microcentrifuge filters; (Millipore Catalog No. UFC30GVNB).
6. Milli-Q water or equivalent.

2.2. Spin Column Affinity Depletion of Plasma or Serum

1. Human plasma or serum.
2. ProteoPrep 20 Plasma Immunodepletion Kit (3 column kit: Sigma Catalog No. PROT20; Single column kit: Sigma Catalog No. PROT20S); Storage: 2–8 °C, Individual components are:
   a. ProteoPrep 20 Plasma Immunodepletion Spin Column (300 µl resin, 8 µl plasma capacity).
   b. ProteoPrep 20 Equilibration Buffer, 10× concentrate (Sigma Catalog No. P1749).
   c. ProteoPrep 20 Elution Solution, 10× concentrate (Sigma Catalog No. P9749).
   d. ProteoPrep Preservative Concentrate (Sigma Catalog No. K3889).
3. Luer Lock caps.
4. Several 5 or 10 ml syringes.
5. Amicon Ultrafree-MC 0.22 µm microcentrifuge filters (Millipore Catalog No. UFC30GVNB).
6. Amicon Ultra-4, 5 kDa MWCO centrifugal filter device (15 ml capacity) (Millipore Catalog No.UFC800524).
7. Milli-Q water or equivalent.

2.3. Large-Scale Spin Column Affinity Depletion of Plasma or Serum

1. Human plasma or serum.
2. ProteoPrep 20 Custom Plasma Immunodepletion Kit; Storage: 2–8 °C, Individual components are:
   a. ProteoPrep 20 Jumbo Plasma Immunodepletion Spin Column (3.7 µl resin, 100 µl plasma capacity).
   b. ProteoPrep 20 Equilibration Buffer, 10x concentrate (Sigma Catalog No. P1749).
   c. ProteoPrep 20 Elution Solution, 10x concentrate (Sigma Catalog No. P9749).
   d. ProteoPrep Preservative Concentrate (Sigma Catalog No. K3889).
3. Luer Lock caps.
4. Several 20 ml syringes.
5. Amicon Ultrafree-CL 0.22 µm microcentrifuge filters, 2 ml capacity (Millipore Catalog No.UFC40GV00).
6. Amicon Ultra-4, 5 kDa MWCO centrifugal filter device (Millipore Catalog No.UFC800524).
7. Milli-Q water or equivalent.

2.4. Ethanol Precipitation

1. Unbound or bound fraction from Prot-20LC or spin column depletion.
2. 200 proof Ethanol, chilled to −20°C (Sigma).
3. Speed-vac centrifuge.

3. Methods

3.1. FPLC Affinity Depletion of Plasma or Serum

Many HPLC systems require pressures greater than 100 psi to operate properly. The ProteoPrep 20 LC column packing has a rated pressure maximum of 30 psi. Hence, an FPLC-type system, capable of operating at low pressures and where a high pressure limit of 30 psi can be accurately set, is strongly preferred. If the available instrument requires higher minimum operating pressures, one option is to generate necessary backpressure in front of the column with a flow restrictor such as an appropriate length of small internal diameter PEEK tubing (e.g. 1–2 feet, 0.005 or 0.007 inch i.d.) and larger ID PEEK tubing (0.030 or 0.040 inch i.d.) after the column to avoid exposing the column to high pressures. Care must be taken to set the maximum pressure limit only slightly above the operating pressure to reduce the risk of compressing the column bed. Fortunately, the column itself has a much higher pressure rating than the column matrix. Hence, if an obstruction in the column or downstream does occur, there is minimal risk of a column explosion as long as the maximum pressure is set well below the pressure limit of the column housing.

1. Prepare Buffer A (1x Equilibration Buffer): Dilute one part of ProteoPrep 20 Equilibration Buffer, 10x concentrate with nine parts of room temperature ultrapure water. Filter the diluted buffer through a 0.22 µm filter unit and degas for 5 min. at room temperature using vacuum filtration with stirring. The final volume needed for each depletion is approximately 55 ml.
2. Prepare Buffer B (1x Elution Solution): Dilute one part of ProteoPrep 20 Elution Solution, 10x concentrate with nine parts of room temperature ultrapure water. Filter the diluted buffer through a 0.22 µm filter and degas for 5 min. at room temperature using vacuum filtration with stirring. The final volume needed for each depletion is approximately 30 ml.
3. Before connecting the column, flush Buffer A through the system to the column inlet line for 15 min at 1 to 3 ml/min. Transfer column to room temperature at this time.
4. Connecting column: to prevent air from being introduced into the column, after flushing the system as described in **step 3,** stop flow, remove the plug from the top of the column only, start the pump at 0.5 ml/min, and while holding the column inlet tubing over the top end of the column, fill the column end fitting with Equilibration Buffer. Stop flow and connect tubing to column inlet.
5. Remove the screw plug from the bottom of the column, connect the detector inlet solvent line to the column bottom, and equilibrate with Buffer A for 5 min at 1 ml/min (*see* **Note 1**).
6. Filter undiluted plasma (generally 100 µl) with a prerinsed 0.22 µm microcentrifuge filter (*see* **Note 2**). Keep filtered sample on ice until ready for use (*see* **Note 3**).
7. Prior to injection of the first sample of the day, run a blank run (no injection) and reequilibrate the column using Buffer A (*see* **Note 4**).
8. Inject 100 µl of filtered plasma at 0.3 ml/min.
9. Elute the depleted plasma (unbound fraction) from the column with Buffer A at 0.3 ml/min. Collect the flow-through fractions and pool the unbound fractions containing protein as it comes off the column (*see* **Note 5**). Keep the pooled sample on ice.
10. Elute bound proteins with Buffer B at 1 ml/min. Collect and pool bound proteins and store on ice (*see* **Note 6**).
11. Reequilibrate column with Buffer A for 10 min at 3 ml/min.
12. Inject the next sample and repeat **steps 8 to 11** until all samples are separated or a sufficient volume of a single sample is depleted.
13. Disconnect and store the column at 4°C in Buffer A. (*see* **Note 7**).
14. Replace Buffers A and B with ultrapure water and flush system, including detector, for 30 min at 1 ml/min followed by 50% isopropanol for 30 min at 1 ml/min (*see* **Note 8**).

3.2. Spin Column Affinity Depletion of Plasma or Serum

There are several strategies for spin-column usage. First, to maximize column load, it is possible to moderately overload the column, which results in depletion of about 90–95% of the targeted proteins. The unbound fraction is then repurified on either the same column or a duplicate column to "polish"

the purification. The repurification step can be conducted on a single unbound fraction after it has been concentrated, or multiple unbound fractions can be pooled, concentrated and repurified in a single repurification run. This two-pass method has the advantage of being able to deplete larger final volumes of a single sample per day. An alternative strategy is to load the spin column at or slightly below the recommended capacity and conduct one or more single-pass purifications. If the plasma concentration is not too high (column capacities are rated by vendors based on volume, not protein concentration), the final sample or pool of multiple samples may not need to be redepleted. However, they will usually need to be concentrated and one is likely to only achieve 95% depletion of targeted proteins using this method. A third and most conservative strategy is to both underload the column and redeplete the initial unbound fraction in a final polishing step. This should provide at least 99% removal of most targeted proteins, but volume of plasma purified per day will be somewhat reduced.

The method presented here is the manufacturer's recommended approach to maximize volume of plasma depleted per given time period. Multiple aliquots of a plasma sample (up to 10) are depleted, pooled, and concentrated, and following elution of the bound proteins, the unbound fraction from all 10 samples is redepleted in a polishing step. While not all vendors recommend a polishing step, the principle of removing small amounts of residual targeted proteins in the unbound pool using a repurification is generally applicable and is a good idea for the most critical work, especially when spin columns are used.

1. Prepare Buffer A (1x Equilibration Buffer): Dilute one part of ProteoPrep 20 Equilibration Buffer, 10x concentrate with nine parts of room temperature ultrapure water. The final volume necessary for each plasma application is 5 ml.
2. Prepare Buffer B (1x Elution Solution): Dilute one part of ProteoPrep 20 Elution Solution, 10x concentrate with nine parts of room temperature ultrapure water. The final volume necessary for each plasma application is 2 ml.
3. Remove the bottom plug and screw cap from the spin column and place into a 2 ml collection tube. Centrifuge the spin column at 1000–2000 × g for 60 sec to remove the storage buffer using either a speed-vac without vacuum or a microfuge.
4. Attach a Luer Lock fitting to the spin column, draw 4 ml of 1x Equilibration Buffer into a syringe, attach the syringe to the Luer Lock cap, and slowly push the buffer through the column to equilibrate the resin.
5. Remove the Luer Lock fitting, loosely recap the column, and place into a collection tube. Centrifuge the spin column at 1000–2000 × g for 60 sec to remove the excess Equilibration Buffer. Discard the buffer and place the column into a clean collection tube.
6. Dilute plasma sample (generally 8 µl per depletion) to 100 µl with Equilibration Buffer (*see* **Note 9**). Filter diluted plasma with a prerinsed 0.22 µm microcentrifuge filter. Keep filtered sample on ice until ready for use.
7. Add 100 µl diluted sample to the top of the packed resin bed, and incubate at room temperature for 20 min.

8. Centrifuge the spin column and collection tube at 1000–2000 × g for 60 sec.
9. Wash the remaining depleted plasma from the column with 100 µl 1x Equilibration Buffer. Collect wash by centrifuging the spin column at 1000–2000 × g for 60 sec. This wash may be collected in the same tube used in **step 8.**
10. Repeat **step 9** for an additional 100 µl wash of the resin, the final pooled volume of the unbound fraction should be approximately 300 µl.
11. Elute bound proteins with 1x Elution Solution. Attach a Luer Lock fitting to the spin column, draw 2 ml of 1x Elution Solution into a syringe, and slowly push the buffer through the column to remove proteins bound to the resin.
12. Neutralize bound proteins with 1M NaOH to bring pH to 8.0 (*see* **Note 6**).
13. Reequilibrate the spin column: Attach a Luer Lock fitting to the spin column, draw 4 ml of 1x Equilibration Buffer into a syringe, and slowly push the buffer through the column to equilibrate the resin.
14. Remove the Luer Lock fitting and place the column into a clean collection tube. Centrifuge the spin column at 1000–2000 × g for 60 sec to remove the excess Equilibration Buffer. Discard the buffer and place the column into a new collection tube.
15. Repeat **steps 7–14** for up to 10 depletions.
16. After all samples have been depleted, begin concentrating the unbound fraction (*see* **Note 10**). Add up to 4 ml of unbound pool to a prerinsed Amicon-Ultra 5K MWCO concentrator. Centrifuge for 15 min at 1500 × g, 4°C.
17. Repeat **step 16** until the unbound pool is concentrated to 100–200 µl.
18. Rinse the concentrator unit with 100 µl Equilibration Buffer, and pool this with the concentrated unbound sample to recover proteins adhering to the concentrator membrane.
19. Add 100 µl of the unbound sample to the reequilibrated and packed resin bed. Incubate for 20 min and centrifuge spin column and collection tube at 1000–2000 × g for 60 sec.
20. Repeat **step 19** until all of the concentrated unbound plasma has been reapplied to the column.
21. Wash the column twice with 100 µl Equilibration Buffer, centrifuge, and pool washes with the twice-depleted plasma. The final volume should be about 500 µl.
22. Repeat **steps 11–14** from this section to elute remaining bound proteins and reequilibrate the column.
23. Store column in 300 µl Equilibration Buffer containing Preservative Solution, with the bottom plug securely in place, and tightly recap the column (*see* **Note 7**).

3.3. Large-Scale ProteoPrep 20 Spin Column Depletion Using a Jumbo Custom Column

As mentioned above, some manufacturers will create custom HPLC or spin columns to meet the needs of investigators who want to deplete larger volumes of plasma or serum more efficiently. This protocol utilizes a custom ProteoPrep 20 Jumbo Plasma Immunodepletion Column (3.7 ml resin). Similar to the

smaller spin column, there are several alternative loading/depletion strategies. For example, this column can be used to deplete 100 µl human plasma without a polishing step, and in one day it is practical to perform approximately 10 first pass depletions for a total volume of 1 ml per day. Alternatively, one can purify 250 µl per cycle and four first pass depletions followed by one polishing cycle of the combined and concentrated unbound fractions (also 1 ml but only 5 total cycles rather than 10 using the single-pass strategy).

1. Prepare Buffer A (1x Equilibration Buffer): Dilute one part of ProteoPrep 20 Equilibration Buffer, 10x concentrate with nine parts of room temperature ultrapure water. The final volume necessary for each plasma application is 60 ml.
2. Prepare Buffer B (1x Elution Solution): Dilute one part of ProteoPrep 20 Elution Solution, 10x concentrate with nine parts of room temperature ultrapure water. The final volume necessary for each plasma application is 24 ml.
3. Remove the bottom plug and screw cap from the spin column and place into a collection tube. Centrifuge the spin column at 1000–2000 × g for 60 sec to remove the storage buffer.
4. Attach a Luer Lock fitting to the spin column, draw 16 ml of 1x Equilibration Buffer into a syringe, attach the syringe to the Luer Lock cap, and slowly push the buffer through the column to equilibrate the resin.
5. Remove the Luer Lock fitting, loosely recap the column, and place into a collection tube. Centrifuge the spin column at 1000–2000 × g for 60 sec to remove the excess Equilibration Buffer. Discard the buffer and place the column into a clean collection tube.
6. Dilute plasma sample (100 or 250 µl per depletion) to 1.25 ml with Equilibration Buffer. Filter diluted plasma with a prerinsed 0.22 µm centrifuge filter. Keep filtered sample on ice until ready for use.
7. Add 1.25 ml diluted sample to the top of the packed resin bed, and incubate at room temperature for 20 min
8. Centrifuge the spin column and collection tube at 1000–2000 × g for 60 sec.
9. Wash the remaining depleted plasma from the column with 1.25 ml 1x Equilibration Buffer. Collect wash by centrifuging the spin column at 1000–2000 × g for 60 sec. This wash may be collected in the same tube used in **step 8.**
10. Repeat **step 9** for an additional 1.25 ml wash of the resin, the final pooled volume should be about 3.75 ml.
11. Elute bound proteins with 1x Elution Solution. Attach a Luer Lock fitting to the spin column, draw 12 ml of 1x Elution Solution into a syringe, and slowly push the buffer through the column to remove proteins bound to the resin.
12. Centrifuge the spin column in collection tube at 1000–2000 × g for 60 sec to remove any additional Elution Solution from the column.
13. Neutralize bound proteins with 1M NaOH to bring pH to 8.0 (*see* **Note 6**).
14. Reequilibrate the spin column: Attach a Luer Lock fitting to the spin column, draw 16 ml of 1x Equilibration Buffer into a syringe, and slowly push the buffer through the column to equilibrate the resin.

15. Remove the Luer Lock fitting and place the column into a clean collection tube. Centrifuge the spin column at 1000–2000 × g for 60 sec to remove the excess Equilibration Buffer. Discard the buffer and place the column into a new collection tube.
16. Repeat **steps 7–14** for up to 10 depletions of 100 µl or 4 depletions of 250 µl. Unbound fractions can be concentrated while subsequent depletions are being performed.
17. After all samples have been depleted, complete concentration of the unbound pool (*see* **Note 10**). Add up to 4 ml of unbound to a prerinsed Amicon-Ultra 5K MWCO concentrator. Centrifuge for 15 min at 1500 × g, 4°C.
18. Repeat **step 17** until the unbound sample is concentrated to approximately 1 ml.
19. Rinse the concentrator unit with 250 µl Equilibration Buffer, and pool this with the concentrated unbound sample to recover any proteins adhering to the concentrator membrane.
20. If 250 µl aliquots were purified per cycle, or if maximum depletion of 100 ml per cycle purifications are desired, add 1.25 ml of the unbound sample to the reequilibrated and packed resin bed. Incubate for 20 min and centrifuge spin column and collection tube at 1000–2000 × g for 60 sec.
21. Repeat **step 20** until all of the concentrated unbound plasma has been reapplied to the column.
22. Wash the column twice with 1.25 ml Equilibration Buffer, centrifuge, and pool washes with the twice-depleted plasma. The final volume should be 3.75 ml.
23. Repeat **steps 11–14** from this section to elute remaining bound proteins and reequilibrate the column.
24. Store column in 1.25 µl Equilibration Buffer containing Preservative Solution, with the bottom plug securely in place, and tightly recap the column (*see* **Note 7**).

3.4. Ethanol Precipitation

We have found that ethanol precipitation is an effective alternative to ultrafiltration for final unbound and bound fractions from either FPLC or spin columns that will be used in subsequent steps that use denaturants such as either 8 M urea or SDS. The ethanol precipitation requires less operator time and more effectively removes salts and detergent. The ethanol should be high quality, absolute proof, and must be chilled to −20°C to facilitate protein precipitation.

1. Add 9 volumes of 200 proof ethanol (−20°C) to the pooled unbound fraction.
2. Incubate overnight at 0°C.
3. Centrifuge sample for 30 min at 1500 × g, 4°C.
4. Carefully remove supernatant and air dry pellet briefly in a fume hood or speed vac (*see* **Note 11**).

4. Notes

1. The ProteoPrep LC column comes packed in a storage solution containing glycerol. For the first use of the column, attach the top of the column to the tubing as described in **Subheading 3.1, step 4.** Do not connect the

column outlet line to the bottom of the column. Instead, place the column over a beaker to collect the glycerol solution. Allow the column to equilibrate with 20–25 ml of 1x Equilibration Buffer at no higher than 0.5 ml/min. Carefully monitor pressure and decrease the flow rate as needed to not exceed 30 psi. Increased pressures at this step may cause bed compression and a void at the top of the resin bed. When the resin has changed from opaque to white, and the buffer runs clear, the column outlet line may be connected. The column should be conditioned with two complete blank cycles prior to injecting a sample. It is also preferable to run a few non-critical control plasma samples before depleting plasma samples that will be used in comparative studies.

2. Earlier versions of this method recommended diluting the plasma sample 5x with Buffer A prior to filtering. To enhance depletion of apolipoproteins and recovery of unbound proteins, the manufacturer recommended omitting the dilution step. However, we have not observed any major changes in apolipoprotein removal nor does a five-fold dilution of the plasma significantly increase the final volume of the unbound pool. Additionally, diluting the sample makes it more convenient to add protease inhibitors to the sample before injection if desired.
3. The manufacturer describes this column's capacity as 100 µl of plasma with a concentration of 40–50mg/ml. However, this is a very low estimate for protein concentration, and most human serum and plasma samples are likely to have substantially higher protein concentrations. For example, the range for total blood protein in normal human serum is 60–85 mg/ml, and plasma samples will have similar or slightly higher values. Furthermore, as indicated above, the normal range is quite broad and ranges in patients with diseases are often even more variable. Total protein concentration will also be affected by the use of different anti-coagulants and collection tubes. Therefore, it is advisable to determine the protein concentration of each sample prior to depletion and base loads upon total protein, not volume. When preparing samples, other considerations to note are: the number of depletions and/or different plasma samples that will be run in a single day. If multiple runs of the same sample are being depleted, it is best to thaw and prepare the entire sample at once and store it on ice until the entire sample is depleted, for optimal reproducibility. If several samples from different donors are being depleted sequentially, it is recommended that a single sample is thawed and filtered shortly before its injection, and while one sample is running, thaw and prepare the next sample. This will minimize proteolysis of the sample. A related option is to add protease inhibitors to the plasma sample prior to injection, although the value of adding protease inhibitors is ambiguous. Plasma and serum intrinsically contain many proteases as well as protease inhibitors, and some proteolysis

of susceptible proteins usually occurs in vivo. While further proteolysis may occur during sample processing, some protease inhibitors may react indiscriminately with plasma proteins ***(9)*** and other inhibitors are proteins or large peptides. Instead of adding protease inhibitors to plasma or serum, we prefer to minimize exposure of samples to conditions that favor proteolysis. The one step where it is not practical to avoid protease favorable conditions is during binding of the targeted proteins to the immunoaffinity resin. This is because in order to optimize binding affinity, conditions close to physiological pH without denaturants must be used, and in order to achieve reasonable binding kinetics, low temperatures should be avoided. However, it should be noted that plasma and serum are far more stable to proteolysis than cell lysates, and moderate length exposure to physiological conditions at room temperature appear to have only very minor effects on proteomes **(9).** Regardless of the precise sample handling methods to be used, the most critical factor is to ensure that all samples to be compared are processed in as consistent a manner as possible.

4. We have found that running an initial "quick blank gradient" at 3 ml/min for the entire gradient with no injection is useful for several reasons. First, it will ensure that the column is equilibrated to room temperature prior to the sample being injected. Also, as the column warms up, solvent outgassing may occur; but the increased flow rate forces any small air bubbles out of the column before large pockets can form and disrupt the column packing. Finally, a blank run at the beginning of the day removes any residual protein that may be bound to the column from previous depletions. Any protein peaks observed during the blank run should be run on 1-D SDS-PAGE and analyzed with silver stain.
5. It is useful to reserve a small aliquot of each fraction before pooling the unbound to analyze individual fractions on 1-D SDS-PAGE.
6. It is recommended that bound proteins typically be collected and frozen for potential future analysis. Prior to storage, the bound pool should be neutralized by adding 1M NaOH to bring the pH to approximately 8.0.
7. Proper storage and monitoring of antibody columns is essential for maintaining optimal column performance. Storage in Equilibration Buffer at 4°C is suitable for short-term storage, i.e., if the column will be reused within a few days. Long-term column storage (1 week or more) requires the addition of a Preservative Solution, included with the ProteoPrep 20-LC and spin columns. Alternatively, flushing the column with Buffer A containing 0.01% sodium azide should protect the antibody column from microbial growth. It is important to keep track of the total number of cycles run on each column. Periodically and especially when the upper limit of recommended uses has been reached, column performance should be critically evaluated. We have found the lifetime of well managed columns is

usually greater than the recommended lifetimes. In addition, as column capacity slowly and inevitably declines, it is usually adequate to simply reduce protein loads slightly to achieve the same degree of depletion as was obtained with a new column. To monitor antibody loss from the column, bound fractions from sample purifications and bound fractions from blank cycles after extended column storage should be periodically monitored by digesting an aliqout of the bound pool with trypsin followed by LC-MS/MS analysis. The resulting data should ideally be searched against an all species database. Alternatively, a human sequence database supplemented with all immunoglobulin sequences from the species of origin for the antibodies on the column should be used. In this manner, one can detect antibody bleed and/or proteolysis of the coupled antibodies.

8. After each use, the FPLC or HPLC system should be thoroughly flushed with water, followed by 50% Isopropanol. This will prevent corrosion due

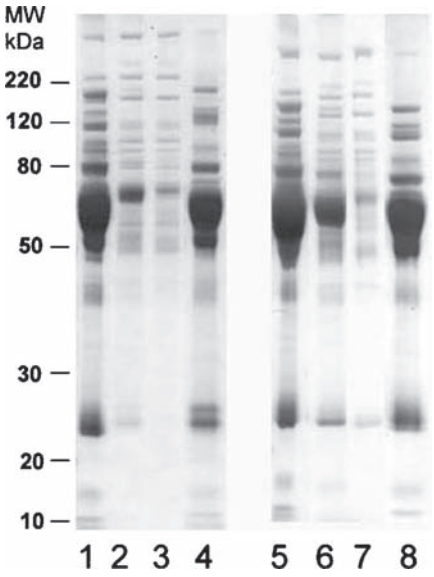

Fig. 1. Depletion of human plasma using spin columns. (***Left***) Results from depletion of ten 8 µl aliquots of human plasma using a standard spin column. Lanes: 1-undepleted plasma; 2-pool of depleted plasma from the ten runs after first cycle of depletion; 3-depleted plasma pool after polishing step; 4-pool of bound proteins eluted from column and concentrated using an Amicon-ultra 5K MWCO centrifugal filters. (***Right***) Results from depletion of a single 250 µl aliquot of human plasma using a large custom spin column. Lanes: 5-undepleted plasma; 6-unbound pool after first cycle of depletion; 7-unbound pool after polishing step; 8-pool of bound proteins after elution and concentration using an Amicon-ultra 5K MWCO centrifugal filters.

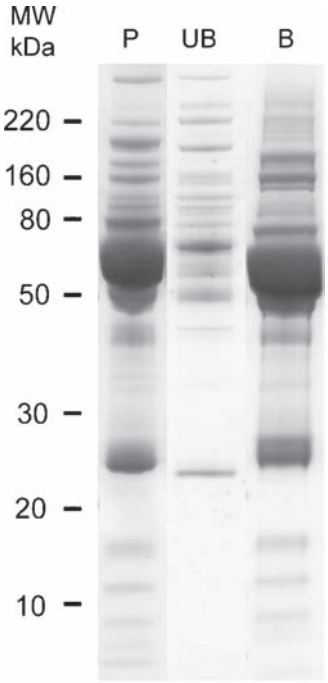

Fig. 2. Depletion of human plasma on a large LC column. Results from depletion of 100 µl human plasma after a single pass through a ProteoPrep 20 LC column. P-undiluted human plasma, UB-pooled unbound fraction after ethanol precipitation, B-pooled and neutralized bound fraction after ethanol precipitation.

to halogen salt-containing buffers or clogging of lines due to bacterial growth.

9. The spin column capacity is based on 8 µl of plasma with a concentration of 40–50mg/ml. If plasma concentration is higher, sample volume should be adjusted accordingly. If multiple aliquots of the same sample are to be depleted in one day, prepare enough sample for all depletions and store sample on ice. If proteolysis is a concern for downstream applications, it is acceptable to add protease inhibitors at this step (**Fig. 1**) (*see* **Note 3**).
10. Following each depletion, the manufacturer recommends continuous concentration of the unbound in the same micro-concentrator unit until the desired number of depletions has been completed. We prefer to pool the unbound, and begin concentration after all the depletions are completed, using a larger capacity concentrator. This will provide a total unbound sample before concentration that can be analyzed in parallel on 1-D

SDS-PAGE with the concentrated sample to check for protein losses during concentration.

11. To completely dry pellet, without risk of airborne contaminants or sample oxidation, it is preferable to dry the pellet under a gentle stream of argon or in a speed vac for a few minutes. The pellet is then resuspended in the desired resolubilization buffer, or the dried pellet may be stored at −20–80°C until it is needed. To check for potential sample loss during the ethanol precipitation, dry 10% of the ethanol supernatant in a speed vac, and run in parallel with proportional volumes of sample before and after precipitation on 1-D SDS-PAGE.

Preparation of Yeast Samples for 2-D PAGE

Joakim Norbeck

1. Introduction

Yeasts are the focus of much research, both in their role as pathogens and as biotechnically important organisms, and not the least in their role as model systems for eukaryotic cells. In particular, *Saccharomyces cerevisiae* has also been the object of several proteomics-related efforts. However, the preparation of protein extract from yeast is complicated by the presence of a cell wall of mainly chitin and glucans, which needs to be disrupted in the extraction process. Several methods presenting solutions to this problem, in connection with sample preparation for two-dimensional polyacrylamide gel electrophoresis (2-D PAGE), have been described ***(1,2)***, in which the cell wall is broken either by vortexing in the presence of glass beads or by sonication.

We have found the method described below to be robust and to yield reproducible results in several studies ***(3–6)***. It is furthermore easy to perform and does not require any specialized equipment.

2. Materials

1. Sample buffer I: sodium dodecyl sulfate (SDS) (0.3 g), β-mercaptoethanol (5.0 mL), Tris-HCl (0.444 g), Tris base (0.266 g), MilliQ (or equivalent) water (to a final volume of 10 mL).
2. Sample buffer II (*see* **Note 1**): 1.5 *M* Tris base (80 µL), 1.5 *M* Tris-HCl (1585 µL), 1 *M* $MgCl_2$ (250 µL), DNase I (Worthington Biochemical Corp., NJ) (5 mg), RNase A (Worthington Biochemical Corp., NJ) (1.25 mg), MilliQ (or equivalent) water (to a final volume of 5 mL).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Immobilized pH gradient (IPG)-rehydration buffer (urea/thiourea buffer): urea (4.8 g; gives a final concentration of 8 *M*; *see* **Note 2**), Triton X-100 or Nonidet P40 (100 µL; *see* **Note 3**), 1 *M* DTT (100 µL), IPG-buffer/ampholine (50 µL; *see* **Note 4**), bromophenol blue (trace amount approx 0.01% w/v), MilliQ (or equivalent) water (to a final volume of 10 mL).

3. Method

The method described in the following sections can be divided into (1) an initial cell disruption step; (2) a protein solubilization step; (3) a nuclease treatment step; and (4) a final phase in which protein extract is diluted in IPG-rehydration buffer immediately prior to application on the first dimension of 2-D PAGE.

The procedure is carried out in 1.5-mL microcentrifuge tubes. A suitable starting material is a pellet of yeast cells from 10 mL of culture with a density of 5–10 million cells/mL, corresponding to an optical density (at 610 nm) of approx 0.5, which will typically yield a pellet of 5–10 µL of cells. The method described below is adjusted to this amount of cells.

The protocol can be scaled up or down; however, care should be taken to not use a final extract volume of more than 500 µL or less than 50 µL, since this will reduce the efficiency of the cell-disruption step.

3.1. Cell Disruption

1. Add 160 µL of ice-cold milliQ-quality water containing protease inhibitors (e.g., Complete™, Roche, Inc.) to the cell pellet.
2. Add 0.25 g of chilled glass beads (diameter 0.5 mm) to the sample.
3. Vortex 4 • 30 s on a table shaker at maximum speed (approx 2500 rpm) with intermittent placement of samples on ice for at least 1 min.

3.2. Protein Solubilization

1. Add 20 µL of sample buffer I and vortex the tube(s) briefly to mix.
2. Place tube(s) at 95°C for 5 min. Make sure to secure the lid of the tube, alternatively to make a small hole in the lid, prior to the heating step.
3. Cool samples on ice for 5 min.

3.3. Nuclease Treatment

1. Add 20 µL of sample buffer II and vortex the tube(s) briefly to mix.
2. Incubate on ice for 10 min.
3. Centrifuge samples at full speed (approx 15,000*g*) in a microcentrifuge at 4°C.
4. Aspire the supernatant (constituting the protein extract) to a new microcentrifuge tube and freeze at −20°C, or use immediately.

3.4. Dilution in IPG-Rehydration Buffer

1. Dissolve sample in required volume of IPG-rehydration buffer (*see* **Note 5**).
2. Incubate the sample at 37°C for 10 min.

3. Spin down sample (15,000*g*, 10 min, room temperature) to remove any particles that might remain.

4. Notes

1. The DNase and RNase should be dissolved in the buffer as the final step.
2. 8 *M* Urea can be substituted by a combination of 7 *M* urea and 2 *M* thiourea. The chaotropic agent thiourea is the most highly beneficial addition to the IPG-rehydration buffer; this addition can strongly improve the solubility of many proteins which may produce "streaking" or which are completely absent on 2-D PAGE gels run with normal urea-based buffer in the first dimension ***(7)***. However, thiourea requires a special permit from inspecting authorities in many countries due to its suspected carcinogenic properties.
3. Triton X-100 can be substituted for 2% (w/v) of CHAPS. CHAPS is considered to be the preferred detergent for the IPG-rehydration buffer ***(7)***. Unfortunately, it is also considerably more expensive than Triton X-100 and Nonidet P-40. We normally use Triton X-100, since in our hands the choice of detergent in the rehydration buffer has only a minor influence on the final protein resolution.
4. IPG buffer or ampholine should be chosen for each type of IPG strip, or for the desired separation interval.
5. The final volume to which the sample is diluted is determined by the system used for running this first dimension. We most often use the precast pH-gradient strips (supplied by, for example, Amersham Biosciences and BioRad, Inc.), for which the rehydration volume is commonly in the range of 125–500 µL. However, the protein extract is also compatible with the original glass tube-based system for running 2-D PAGE ***(8)***, or for application on IPG strips using sample cups, in which the sample volume will typically be <100 µL. In the simplest case, the desired amount of protein extract to be loaded is less than 10% of the final volume and contains low amounts of salt. The extract can then be mixed directly with IPG-rehydration buffer to the required volume immediately prior to application on the first dimension. If the desired amount of protein extract is greater than 10% of the final volume, or if the sample contains large amounts of substances that may disturb the isoelectric focusing (e.g., salts), additional steps such as precipitation or dialysis are required: A simple and straightforward way to concentrate the sample and remove low-molecular-weight compounds is the use of precipitation, either by acetone or trichloroacetic acid, or a combination of the two ***(9)***. The precipitate is then dissolved in a proper amount of IPG-rehydration buffer. Alternatively, the protein extract can be adjusted to a final concentration of 8 *M* urea (or 7 *M* urea/2 *M* thiourea), followed by dialysis against a large volume of IPG-rehydration buffer. In the latter case, a micro-dialysis kit with a cutoff of 1 kDa should be used (e.g., PlusOne™ Micro Dialysis kit,

Amersham Biosciences). Following dialysis, the sample is adjusted to the required volume, using IPG-rehydration buffer. However, it should be cautioned that both precipitation and dialysis may cause the loss of certain proteins from the extract. The amount of extract to be diluted also depends on whether a constant amount of protein (in μg) or a constant amount of radioactivity (in dpm of radioactively labeled amino acid) is desired. When measuring protein concentration in the extract, it is important to use a method that tolerates the presence of detergents and mercaptoethanol (e.g., a method which incorporates an initial protein precipitation step).

Membrane Protein Preparation Using Aqueous Polymer Two-Phase Systems

Jens Schindler and Hans Gerd Nothwang

1. Introduction

Membrane proteins serve many fundamental functions for cells such as cell-cell interactions, signal transduction, and molecular transport both within and between cells. Bioinformatic analysis has estimated that transmembrane domain containing proteins represent about 20-30% of all open reading frames in sequenced genomes ***(1)***. In addition, many proteins are anchored to the membranes via lipidic posttranslational modifications such as glycosylphosphatidyl inositol anchors or via interaction with other membrane proteins. In total, embrane anchored proteins represent a considerable portion of all cellular proteins. They also represent 70% of all known drug targets, which prioritize them in biomedical research ***(2)***. Consequently, profiling membrane proteomes will aid in both understanding basic biological processes and discovering novel targets for therapeutic agents. Membrane proteomics, however, is rendered difficult on several levels.

Notorious difficulties in membrane proteomics include the solubilization, digestion, and separation of membrane proteins. They contain both hydrophilic and hydrophobic domains, which preclude their routine analysis by conventional two-dimensional polyacrylamide gel electrophoresis due to solubilization difficulties. Furthermore, membrane proteins contain stretches of highly hydrophobic transmembrane domains that lack an adequate number of arginine and lysine residues, which are required for in gel digestion with the commonly used endoproteinase trypsin. The sequence coverage of membrane proteins can hence be relatively poor when only this endoproteinase is used.

Some of these problems have been overcome by advances using nongel-based liquid chromatography techniques applying a wide variety of stationary

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

and mobile phases and chromatography types ***(3)***. Recent separation protocols made use of size-exclusion chromatography (SEC), affinity chromatography (AC), ion-exchange chromatography (IEX) and reversed-phase chromatography (RPC) ***(3)***. In the multidimensional protein identification technology (Mud-PIT), for instance, peptide mixtures are loaded onto a biphasic microcapillary column packed with reversed-phase and strong-cation-exchange material. Sequentially, eluted peptides are detected and identified by MS/MS ***(4)***. This approach was recently taken a step forward by combining it with methanol-facilitated solubilization and digestion of the protein sample. This combination allowed identification of 1,500-2,500 proteins starting with 100-200 µg of membrane proteins ***(5)***.

Another serious, but often underestimated challenge in membrane proteomics is the complexity of a eukaryotic cell. A typical eukaryotic cell contains many different subcellular compartments each with its own subset of membrane proteins. In addition, the subcellular distribution pattern of a given protein might change under different conditions and this might alter its function. Striking example are integral plasma membrane proteins such as the glucose transporter Glut4 in muscle and fat cells ***(6)*** or the glutamate receptors ***(7)*** in the brain, which can shuttle between intracellular stores and the plasma membrane under different physiological conditions. Therefore, it is mandatory to characterize these subproteomes separately in order to identify compartment-specific proteins, to describe the physiological state of a tissue under defined conditions, and to gain insight into pathophysiological mechanisms.

Unfortunately, most of the approaches mentioned before do not address this issue or fail to perform sufficiently well in separating the different membraneous compartments ***(8)***. There is hence a clear need for the reproducible production of well-characterized membrane protein samples. In this chapter, we provide a robust and efficient protocol to isolate plasma membranes from brain tissue ***(9)***. It is based on an aquous polymer two-phase system exploiting the principle of countercurrent distribution. Advantages of this protocol include its ease and efficiency as well as the low costs. Furthermore, two phase systems are very versatile allowing also isolation of substructures of membranes such as caveolae (for further details on membrane partitioning see ***[10]***). The protocol can be adapted to other tissues as well.

2. Materials

Due to the strong influence of ions on membrane partitioning in the two-phase systems, double distilled water should be used throughout the experiments.

1. Glass-Teflon homogenizer.
2. Dextran stock solution: Dextran T500 (20% w/w) (*see* **Note 1**).
3. PEG stock solution: PEG 3350 (40% w/w).
4. Tris-H_2SO_4: 200 mM Tris, pH 7.8 adjusted with H_2SO_4.

3. Methods

3.1 Two-Phase Partitioning

All steps of the affinity two-phase partitioning protocol should be performed at 4 °C. Working at room temperature prevents phase separation. The procedure is illustrated in **Fig. 1**. The numbers in **Fig. 1** correspond to the numbered two-phase systems given in **Table 1**, and the letters refer to the phases as indicated in the protocol given below.

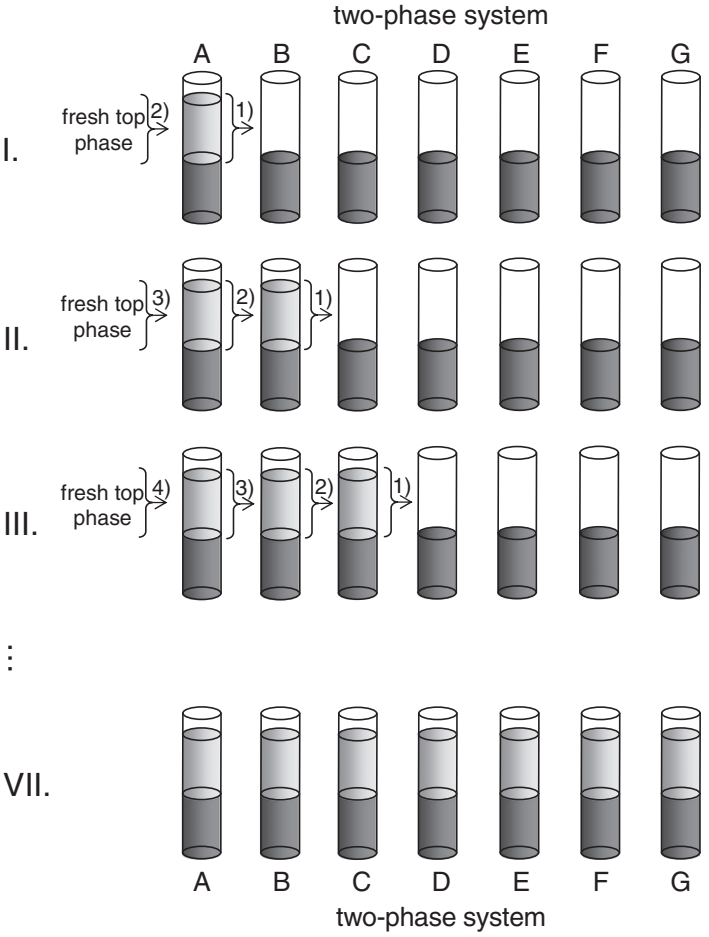

Fig. 1. Scheme of countercurrent distribution. In CD experiments, the top phase of the first two-phase system A is transferred to a fresh bottom phase B and the bottom phase of two-phase system A is reextracted with a fresh top phase. After six iterations, biomaterial is efficiently separated.

Table 1
Composition of Two-Phase Systems

	Two-phase system "A"	Two-phase systems "B-G"
Dextran stock solution	1.035 g	1.035 g
PEG stock solution	0.518 g	0.518 g
Tris-H_2SO_4	0,750 g	0.750 g
Water	0.598 g	0.698 g

1. Prepare seven two-phase systems with the compositions indicated in **Table 1** one day prior to use. Mix them by 20 invertations, vortexing for 10 sec, another 20 invertations and store the mixtures at 4°C overnight. Two-phase systems will form over night with the top phase enriched in PEG and the bottom phase enriched in dextran.
2. On the next day, remove all top phases from two phase systems "B-G" and store them separately.
3. Homogenize 0.100 g brain tissue (*see* **Note 2**) in two-phase system "A" using a glass-teflon homogenizer followed by 45 sec of sonication. Centrifuge at 700 × g for 5 min to accelerate phase separation.
4. Transfer the top phase (Top) of two-phase system "A" onto the bottom-phase (Bot) of two-phase system "B" (TopA -> BotB) (*see* **Note 3**). Add an equal amount of fresh top-phase (stored in **step 2**) onto bottom-phase "A" (I. in **Fig. 1**). Mix both two phase systems by 20 invertations, vortex for 10 s, then mix again by another 20 invertations. Centrifuge at 700 × g for 5 min to accelerate phase separation.
5. Transfer top phases in the following order (II. in **Fig. 1**): 1) TopB -> BotC; 2) TopA -> BotB. Add an equal amount of fresh top-phase (stored in **step 2**) onto bottom-phase "A." Mix all two-phase systems by 20 invertations, vortexing for 10 sec, and another 20 invertations. Centrifuge at 700 × g for 5 min to accelerate phase separation.
6. Transfer top phases in the following order (III. in **Fig. 1**): (1) TopC -> BotD; (2) TopB -> BotC; (3) Top A -> BotB. Add an equal amount of fresh top-phase (stored in **step 2**) on to bottom-phase "A."
7. Mix all two-phase systems by 20 invertations, vortexing for 10 sec, and another 20 invertations. Centrifuge at 700 × g for 5 min to accelerate phase separation.
8. Transfer top phases in the following order: (1) Top D -> BotE; (2) TopC -> BotD; (3) TopB -> BotC; (4) Top A -> BotB. Add an equal amount of fresh top-phase (stored in **step 2**) onto bottom-phase "A." Mix all two-phase systems by 20 invertations, vortexing for 10 sec, and another 20 invertations. Centrifuge at 700 × g for 5 min to accelerate phase separation.
9. Transfer top phases in the following order: (1) TopE -> BotF; (2) Top D -> BotE; (3) TopC -> BotD; (4) TopB -> BotC; (5) Top A -> BotB. Add an equal amount of fresh top-phase (stored in **step 2**) onto bottom-phase "A". Mix all two-phase systems by 20 invertations, vortexing for 10 sec, and another 20 invertations. Centrifuge at 700 × g for 5 min to accelerate phase separation.

10. Transfer top phases in the following order: (1) TopF -> BotG; (2) TopE -> BotF; (3) Top D -> BotE; (4) TopC -> BotD; (5) TopB -> BotC; 6) Top A -> BotB. Add an equal amount of fresh top-phase (stored in **step 2**) onto bottom-phase "A."
11. Mix all two phase systems by 20 invertations, vortexing for 10 sec, and another 20 invertations. Centrifuge at 700 × g for 5 min to accelerate phase separation. After phase separation you end up with 7 two-phase systems (VII. in **Fig. 1**). Plasma membranes are enriched in top phases "F+G."
12. To proceed further, isolate membranes out of TopG (maximum purity) or from TopG combined with TopF (maximum yield) by diluting the phases 1:10 with water and spin for 1 h at 150,000 × g (*see* **Note 4**).
13. Proteins in the pellet are solubilized by sonication in Laemmli-sample buffer. After incubation for 15 min at 37 °C the sample is separated by SDS-PAGE (*see* Note 5).

4. Notes

1. Dextran can contain up to 10% water and for that reason the 20% stock solution has to be prepared from freeze-dried dextran. For freeze drying, dissolve dextran in distilled water in a plastic dish with a large surface (e.g. Petri dish), freeze it at −80 °C and dry it by sublimating the water under vacuum. Store the freeze-dried dextran in closed plastic tubes sealed tightly with parafilm at −20 °C. Let it come to room temperature before opening to protect it from humidity.
2. The protocol can also be applied to other tissues. Applicants should take care that the tissue is thoroughly homogenized (e.g., sceletal muscle and heart tissue are much harder to homogenize than brain tissue) or the yield of plasma membranes will decrease. Altering the polymer concentration or the buffer conditions might be considered to optimize the protocol for the fractionation of other tissues (for review see Schindler and Nothwang, 2006)
3. In two-phase systems, interphases are always assigned to the bottom phase.
4. The amount of peripheral membrane proteins in the pellet can be reduced by extractions with Na_2CO_3. The procedure solubilizes peripheral membrane proteins whereas integral proteins remain in the pellet **(10).** For this purpose, resuspend the pellet in ice cold Na_2CO_3 (0.2 M), incubate for 15 min on ice and pellet the membranes by ultracentrifugation at 233,000 × g for 1 h. This step might be repeated twice.
5. Proteins can also be solubilized in different buffers, depending on further processing (e.g., 16-BAC-SDS-PAGE, BN-PAGE, immunoprecipitation)

Acknowledgments

This work was funded in part by the Nano+Bio-Center of the University of Kaiserslautern.

Subcellular Fractionation of Small Sample Amounts

Hans Gerd Nothwang, Isabelle Guillemin, and Jens Schindler

1. Introduction

A central issue in proteomics is the generation of qualitative and quantitative protein inventories for a given tissue, organ, or organism. In many eukaryotes, this amounts to a formidable task. Mammals may express more than 200,000 different transcripts with a quarter of them encoding proteins ***(1)***. In addition, there exist several hundred different ***(2)*** posttranslational modifications, increasing the number of different protein species by an estimated factor of 10, compared to the number of different mRNAs ***(3,4)***. Consequently, higher organism will display more than 1,000,000 different proteins ***(5)***. Considering as a lower, very conservative limit, the expression of 5–10% of the transcriptome in an organ, about 50,000–100,000 different protein species will be present in such a sample. Even in a single cell, > 10,000 different protein species likely exist. This number easily exceeds the potential of any known proteomic approach. Another important issue in protein analysis is the high range of protein abundance. Protein concentrations likely vary between 10^6–10^{10}, depending on the tissue analyzed ***(6,7)***. This renders the identification of low abundant proteins impossible in the bulk of total protein extracts.

To overcome these hurdles, many novel sample fraction approaches have been developed. These include SDS-PAGE combined with liquid chromatography coupled mass spectrometry or multidimensional liquid chromatography techniques ***(8,9)***. However, when aiming at proteomics as a bottom-up process to understand a biological system, most of these approaches fall short by neglecting the importance of the compartmentalized organization of any living cell. A cell is highly structured and organized. Most, if not all proteins have precise subcellular locations and mistargeting might have severe pathophysiological consequences. It matters, whether a transcription factor such as NF-kappaB is in the cytosol

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

or in the nucleus. Furthermore, posttranslational modifications depend on the localization of a protein. A striking example is the addition and modification of sugar residues during the passage of plasma membrane proteins through the biosynthetic secretory pathway. Therefore, everything in proteomics makes only sense in the light of subcellular organization and this information should be retained during sample preparation. Here, we present a subcellular fractionation protocol, developed for minute amounts of tissue or cell cultures ***(10)***. The protocol is based on hypotonic cell lysis, followed by differential centrifugation. It yields three fractions, a nuclei-enriched fraction, a combined membrane and organelle enriched fraction, and a cytoplasmic fraction.

2. Materials

1. CLB: 10 mM HEPES, 10 mM NaCl, 1 mM KH_2PO_4, 5 mM $NaHCO_3$, 5 mM EDTA,1 mM$CaCl_2$, 0.5 mM $MgCl_2$, and Complete protease inhibitor (Roche, Penzberg, Germany).
2. TSE: 10 mM Tris, 300 mM sucrose, 1 mM EDTA, 0.1% IGEPAL-CA 630 (v/v), pH 7.5 (*see* **Note 1**).
3. 2.5 M sucrose.
4. PBS: 130 mM NaCl, 7 mM Na_2HPO_4, 3 mM NaH_2PO_4, pH 7.4.
5. Motorized Teflon/glass homogenizer.
6. Table top centrifuge (e.g. 5417R, Eppendorf, Hamburg, Germany).
7. Beckman 70Ti rotor and Beckman ultracentrifuge (Beckman Coulter, Krefeld, Germany).
8. Micro-BCA assay (Pierce, Bonn, Germany).
9. 2-D gel clean-up kit (GE Healthcare, Freiburg, Germany).
10. Rehydration buffer: 5 M urea, 2 M thiourea, 2% CHAPS, 2% SB-3-10, 40 mM Tris, trace of bromophenol blue.

3. Methods

3.1. Fractionation of Cultures Cells

All steps of the protocol should be performed on ice. The procedure is illustrated in **Fig. 1**.

1. Harvest ~8×10^6 cells of a monolayer culture (75 cm^2) by trypsination.
2. Incubate the cells in 1 ml of CLB for 5 min on ice.
3. Homogenize the cells with 50 strokes in a motor-driven homogenizer at 250 rpm. Keep the sample on ice.
4. Add 100 µl of 2.5 M sucrose to the sample to restore isotonic condition.
5. Centrifuge the sample at 6,300 × g for 5 min at 4°C.
6. Transfer the supernatant to a new tube. It will be processed in **step 11**.
7. Homogenize the pellet in 500 µl of CLB /0.25 M sucrose with a 1 ml pipette tip.
8. Centrifuge the sample at 6,300 × g for 5 min at 4°C.
9. Combine the supernatant with the supernatant of **step 6**.

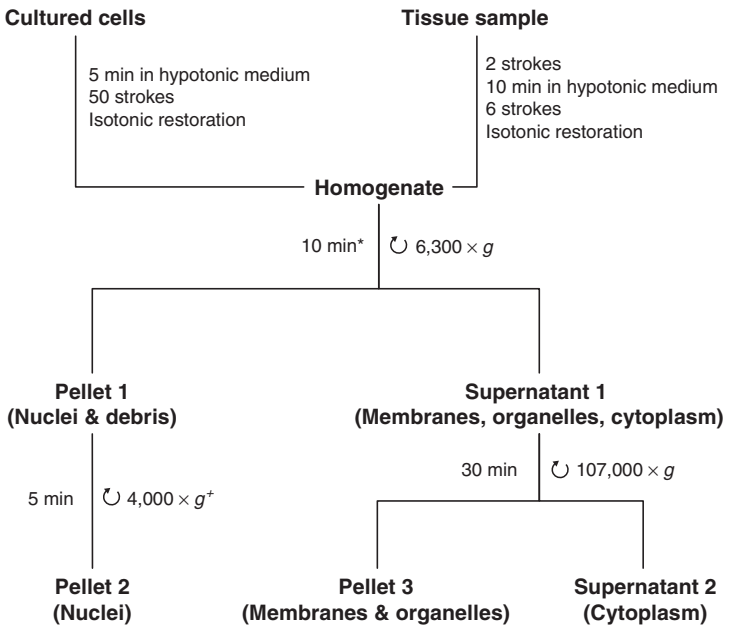

Fig. 1. Schematic illustration of the subcellular fractionation protocol. Conditions of homogenization depend on the starting material, that is, either cultured cells or tissue. After homogenization, two rounds of differential centrifugation with increasing centrifugal force yield three final fractions. * for cultured cells, the first round of centrifugation lasted only 5 min; + for freshly prepared tissue, nuclei should be pelleted at only 1000 × g to prevent cosedimentation with other subcellular compartments.

10. Homogenize the pellet in 1 ml TSE with 30 strokes in a motor-driven homogenizer at 250 rpm.
11. Centrifuge the suspension at 4,000 × g for 5 min at 4°C (see **Note 2**).
12. Discard the supernatant and repeat **steps 10** and **11** until the supernatant remains clear. Resuspend the final pellet in 200 µl of TSE and store it at −20°C until further usage. This suspension represents the nuclei enriched fraction.
13. Sediment the combined supernatants from step 6 and 9 at 107,000 × g for 30 min at 4°C min using a Beckman 70Ti rotor (or equivalent) in a Beckman ultracentrifuge (*see* **Note 3**).
14. Transfer the supernatant to a new tube and store it at −20 °C until further usage. It represents the cytosolic fraction.
15. Resuspend the pellet in 80 µl of PBS. It represents the membrane and organelle enriched fraction. Store it at −20°C until further usage.

3.2. Fractionation of Tissue

1. Transfer 500 mg of frozen tissue (e.g. brain) to 1 ml of ice cold CLB.
2. Prehomogenize the tissue by 2 strokes in a glass/Teflon homogenizer on ice.

3. Incubate the pre-homogenate on ice for 10 min.
4. Homogenize the prehomogenate by 6 strokes in a motorized glass/Teflon homogenizer at 250 rpm (*see* **Note 4**).
5. Add 100 µl of 2.5 M sucrose to restore isotonic condition.
6. Centrifuge the sample at 6,300 × g for 10 min at 4°C (*see* **Notes 5** and **6**).
7. Transfer the supernatant to a new tube. It will be processed in **step 11**.
8. Homogenize the pellet in 500 µl of CLB /0.25 M sucrose with a 1 ml pipette tip.
9. Centrifuge the sample at 6,300 × g for 5 min at 4°C
10. Combine the supernatant with the supernatant of **step 7**.
11. Homogenize the pellet in 1 ml of TSE by 30 strokes in a motor-driven homogenizer at 250 rpm.
12. Centrifuge the sample at 4,000 × g for 5 min at 4°C (*see* **Note 2**).
13. Discard the supernatant and repeat **steps 7** and **8** until the supernatant remains clear.
14. Resuspend the final pellet in 200 µl of TSE and store it at −20°C until further usage. This suspension represents the nuclei enriched fraction.
15. Sediment the supernatant from steps 7 and 10 at 107,000 × g for 30 min at 4°C min using a Beckman Ti70 rotor (or equivalent) in a Beckman ultracentrifuge (*see* **Note 3**).
16. Transfer the supernatant to a new tube and store it at −20°C until further usage. It represents the cytosolic fraction.
17. Resuspend the pellet in 80 µl of PBS. It represents the membrane and organelle enriched fraction. Store it at −20°C until further use.

3.3. Protein Quantification and Clean-Up

The following procedure is applied to analyze the samples by conventional two-dimensional gel electrophoresis.

1. Determine the protein concentration of the cytosolic fraction by the Micro BCA Protein Assay Reagent Kit according to the manuracturer's instructions. Use 1, 2, and 5 µl of the sample and BSA as standard.
2. If required for further analysis, concentrate the sample by acetone precipitation, as outlined in **steps 3 to 8.**
3. Add 4 times the sample volume of cold (−20°C) acetone to the sample.
4. Mix well and incubate at −20°C for 1 h.
5. Centrifuge the sample 10 min at 14,000 rpm.
6. Decant the supernatant and remove all remaining liquids carefully with a pipette tip.
7. Allow the acetone to evaporate from the open tube for 30 min (*see* **Note 7**).
8. Resuspend the pellet in the appropriate volume of the desired buffer (e.g., rehydration buffer).
9. Clean-up nuclear and membrane & organelle fractions using a clean-up kit (e.g., 2-D clean up kit, GE Healthcare, Freiburg, Germany) according to the manufacturer's instructions.
10. Dissolve the resulting pellets in 200 µl rehydration buffer (*see* **Note 8**).

11. Estimate the protein content of the nuclei and of the membrane and organelles enriched fraction by comparing an aliquot of these fractions with a dilution series of the cytosolic proteins quantified in **step 1,** after separation in a SDS-PAGE and staining with Coomassie or fluorescent dyes (*see* **Note 9**).

4. Notes

1. IGEPAL-CA 630 is identical to Nonidet P40 substitute.
2. This washing step purifies the nuclear pellet by removing nonnuclear membrane vesicles. Omitting this step will increase the yield but will reduce the purity of the fraction in parallel.
3. Alternatively, this step can be performed for 150 min at 14,000 rpm (corresponding to ~21,000 × g) at 4°C in a tabletop centrifuge. This by-passes the requirement of an ultracentriguge without affecting yield or purity.
4. Cultured cells require a higher number of strokes compared to tissue samples, as their cytoskeleton differs from the cytoskeleton in brain tissue. Tissues such as heart, liver or placenta will also need harsher conditions for homogenization.
5. When fresh tissue is used, centrifuge only at 3,000 rpm.
6. The prolonged centrifugation time compared to cultured cells results in an increased recovery of nuclear marker proteins.
7. Do not overdry, as the samples may not dissolve properly afterward.
8. This buffer with non-ionic detergents is required if samples will be separated by isoelectric focusing. for other downstream applications, an SDS containing buffer might be used. This will improve the resuspension of the pellets. Due to the presence of thiourea in the rehydration buffer, most colorimetric quantification methods will not work.

Nondenaturing Polyacrylamide Gel Electrophoresis of Proteins

John M. Walker

1. Introduction

SDS-PAGE (Chapter 21) is probably the most commonly used gel electrophoretic system for analyzing proteins. However, it should be stressed that this method separates denatured protein. Sometimes one needs to analyze native, nondenatured proteins, particularly if wanting to identify a protein in the gel by its biological activity (for example, enzyme activity, receptor binding, antibody binding, and so on). On such occasions it is necessary to use a nondenaturing system such as described in this chapter. For example, when purifying an enzyme, a single major band on a gel would suggest a pure enzyme. However this band could still be a contaminant; the enzyme could be present as a weaker (even nonstaining) band on the same gel. Only by showing that the major band had enzyme activity would you be convinced that this band corresponded to your enzyme. The method described here is based on the gel system first described by Davis ***(1)***. To enhance resolution a stacking gel can be included (*see* Chapter 21 for the theory behind the stacking gel system).

2. Materials

1. Stock acrylamide solution: 30 g acrylamide, 0.8 g *bis*-acrylamide. Make up to 100 mL in distilled water and filter. Stable at 4°C for months (*see* **Note 1**). **Care: Acrylamide Monomer Is a Neurotoxin**. Take care in handling acrylamide (wear gloves) and avoid breathing in acrylamide dust when weighing out.
2. Separating gel buffer: 1.5 *M* Tris-HCl, pH 8.8.
3. Stacking gel buffer: 0.5 *M* Tris-HCl, pH 6.8.
4. 10% Ammonium persulfate in water.
5. *N,N,N ,N* -tetramethylethylenediamine (TEMED).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

6. Sample buffer (5X). Mix the following:
   a. 15.5 mL of 1 *M* Tris-HCl pH 6.8;
   b. 2.5 mL of a 1% solution of bromophenol blue;
   c. 7 mL of water; and
   d. 25 mL of glycerol.

   Solid samples can be dissolved directly in IX sample buffer. Samples already in solution should be diluted accordingly with 5X sample buffer to give a solution that is 1X sample buffer. Do not use protein solutions that are in a strong buffer that is not near to pH 6.8 as it is important that the sample is at the correct pH. For these samples it will be necessary to dialyze against 1X sample buffer.
7. Electrophoresis buffer: Dissolve 3.0 g of Tris base and 14.4 g of glycine in water and adjust the volume to 1 L. The final pH should be 8.3.
8. Protein stain: 0.25 g Coomassie brilliant blue R250 (or PAGE blue 83), 125 mL methanol, 25 mL glacial acetic acid, and 100 mL water. Dissolve the dye in the methanol component first, then add the acid and water. Dye solubility is a problem if a different order is used. Filter the solution if you are concerned about dye solubility. For best results do not reuse the stain.
9. Destaining solution: 100 mL methanol, 100 mL glacial acetic acid, and 800 mL water.
10. A microsyringe for loading samples.

3. Method

1. Set up the gel cassette.
2. To prepare the separating gel (*see* **Note 2**) mix the following in a Buchner flask: 7.5 mL stock acrylamide solution, 7.5 mL separating gel buffer, 14.85 mL water, and 150 mL 10% ammonium persulfate.

   "Degas" this solution under vacuum for about 30 s. This degassing step is necessary to remove dissolved air from the solution, since oxygen can inhibit the polymerization step. Also, if the solution has not been degassed to some extent, bubbles can form in the gel during polymerization, which will ruin the gel. Bubble formation is more of a problem in the higher percentage gels where more heat is liberated during polymerization.
3. Add 15 µL of TEMED and gently swirl the flask to ensure even mixing. The addition of TEMED will initiate the polymerization reaction, and although it will take about 20 min for the gel to set, this time can vary depending on room temperature, so it is advisable to work fairly quickly at this stage.
4. Using a Pasteur (or larger) pipet, transfer the separating gel mixture to the gel cassette by running the solution carefully down one edge between the glass plates. Continue adding this solution until it reaches a position 1 cm from the bottom of the sample loading comb.
5. To ensure that the gel sets with a smooth surface, *very* carefully run distilled water down one edge into the cassette using a Pasteur pipet. Because of the great difference in density between the water and the gel solution, the water will

spread across the surface of the gel without serious mixing. Continue adding water until a layer about 2 mm exists on top of the gel solution.

6. The gel can now be left to set. When set, a very clear refractive index change can be seen between the polymerized gel and overlaying water.
7. While the separating gel is setting, prepare the following stacking gel solution. Mix the following quantities in a Buchner flask: 1.5 mL stock acrylamide solution, 3.0 mL stacking gel buffer, 7.4 mL water, and 100 µL 10% ammonium persulfate. Degas this solution as before.
8. When the separating gel has set, pour off the overlaying water. Add 15 µL of TEMED to the stacking gel solution and use some (2 mL) of this solution to wash the surface of the polymerized gel. Discard this wash, then add the stacking gel solution to the gel cassette until the solution reaches the cutaway edge of the gel plate. Place the well-forming comb into this solution and leave to set. This will take about 30 min. Refractive index changes around the comb indicate that the gel has set. It is useful at this stage to mark the positions of the bottoms of the wells on the glass plates with a marker pen.
9. Carefully remove the comb from the stacking gel, remove any spacer from the bottom of the gel cassette, and assemble the cassette in the electrophoresis tank. Fill the top reservoir with electrophoresis buffer ensuring that the buffer fully fills the sample loading wells, and look for any leaks from the top tank. If there are no leaks, fill the bottom tank with electrophoresis buffer, then tilt the apparatus to dispel any bubbles caught under the gel.
10. Samples can now be loaded onto the gel. Place the syringe needle through the buffer and locate it just above the bottom of the well. Slowly deliver the sample (5–20 µL) into the well. The dense sample solvent ensures that the sample settles to the bottom of the loading well. Continue in this way to fill all the wells with unknowns or standards, and record the samples loaded.
11. The power pack is now connected to the apparatus and a current of 20–25 mA passed through the gel (constant current) (*see* **Note 3**). Ensure that the electrodes are arranged so that the proteins are running to the anode (*see* **Note 4**). In the first few minutes the samples will be seen to concentrate as a sharp band as it moves through the stacking gel. (It is actually the bromophenol blue that one is observing, not the protein but, of course, the protein is stacking in the same way.) Continue electrophoresis until the bromophenol blue reaches the bottom of the gel. This will usually take about 3 h. Electrophoresis can now be stopped and the gel removed from the cassette. Remove the stacking gel and immerse the separating gel in stain solution, or proceed to step 13 if you wish to detect enzyme activity (*see* **Notes 5** and **6**).
12. Staining should be carried out, with shaking, for a minimum of 2 h and preferably overnight. When the stain is replaced with destain, stronger bands will be immediately apparent and weaker bands will appear as the gel destains. Destaining can be speeded up by using a foam bung, such as those used in microbiological flasks. Place the bung in the destain and squeeze it a few times to expel air bubbles and ensure the bung is fully wetted. The bung rapidly absorbs dye, thus speeding up the destaining process.

13. If proteins are to be detected by their biological activity, duplicate samples should be run. One set of samples should be stained for protein and the other set for activity. Most commonly one would be looking for enzyme activity in the gel. This is achieved by washing the gel in an appropriate enzyme substrate solution that results in a colored product appearing in the gel at the site of the enzyme activity (*see* **Note 7**).

4. Notes

1. The stock acrylamide used here is the same as used for SDS gels (*see* Chapter 21) and may already be availabe in your laboratory.
2. The system described here is for a 7.5% acrylamide gel, which was originally described for the separation of serum proteins ***(1)***. Since separation in this system depends on both the native charge on the protein and separation according to size owing to frictional drag as the proteins move through the gel, it is not possible to predict the electrophoretic behavior of a given protein the way that one can on an SDS gel, where separation is based on size alone. A 7.5% gel is a good starting point for unknown proteins. Proteins of mol wt >100,000 should be separated in 3–5% gels. Gels in the range 5–10% will separate proteins in the range 20,000–150,000, and 10–15% gels will separate proteins in the range 10,000–80,000. The separation of smaller polypeptides is described in Chapter 23. To alter the acrylamide concentration, adjust the volume of stock acrylamide solution in **Subheading 3., step 2** accordingly, and increase/decrease the water component to allow for the change in volume. For example, to make a 5% gel change the stock acrylamide to 5 mL and increase the water to 17.35 mL. The final volume is still 30 mL, so 5 mL of the 30% stock acrylamide solution has been diluted in 30 mL to give a 5% acrylamide solution.
3. Because one is separating native proteins, it is important that the gel does not heat up too much, since this could denature the protein in the gel. It is advisable therefore to run the gel in the cold room, or to circulate the buffer through a cooling coil in ice. (Many gel apparatus are designed such that the electrode buffer cools the gel plates.) If heating is thought to be a problem it is also worthwhile to try running the gel at a lower current for a longer time.
4. This separating gel system is run at pH 8.8. At this pH most proteins will have a negative charge and will run to the anode. However, it must be noted that any basic proteins will migrate in the opposite direction and will be lost from the gel. Basic proteins are best analyzed under acid conditions, as described in Chapters 27 and 28.
5. It is important to note that concentration in the stacking gel may cause aggregation and precipitation of proteins. Also, the pH of the stacking gel (pH

6.8) may affect the activity of the protein of interest. If this is thought to be a problem (e.g., the protein cannot be detected on the gel), prepare the gel without a stacking gel. Resolution of proteins will not be quite so good, but will be sufficient for most uses.

6. If the buffer system described here is unsuitable (e.g., the protein of interest does not electrophorese into the gel because it has the incorrect charge, or precipitates in the buffer, or the buffer is incompatible with your detection system) then one can try different buffer systems (without a stacking gel). A comprehensive list of alternative buffer systems has been published ***(2)***.
7. The most convenient substrates for detecting enzymes in gels are small molecules that freely diffuse into the gel and are converted by the enzyme to a colored orfluorescent product within the gel. However, for many enzymes such convenient substrates do not exist, and it is necessary to design a linked assay where one includes an enzyme together with the substrate such that the products of the enzymatic reaction of interest is converted to a detectable product by the enzyme included with the substrate. Such linked assays may require the use of up to two or three enzymes and substrates to produce a detectable product. In these cases the product is usually formed on the surface of the gel because the coupling enzymes cannot easily diffuse into the gel. In this case the zymogram technique is used where the substrate mix is added to a cooled (but not solidified) solution of agarose (1%) in the appropriate buffer. This is quickly poured over the solid gel where it quickly sets on the gel. The product of the enzyme assay is therefore formed at the gel–gel interface and does not get washed away. A number of review articles have been published which described methods for detecting enzymes in gels ***(3–7)***. A very useful list also appears as an appendix in **ref. *8***.

SDS Polyacrylamide Gel Electrophoresis of Proteins

John M. Walker

1. Introduction

SDS-PAGE is the most widely used method for qualitatively analyzing protein mixtures. It is particularly useful for monitoring protein purification, and because the method is based on the separation of proteins according to size, the method can also be used to determine the relative molecular mass of proteins (*see* **Note 14**).

1.1. Formation of Polyacrylamide Gels

Crosslinked polyacrylamide gels are formed from the polymerization of acrylamide monomer in the presence of smaller amounts of *N,N′* -methylene-*bis*-acrylamide (normally referred to as "*bis*-acrylamide") (**Fig. 1**). Note that *bis*-acrylamide is essentially two acrylamide molecules linked by a methylene group and is used as a crosslinking agent. Acrylamide monomer is polymerized in a head-to-tail fashion into long chains, and occasionally a *bis*-acrylamide molecule is built into the growing chain, thus introducing a second site for chain extension. Proceeding in this way, a crosslinked matrix of fairly well-defined structure is formed (**Fig. 1**). The polymerization of acrylamide is an example of free-radical catalysis, and is initiated by the addition of ammonium persulfate and the base *N,N,N′,N′*-tetramethylenediamine (TEMED). TEMED catalyzes the decomposition of the persulfate ion to give a free radical (i.e., a molecule with an unpaired electron):

$$S_2O_8^{2-} + e^- \rightarrow SO_4^{2-} + SO_4^{-\bullet} \quad (1)$$

If this free radical is represented as R$^\bullet$ (where the dot represents an unpaired electron) and M as an acrylamide monomer molecule, then the polymerization can be represented as follows:

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

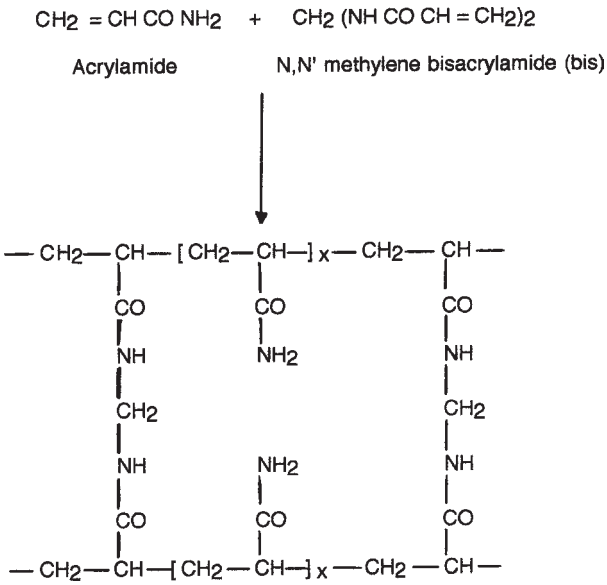

Fig. 1. Polymerization of acrylamide.

$$\begin{aligned} R^{\bullet} + M &\rightarrow RM^{\bullet} \\ RM^{\bullet} + M &\rightarrow RMM^{\bullet} \\ RMM^{\bullet} + M &\rightarrow RMMM^{\bullet}, \text{ and so forth} \end{aligned} \qquad (2)$$

In this way, long chains of acrylamide are built up, being crosslinked by the introduction of the occasional *bis*-acrylamide molecule into the growing chain. Oxygen "mops up" free radicals, and therefore the gel mixture is normally degassed (the solutions are briefly placed under vacuum to remove loosely dissolved oxygen) prior to addition of the catalyst.

1.2. The Use of Stacking Gels

For both SDS and buffer gels samples may be applied directly to the top of the gel in which protein separation is to occur (the separating gel). However, in these cases, the sharpness of the protein bands produced in the gel is limited by the size (volume) of the sample applied to the gel. Basically the separated bands will be as broad (or broader, owing to diffusion) as the sample band applied to the gel. For some work, this may be acceptable, but most workers require better resolution than this. This can be achieved by polymerizing a short stacking gel on top of the separating gel. The purpose of this stacking gel is to concentrate the protein sample into a sharp band before it enters the main separating gel,

thus giving sharper protein bands in the separating gel. This modification allows relatively large sample volumes to be applied to the gel without any loss of resolution. The stacking gel has a very large pore size (4% acrylamide) which allows the proteins to move freely and concentrate, or stack under the effect of the electric field. Sample concentration is produced by isotachophoresis of the sample in the stacking gel. The band-sharpening effect (isotachophoresis) relies on the fact that the negatively charged glycinate ions (in the reservoir buffer) have a lower electrophoretic mobility than the protein–SDS complexes. which in turn, have lower mobility than the Cl^- ions if they are in a region of higher field strength. Field strength is inversely proportional to conductivity, which is proportional to concentration. The result is that the three species of interest adjust their concentrations so that $[Cl^-] > [\text{protein-SDS}] > [\text{glycinate}]$. There are only a small quantity of protein–SDS complexes, so they concentrate in a very tight band between the glycinate and Cl^- ion boundaries. Once the glycinate reaches the separating gel, it becomes more fully ionized in the higher pH environment and its mobility increases. (The pH of the stacking gel is 6.8 and that of the separating gel is 8.8.) Thus, the interface between glycinate and the Cl^- ions leaves behind the protein–SDS complexes, which are left to electrophorese at their own rates. A more detailed description of the theory of isotachophoresis and electrophoresis generally is given in **ref. *1***.

1.3. SDS-PAGE

Samples to be run on SDS-PAGE are first boiled for 5 min in sample buffer containing β-mercaptoethanol and SDS. The mercaptoethanol reduces any disulfide bridges present that are holding together the protein tertiary structure. SDS (CH_3-$[CH_2]_{10}$ - $CH_2OSO_{3^-}Na^+$) is an anionic detergent and binds strongly to, and denatures, the protein. Each protein in the mixture is therefore fully denatured by this treatment and opens up into a rod-shaped structure with a series of negatively charged SDS molecules along the polypeptide chain. On average, one SDS molecule binds for every two amino acid residues. The original native charge on the molecule is therefore completely swamped by the SDS molecules. The sample buffer also contains an ionizable tracking dye usually bromophenol blue that allows the electrophoretic run to be monitored, and sucrose or glycerol which gives the sample solution density, thus allowing the sample to settle easily through the electrophoresis buffer to the bottom when injected into the loading well. When the main separating gel has been poured between the glass plates and allowed to set, a shorter stacking gel is poured on top of the separating gel, and it is into this gel that the wells are formed and the proteins loaded. Once all samples are loaded, a current is passed through the gel. Once the protein samples have passed through the stacking gel and have entered the separating gel, the negatively charged protein–SDS complexes continue to move toward the

anode, and because they have the same charge per unit length they travel into the separating gel under the applied electric field with the same mobility. However, as they pass through the separating gel the proteins separate, owing to the molecular sieving properties of the gel. Quite simply, the smaller the protein, the more easily it can pass through the pores of the gel, whereas large proteins are successively retarded by frictional resistance owing to the sieving effect of the gel. Being a small molecule, the bromophenol blue dye is totally unretarded and therefore indicates the electrophoresis front. When the dye reaches the bottom of the gel the current is turned off and the gel is removed from between the glass plates, shaken in an appropriate stain solution (usually Coomassie brilliant blue) for a few hours, and then washed in destain solution overnight. The destain solution removes unbound background dye from the gel, leaving stained proteins visible as blue bands on a clear background. A typical large format gel would take about 1 h to prepare and set, 3 h to run at 30 mA, and have a staining time of 2–3 h with an overnight destain. Minigels (e.g., Bio-Rad minigel) run at 200 V. Constant voltage can run in about 40 min, and require only 1 h staining. Most bands can be seen within 1 h of destaining. Vertical slab gels are invariably run since this allows up to 20 different samples to be loaded onto a single gel.

2. Materials

1. Stock acrylamide solution: 30% acrylamide, 0.8% *bis*-acrylamide. Filter through Whatman No. 1 filter paper and store at 4°C (*see* **Note 1**).
2. Buffers:
   a. 1.875 *M* Tris-HCl, pH 8.8.
   b. 0.6 *M* Tris-HCl, pH 6.8.
3. 10% Ammonium persulfate. Make fresh.
4. 10% SDS (*see* **Note 2**).
5. TEMED.
6. Electrophoresis buffer: Tris (12 g), glycine (57.6 g), and SDS (2.0 g). Make up to 2 L with water. No pH adjustment is necessary.
7. Sample buffer (*see* **Notes 3** and **4**):

0.6 *M* Tris-HCl, pH 6.8	5.0 mL
SDS	0.5 g
Sucrose	5.0 g
β -Mercaptoethanol	0.25 mL
Bromophenol blue, 0.5% stock	5.0 mL

   Make up to 50 mL with distilled water.
8. Protein stain: 0.1% Coomassie brilliant blue R250 in 50% methanol, 10% glacial acetic acid. Dissolve the dye in the methanol and water component first, and then add the acetic acid. Filter the final solution through Whatman No. 1 filter paper if necessary.

9. Destain: 10% methanol, 7% glacial acetic acid.
10. Microsyringe for loading samples. Micropipet tips that are drawn out to give a fine tip are also commercially available.

3. Method

The system of buffers used in the gel system described below is that of Laemmli *(2)*.

1. Samples to be run are first denatured in sample buffer by heating to 95–100°C for 5 min (*see* **Note 3**).
2. Clean the internal surfaces of the gel plates with detergent or methylated spirits, dry, then join the gel plates together to form the cassette, and clamp it in a vertical position. The exact manner of forming the cassette will depend on the type of design being used.
3. Mix the following in a 250-mL Buchner flask (*see* **Note 5**):

	For 15% gels	For 10% gels
1.875 *M* Tris-HCl, pH 8.8	8.0 mL	8.0 mL
Water	11.4 mL	18.1 mL
Stock acrylamide	20.0 mL	13.3 mL
10% SDS	0.4 mL	0.4 mL
Ammonium persulfate (10%)	0.2 mL	0.2 mL

4. "Degas" this solution under vacuum for about 30 s. Some frothing will be observed, and one should not worry if some of the froth is lost down the vacuum tube: you are only losing a very small amount of liquid (*see* **Note 6**).
5. Add 14 µL of TEMED, and gently swirl the flask to ensure even mixing. The addition of TEMED will initiate the polymerization reaction and although it will take about 15 min for the gel to set, this time can vary depending on room temperature, so it is advisable to work fairly quickly at this stage.
6. Using a Pasteur (or larger) pipet transfer this separating gel mixture to the gel cassette by running the solution carefully down one edge between the glass plates. Continue adding this solution until it reaches a position 1 cm from the bottom of the comb that will form the loading wells. Once this is completed, you will find excess gel solution remaining in your flask. Dispose of this in an appropriate waste container **not** down the sink.
7. To ensure that the gel sets with a smooth surface **very carefully** run distilled water down one edge into the cassette using a Pasteur pipet. Because of the great difference in density between the water and the gel solution the water will spread across the surface of the gel without serious mixing. Continue adding water until a layer of about 2 mm exists on top of the gel solution (*see* **Notes 7** and **8**).
8. The gel can now be left to set. As the gel sets, heat is evolved and can be detected by carefully touching the gel plates. When set, a very clear refractive index change can be seen between the polymerized gel and overlaying water.

9. While the separating gel is setting prepare the following stacking gel (4°C) solution. Mix the following in a 100-mL Buchner flask (*see* **Notes 8** and **9**):

0.6 *M* Tris-HCl, pH 6.8	1.0 mL
Stock acrylamide	1.35 mL
Water	7.5 mL
10% SDS	0.1 mL
Ammonium persulfate (10%)	0.05 mL

   Degas this solution as before.
10. When the separating gel has set, pour off the overlaying water. Add 14 µL of TEMED to the stacking gel solution and use some (~2 mL) of this solution to wash the surface of the polymerized gel. Discard this wash, and then add the stacking gel solution to the gel cassette until the solution reaches the cutaway edge of the gel plate. Place the well-forming comb into this solution, and leave to set. This will take about 20 min. Refractive index changes around the comb indicate that the gel has set. It is useful at this stage to mark the positions of the bottoms of the wells on the glass plates with a marker pen to facilitate loading of the samples (*see* also **Note 9**).
11. Carefully remove the comb from the stacking gel, and then rinse out any non-polymerized acrylamide solution from the wells using electrophoresis buffer. Remove any spacer from the bottom of the gel cassette, and assemble the cassette in the electrophoresis tank. Fill the top reservoir with electrophoresis buffer, and look for any leaks from the top tank. If there are no leaks fill the bottom tank with electrophoresis buffer, and then tilt the apparatus to dispel any bubbles caught under the gel.
12. Samples can now be loaded onto the gel. Place the syringe needle through the buffer and locate it just above the bottom of the well. Slowly deliver the sample into the well. Five- to 10-µL samples are appropriate for most gels. The dense sample buffer ensures that the sample settles to the bottom of the loading well (*see* **Note 10**). Continue in this way to fill all the wells with unknowns or standards, and record the samples loaded.
13. Connect the power pack to the apparatus, and pass a current of 30 mA through the gel (constant current) for large format gels, or 200 V (constant voltage) for minigels (Bio-Rad). Ensure your electrodes have correct polarity: all proteins will travel to the anode (+). In the first few minutes, the samples will be seen to concentrate as a sharp band as it moves through the stacking gel. (It is actually the bromophenol blue that one is observing not the protein, but of course the protein is stacking in the same way.) Continue electrophoresis until the bromophenol blue reaches the bottom of the gel. This will take 2.5–3.0 h for large format gels (16 cm × 16 cm) and about 40 min for minigels (10 cm × 7 cm) (*see* **Note 11**).
14. Dismantle the gel apparatus, pry open the gel plates, remove the gel, discard the stacking gel, and place the separating gel in stain solution.
15. Staining should be carried out with shaking, for a minimum of 2 h. When the stain is replaced with destain, stronger bands will be immediately apparent, and weaker bands will appear as the gel destains (*see* **Notes 12** and **13**).

4. Notes

1. Acrylamide is a potential neurotoxin and should be treated with great care. Its effects are cumulative, and therefore, regular users are at greatest risk. In particular, take care when weighing out acrylamide. Do this in a fume hood, and wear an appropriate face mask.
2. SDS come out of solution at low temperature, and this can even occur in a relatively cold laboratory. If this happens, simply warm up the bottle in a water bath. Store at room temperature.
3. Solid samples can be dissolved directly in sample buffer. Pure proteins or simple mixtures should be dissolved at 1–0.5 mg/mL. For more complex samples suitable concentrations must be determined by trial and error. For samples already in solution dilute them with an equal volume of double-strength sample buffer. Do not use protein solutions that are in a strong buffer, that is, not near pH 6.5, since it is important that the sample be at the correct pH. For these samples, it will be necessary to dialyze them first. Should the sample solvent turn from blue to yellow, this is a clear indication that your sample is acidic.
4. The β-mercaptoethanol is essential for disrupting disulfide bridges in proteins. However, exposure to oxygen in the air means that the reducing power of β-mercaptoethanol in the sample buffer decreases with time. Every couple of weeks, therefore, mercaptoethanol should be added to the stock solution or the solution remade. Similarly protein samples that have been prepared in sample buffer and stored frozen should, before being rerun at a later date, have further mercaptoethanol added.
5. Typically, the separating gel used by most workers is a 15% polyacrylamide gel. This give a gel of a certain pore size in which proteins of relative molecular mass (M_r) 10,000 move through the gel relatively unhindered, whereas proteins of 100,000 can only just enter the pores of this gel. Gels of 15% polyacrylamide are therefore useful for separating proteins in the range of 100,000–10,000. However, a protein of 150,000 for example, would be unable to enter a 15% gel. In this case, a larger-pored gel (e.g., a 10% or even 7.5% gel) would be used so that the protein could now enter the gel, and be stained and identified. It is obvious, therefore, that the choice of gel to be used depends on the size of the protein being studied. If proteins covering a wide range of mol-wt values need to be separated, then the use of a gradient gel is more appropriate (*see* Chapter 32).
6. Degassing helps prevent oxygen in the solution from "mopping up" free radicals and inhibiting polymerization although this problem could be overcome by the alternative approach of increasing the concentration of catalyst. However, the polymerization process is an exothermic one. For 15% gels, the heat liberated can result in the formation of small air bubbles

in the gel (this is not usually a problem for gels of 10% or less where much less heat is liberated). It is advisable to carry out degassing as a matter of routine.

7. An alternative approach is to add a water-immiscible organic solvent, such as isobutanol, to the top of the gel. Less caution is obviously needed when adding this, although if using this approach, this step should be carried out in a fume cupboard, not in the open laboratory.
8. To save time some workers prefer to add the stacking gel solution directly and carefully to the top of the separating gel, i.e., the overlaying step (**step 7**) is omitted, the stacking gel solution itself providing the role of the overlaying solution.
9. Some workers include a small amount of bromophenol blue in this gel mix. This give a stacking gel that has a pale blue color, thus allowing the loading wells to be easily identified.
10. Even if the sample is loaded with too much vigor, such that it mixes extensively with the buffer in the well, this is not a problem, since the stacking gel system will still concentrate the sample.
11. When analyzing a sample for the first time, it is sensible to stop the run when the dye reaches the bottom of the gel, because there may be low mol-wt proteins that are running close to the dye, and these would be lost if electrophoresis was continued after the dye had run off the end of the gel. However, often one will find that the proteins being separated are only in the top two-thirds of the gel. In this case, in future runs, the dye would be run off the bottom of the gel, and electrophoresis carried out for a further 30 min to 1 h to allow proteins to separate across the full length of the gel thus increasing the separation of bands.
12. Normally, destain solution needs to be replaced at regular intervals since a simple equilibrium is quickly set up between the concentration of stain in the gel and destain solution, after which no further destaining takes place. To speed up this process and also save on destain solution, it is convenient to place some solid material in with the destain that will absorb the Coomassie dye as it elutes from the gel. We use a foam bung such as that used in culture flasks (ensure it is well wetted by expelling all air in the bung by squeezing it many times in the destain solution), although many other materials can be used (e.g., polystyrene packaging foam).
13. It is generally accepted that a very faint protein band detected by Coomassie brilliant blue, is equivalent to about 0.1 µg (100 ng) of protein. Such sensitivity is suitable for many people's work. However if no protein bands are observed or greater staining is required, then silver staining (Chapter 48) can be further carried out on the gel.

14. Because the principle of this technique is the separation of proteins based on size differences, by running calibration proteins of known molecular weight on the same gel run as your unknown protein, the molecular weight of the unknown protein can be determined. For most proteins a plot of $\log_{10}$ molecular mass vs relative mobility provides a straight line graph, although one must be aware that for any given gel concentration this relationship is only linear over a limited range of molecular masses. As an approximate guide, using the system described here, the linear relationship is true over the following ranges: 15% acrylamide, 10,000–50,000; 10% acrylamide 15,000–70,000; 5% acrylamide 60,000–200,000. It should be stressed that this relationship only holds true for proteins that bind SDS in a constant weight ratio. This is true of many proteins but some proteins for example, highly basic proteins, may run differently than would be expected on the basis of their known molecular weight. In the case of the histones, which are highly basic proteins, they migrate more slowly than expected, presumably because of a reduced overall negative charge on the protein owing to their high proportion of positively-charged amino acids. Glycoproteins also tend to run anomalously presumably because the SDS only binds to the polypeptide part of the molecule.
    To determine the molecular weight of an unknown protein the relative mobilities (*Rf*) of the standard proteins are determined and a graph of log molecular weight vs *Rf* plotted.

$$Rf = (\text{distance migrated by proteins/distance migrated by dye}) \quad (3)$$

    Mixtures of standard mol-wt markers for use on SDS gels are available from a range of suppliers. The *Rf* of the unknown protein is then determined and the logMW (and hence molecular weight) determined from the graph. A more detailed description of protein mol-wt determination on SDS gels is described in **refs. *1*** and ***3***.

Gradient SDS Polyacrylamide Gel Electrophoresis of Proteins

John M. Walker

1. Introduction

The preparation of fixed-concentration polyacrylamide gels has been described in Chapters 20 and 21. However, the use of polyacrylamide gels that have a gradient of increasing acrylamide concentration (and hence decreasing pore size) can sometimes have advantages over fixed-concentration acrylamide gels. During electrophoresis in gradient gels, proteins migrate until the decreasing pore size impedes further progress. Once the "pore limit" is reached, the protein banding pattern does not change appreciably with time, although migration does not cease completely *(**1**)*. There are two main advantages of gradient gels over linear gels.

First, a much greater range of protein M_r values can be separated than on a fixed-percentage gel. In a complex mixture, very low-mol-wt proteins travel freely through the gel to begin with, and start to resolve when they reach the smaller pore size toward the lower part of the gel. Much larger proteins, on the other hand, can still enter the gel but start to separate immediately owing to the sieving effect of the gel. The second advantage of gradient gels is that proteins with very similar M_r values may be resolved, which otherwise cannot resolve in fixed percentage gels. As each protein moves through the gel, the pore size become smaller until the protein reaches its pore size limit. The pore size in the gel is now too small to allow passage of the protein, and the protein sample stacks up at this point as a sharp band. A similar-sized protein, but with slightly lower M_r, will be able to travel a little further through the gel before reaching its pore size limit, at which point it will form a sharp band. These two proteins, of slightly different M_r values, therefore separate as two, close, sharp bands.

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

The usual limits of gradient gels are 3–30% acrylamide in linear or concave gradients. The choice of range will of course depend on the size of proteins being fractionated. The system described here is for a 5–20% linear gradient using SDS polyacrylamide gel electrophoresis. The theory of SDS polyacrylamide gel electrophoresis has been decribed in Chapter 21.

2. Materials

1. Stock acrylamide solution: 30% acrylamide, 0.8% *bis*-acrylamide. Dissolve 75 g of acrylamide and 2.0 g of *N,N′* -methylene *bis*-acrylamide in about 150 mL of water. Filter and make the volume to 250 mL. Store at 4°C. The solution is stable for months.
2. Buffers:
   a. 1.875 *M* Tris-HCl, pH 8.8.
   b. 0.6 *M* Tris-HCl, pH 6.8.
   Store at 4°C.
3. Ammonium persulfate solution (10% [w/v]). Make fresh as required.
4. SDS solution (10% [w/v]). Stable at room temperature. In cold conditions, the SDS can come out of solution, but may be redissolved by warming.
5. *N,N,N′ ,N′* -Tetramethylene diamine (TEMED).
6. Gradient forming apparatus (*see* **Fig. 1**). Reservoirs with dimensions of 2.5 cm id and 5.0 cm height are suitable. The two reservoirs of the gradient former should be linked by flexible tubing to allow them to be moved independently. This is necessary since although equal volumes are placed in each reservoir, the solutions differ in their densities and the relative positions of A and B have to be adjusted to balance the two solutions when the connecting clamp is opened (*see* **Note 3**).

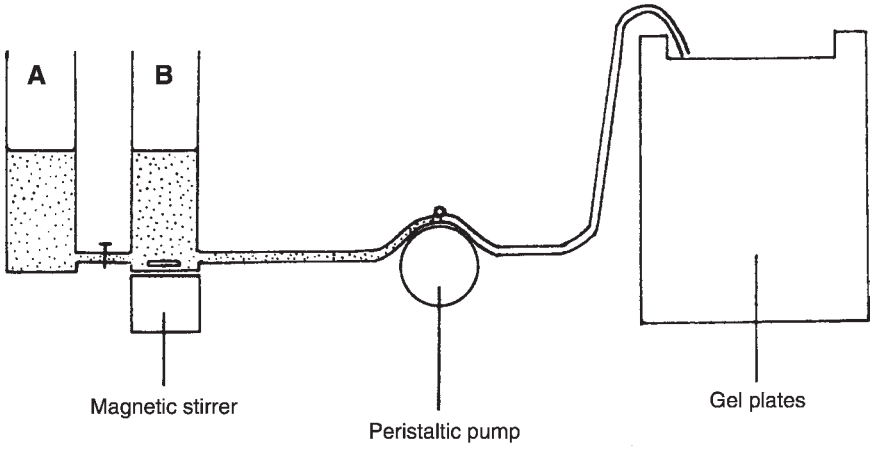

Fig. 1. Gradient forming apparatus.

3. Method

1. Prepare the following solutions:

	Solution A, mL	Solution B, mL
1.875 *M* Tris-HCl, pH 8.8	3.0	3.0
Water	9.3	0.6
Stock acrylamide, 30%	2.5	10.0
10% SDS	0.15	0.15
Ammonium persulfate (10%)	0.05	0.05
Sucrose	—	2.2 g (equivalent to 1.2 mL volume)

2. Degas each solution under vacuum for about 30 s and then, when you are ready to form the gradient, add TEMED (12 µL) to each solution.
3. Once the TEMED is added and mixed in, pour solutions A and B into the appropriate reservoirs (*see* **Fig. 1**.)
4. *With the stirrer stirring,* fractionally open the connection between A and B and adjust the relative heights of A and B such that there is no flow of liquid between the two reservoirs (easily seen because of the difference in densities). Do not worry if there is some mixing between reservoirs—this is inevitable.
5. When the levels are balanced, completely open the connection between A and B, turn the pump on, and fill the gel apparatus by running the gel solution down one edge of the gel slab. Surprisingly, very little mixing within the gradient occurs using this method. A pump speed of about 5 mL/min is suitable. If a pump is not available, the gradient may be run into the gel under gravity.
6. When the level of the gel reaches about 3 cm from the top of the gel slab, connect the pump to distilled water, reduce pump speed, and overlay the gel with 2–3 mm of water.
7. The gradient gel is now left to set for 30 min. Remember to rinse out the gradient former before the remaining gel solution sets in it.
8. When the separating gel has set, prepare a stacking gel by mixing the following:
   a. 1.0 mL 0.6 *M* Tris-HCl, pH 6.8;
   b. 1.35 mL Stock acrylamide;
   c. 7.5 mL Water;
   d. 0.1 mL 10% SDS;
   e. 0.05 mL Ammonium persulfate (10%).
9. Degas this mixture under vacuum for 30 s and then add TEMED (12 µL).
10. Pour off the water overlayering the gel and wash the gel surface with about 2 mL of stacking gel solution and then discard this solution.
11. The gel slab is now filled to the top of the plates with stacking gel solution and the well-forming comb placed in position (*see* Chapter 21).
12. When the stacking gel has set (~15 min), carefully remove the comb. The gel is now ready for running. The conditions of running and sample preparation are exactly as described for SDS gel electrophoresis in Chapter 21.

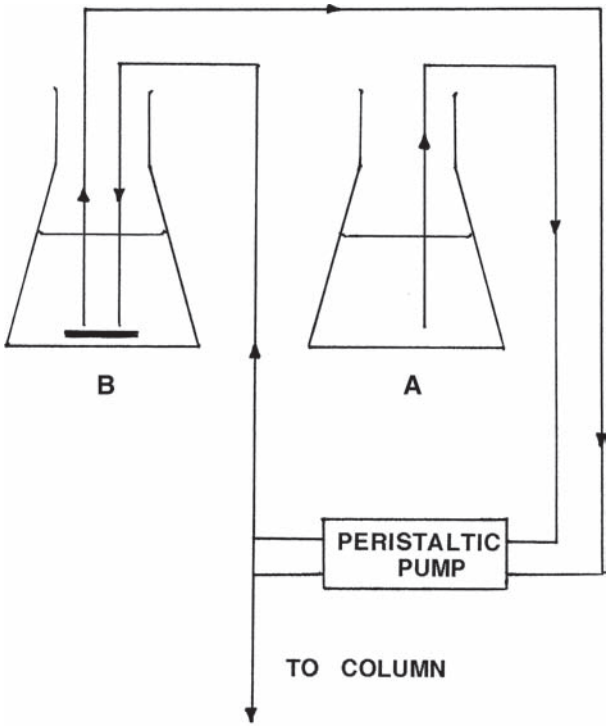

Fig. 2. Diagrammatic representation of a method for producing a gradient using a two-channel peristaltic pump. Reservoir B has the high percentage acrylamide concentration, reservoir A the lower.

4. Notes

1. The total volume of liquid in reservoirs A and B should be chosen such that it approximates to the volume available between the gel plates. However, allowance must be made for some liquid remaining in the reservoirs and tubing.
2. As well as a gradient in acrylamide concentration, a density gradient of sucrose (glycerol could also be used) is included to minimize mixing by convectional disturbances caused by heat evolved during polymerization. Some workers avoid this problem by also including a gradient of ammienium persulfate to ensure that polymerization occurs first at the top of the gel, progressing to the bottom. However, we have not found this to be necessary in our laboratory.

3. The production of a linear gradient has been described in this chapter. However, the same gradient mixed can be used to produce a concave (exponential) gradient. This concave gradient provides a very shallow gradient in the top half of the gel such that the percentage of acrylamide only varies from about 5–7% over the first half of the gel. The gradient then increases much more rapidly from 7–20% over the next half of the gel. The shallow part of the gradient allows high-mol-wt proteins of similar size to sufficiently resolve while at the same time still allowing lower mol-wt proteins to separate lower down the gradient. To produce a concave gradient, place 7.5 mL of solution B in reservoir B, then tightly stopper this reservoir with a rubber bung. Equalize the pressure in the chamber by briefly inserting a syringe needle through the bung. Now place 22.5 mL of solution A in reservoir A, open the connector between the two chambers, and commence pouring the gel. The volume of reservoir B will be seen to remain constant as liquid for reservoir A is drawn into this reservoir and diluted.
4. We have described the production of a linear gradient using a purpose built gradient mixer. However, it is not necessary to purchase this since the simple arrangement, shown in **Fig. 2** using just flasks or beakers, a stirrer, and a dual channel peristaltic pump, can just as easily be used.

SDS-Polyacrylamide Gel Electrophoresis of Peptides

Ralph C. Judd

1. Introduction

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) has proven to be among the most useful tools yet developed in the area of molecular biology. The discontinuous buffer system, first described by Laemmli ***(1),*** has made it possible to separate, visualize, and compare readily the component parts of complex mixtures of molecules (e.g., tissues, cells). SDS-PAGE separation of proteins and peptides makes it possible to quantify the amount of a particular protein/peptide in a sample, obtain fairly reliable molecular mass information, and, by combining SDS-PAGE with immunoelectroblotting, evaluate the antigenicity of proteins and peptides. SDS-PAGE is both a powerful separation system and a reliable preparative purification technique *(**2***; and *see* Chapter 21*)*.

Parameters influencing the resolution of proteins or peptides separated by SDS-PAGE include the ratio of acrylamide to crosslinker (*bis*-acrylamide), the percentage of acrylamide/crosslinker used to form the stacking and separation gels, the pH of (and the components in) the stacking and separation buffers, and the method of sample preparation. Systems employing glycine in the running buffers (e.g., Laemmli ***[1]***, Dreyfuss et al. ***[3]***) can resolve proteins ranging in molecular mass from over 200,000 Daltons (200 kDa) down to about 3 kDa. Separation of proteins and peptides below 3 kDa necessitates slightly different procedures to obtain reliable molecular masses and to prevent band broadening. Further, the increased use of SDS-PAGE to purify proteins and peptides for N-terminal sequence analysis demands that glycine, which interferes significantly with automated sequence technology, be replaced with noninterfering buffer components.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

This chapter describes a modification of the tricine gel system of Schagger and von Jagow ***(4)*** by which peptides as small as 500 Daltons can be separated. This makes it possible to use SDS-PAGE peptide mapping (*see* Chapter 104); epitope mapping ***(5)***, and protein and peptide separation for N-terminal sequence analyses ***(6)*** when extremely small peptide fragments are to be studied. Since all forms of SDS-PAGE are denaturing, they are unsuitable for separation of proteins or peptides to be used in functional analyses (e.g., enzymes, receptors).

2. Materials

2.1. Equipment

1. SDS-PAGE gel apparatus.
2. Power pack.
3. Blotting apparatus.

2.2. Reagents

1. Separating/spacer gel acrylamide (1X crosslinker): 48 g acrylamide, 1.5 g *N,N′* -methylene-*bis*-acrylamide. Bring to 100 mL, and then filter through qualitative paper to remove cloudiness (*see* **Note 1**).
2. Separating gel acrylamide (2X crosslinker): 48 g acrylamide, 3 g *N,N′* -methylenebis-acrylamide. Bring to 100 mL, and then filter through qualitative paper to remove cloudiness (*see* **Note 2**).
3. Stacking gel acrylamide: 30 g acrylamide, 0.8 g *N,N′* -methylene-*bis*-acrylamide. Bring to 100 mL, and then filter through qualitative paper to remove cloudiness.
4. Separating/spacer gel buffer: 3 *M* Tris base, 0.3% sodium dodecyl sulfate (*see* **Note 3**). Bring to pH 8.9 with HCl.
5. Stacking gel buffer: 1 *M* Tris-HCl, pH 6.8.
6. Cathode (top) running buffer (10X stock): 1 *M* Tris base, 1 *M* tricine, 1% SDS (*see* **Note 3**). Dilute 1:10 immediately before use. Do not adjust pH; it will be about 8.25.
7. Anode (bottom) buffer (10X stock): 2 *M* Tris base. Bring to pH 8.9 with HCl. Dilute 1:10 immediately before use.
8. 0.2 *M* tetrasodium EDTA.
9. 10% ammonium persulfate (make fresh as required).
10. TEMED.
11. Glycerol.
12. Fixer/destainer: 25% isopropanol, 7% glacial acetic acid in dH_2O (v/v/v).
13. 1% Coomassie brilliant blue (CBB) (w/v) in fixer/destainer.
14. Sample solubilization buffer: 2 mL 10% SDS (w/v) in dH_2O, 1.0 mL glycerol, 0.625 mL 1 *M* Tris-HCl, pH 6.8, 6 mL dH_2O, bromphenol blue to color.
15. Dithiothreitol.
16. 2% Agarose.

17. Molecular-mass markers, e.g., low-mol-wt kit (Bio-Rad, Hercules, CA), or equivalent, and peptide molecular-mass markers (Pharmacia Inc., Piscataway, NJ), or equivalent.
18. PVDF (nylon) membranes.
19. Methanol.
20. Blotting transfer buffer: 20 m*M* phosphate buffer, pH 8.0: 94.7 mL 0.2 *M* Na_2HPO_4 stock, 5.3 mL 0.2 *M* NaH_2PO_4 stock in 900 mL H_2O.
21. Filter paper for blotting (Whatman No. 1), or equivalent.
22. Distilled water (dH_2O).

2.3. Gel Recipes

2.3.1. Separating Gel Recipe

Add reagents in order given (*see* **Note 4**): 6.7 mL water, 10 mL separating/spacer gel buffer, 10 mL separating/spacer gel acrylamide (1X or 2X crosslinker), 3.2 mL glycerol, 10 µL TEMED, 100 µL 10% ammonium persulfate.

2.3.2. Spacer Gel Recipe

Add reagents in order given (*see* **Note 4**): 6.9 mL water, 5.0 mL separating/spacer gel buffer, 3.0 mL separating/spacer gel acrylamide (1X crosslinker only), 5 µL TEMED, 50 µL 10% ammonium persulfate.

2.3.3. Stacking Gel Recipe

Add reagents in order given (*see* **Note 4**): 10.3 mL water, 1.9 mL stacking gel buffer, 2.5 mL stacking gel acrylamide, 150 µL EDTA, 7.5 µL TEMED, 150 µL 10% ammonium persulfate.

3. Methods

3.1. Sample Solubilization

1. Boil samples in sample solubilization buffer for 10–30 min. Solubilize sample at 1 mg/mL and run 1–2 µL/lane (1–2 µg/lane) (*see* **Note 5**). For sequence analysis, as much sample as is practical should be separated.

3.2. Gel Preparation/Electrophoresis

1. Assemble the gel apparatus (*see* **Note 6**). Make two marks on the front plate to identify top of separating gel and top of spacer gel (*see* **Note 7**). Assuming a well depth of 12 mm, the top of the separating gel should be 3.5 cm down from the top of the back plate, and the spacer gel should be 2 cm down from the top of the back plate, leaving a stacking gel of 8 mm (*see* **Note 8**).
2. Combine the reagents to make the separating gel, mix gently, and pipet the solution between the plates to lowest mark on the plate. Overlay the gel solution with

2 mL of dH_2O by gently running the dH_2O down the center of the inside of the front plate. Allow the gel to polymerize for about 20 min. When polymerized, the water–gel interface will be obvious.

3. Pour off the water, and dry between the plates with filter paper. Do not touch the surface of the separating gel with the paper. Combine the reagents to make the spacer gel, mix gently, and pipet the solution between the plates to second mark on the plate. Overlay the solution with 2 mL of dH_2O by gently running the dH_2O down the center of the inside of the front plate. Allow the gel to polymerize for about 20 min. When polymerized, the water–gel interface will be obvious.
4. Pour off the water, and dry between the plates with filter paper. Do not touch the surface of spacer gel with the paper. Combine the reagents to make the stacking gel and mix gently. Place the well-forming comb between the plates, leaving one end slightly higher than the other. Slowly add the stacking gel solution at the raised end (this allows air bubbles to be pushed up and out from under the comb teeth). When the solution reaches the top of the back plate, gently push the comb all the way down. Check to be sure that no air pockets are trapped beneath the comb. Allow the gel to polymerize for about 20 min.
5. When the stacking gel has polymerized, carefully remove the comb. Straighten any wells that might be crooked with a straightened metal paper clip. Remove the acrylamide at each edge to the depth of the wells. This helps prevent "smiling" of the samples at the edge of the gel. Seal the edges of the gel with 2% agarose.
6. Add freshly diluted cathode running buffer to the top chamber of the gel apparatus until it is 5–10 mm above the top of the gel. Squirt running buffer into each well with a Pasteur pipet to flush out any unpolymerized acrylamide. Check the lower chamber to ensure that no cathode running buffer is leaking from the top chamber, and then fill the bottom chamber with anode buffer. Remove any air bubbles from the under edge of the gel with a benttip Pasteur pipet. The gel is now ready for sample loading.
7. After loading the samples and the molecular-mass markers, connect leads from the power pack to the gel apparatus (the negative lead goes on the top, and the positive lead goes on the bottom). Gels can be run on constant current, constant voltage, or constant power settings. When using the constant current setting, run the gel at 50 mA. The voltage will be between 50 and 100 V at the beginning, and will slowly increase during the run. For a constant voltage setting, begin the electrophoresis at 50 mA. As the run progresses, the amperage will decrease, so adjust the amperage to 50 mA several times during the run or the electrophoresis will be very slow. If running on constant power, set between 5 and 7 W. Voltage and current will vary to maintain the wattage setting. Each system varies, so empirical information should be used to modify the electrophoresis conditions so that electrophoresis is completed in about 4 h (*see* **Note 9**).
8. When the dye front reaches the bottom of the gel, turn off the power, disassemble the gel apparatus, and place the gel in 200–300 mL of fixer/destainer. Gently shake for 16 h (*see* **Note 10**). Pour off spent fixer/destainer, and add CBB. Gently shake for 30 min. Destain the gel in several changes of fixer/destainer until the background is almost clear. Then place the gel in dH_2O, and gently mix until

the background is completely clear. The peptide bands will become a deep purple-blue. The gel can now be photographed or dried. To store the gel wet, soak the gel in 7% glacial acetic acid for 1 h, and seal in a plastic bag.

Figure 1 demonstrates the molecular mass range of separation of a 1X crosslinker tricine gel. Whole-cell (WC) lysates and 1X and 2X purified (*see* Chapter 104) 44 kDa proteins of *Neisseria gonorrhoeae*, Bio-Rad low-mol-wt markers (mw), and Pharmacia peptide markers (pep mw) were separated and stained with CBB. The top of the gel in this figure is at the spacer gel–separating gel interface. Proteins larger than about 100 kDa remained trapped at the spacer gel–separating gel interface, resulting in the bulging of the outside lanes. Smaller proteins all migrated into the gel, but many remained tightly bunched at the top of the separating gel. The effective separation range is below 40 kDa. Comparison of this figure with **Fig. 1** in Chapter 104, which shows gonococcal whole cells and the two mol-wt marker preparations separated in a standard 15% Laemmli gel ***(1)***, demonstrates the tremendous resolving power of low-mol-wt components by this tricine gel system.

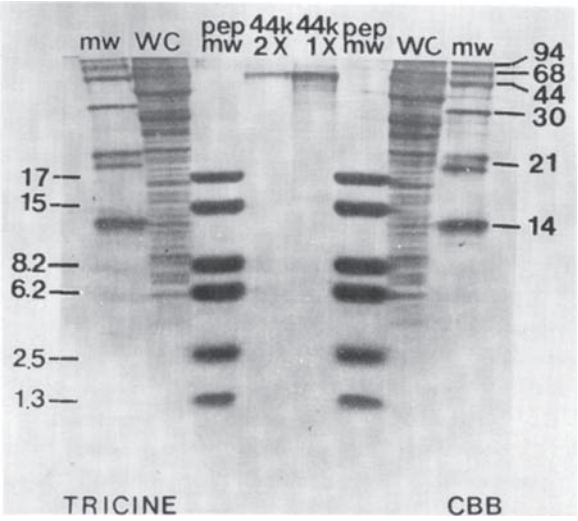

Fig. 1. WC Iysates and 1X and 2X purified 44 kDa protein of *Neisseria gonorrhoeae* (*see* Chapter 104, **Subheading 3.1.,**), Bio-Rad mw (1 µg of each protein), and Pharmacia pep mw (to which the 1.3-kDa protein kinase C substrate peptide [Sigma, St. Louis, MO] was added) (3 µg of each peptide), separated in a 1X crosslinker tricine gel, fixed, and stained with CBB. Molecular masses are given in thousands of daltons.

3.3. Blotting of Peptides

Separated peptides can be electroblotted to PVDF membranes for sequencing or immunological analyses (*see* **Note 11**).

1. Before the electrophoresis is complete, prepare enough of the 20 m*M* sodium phosphate transfer buffer, pH 8.0 (*see* **Note 12**) to fill the blotting chamber (usually 2–4 L). Degas about 1 L of transfer buffer for at least 15 min before use. Cut two sheets of filter paper to fit blotting apparatus, and cut a piece of PVDF membrane a little larger than the gel. Place the PVDF membrane in 10 mL of methanol until it is wet (this takes only a few seconds), and then place the membrane in 100 mL of degassed transfer buffer.
2. Following electrophoresis, remove the gel from the gel apparatus, and place it on blotting filter paper that is submersed in the degassed transfer buffer. Immediately overlay the exposed side of the gel with the wetted PVDF membrane, being sure to remove all air pockets between the gel and the membrane. Overlay the PVDF membrane with another piece of blotting filter paper, and place the gel "sandwich" into the blotting chamber using the appropriate spacers and holders.
3. Connect the power pack electrodes to the blotting chamber (the positive electrode goes on the side of the gel having the PVDF membrane). Electrophorese for 16 h at 25 V, 0.8 A. Each system varies, so settings may be somewhat different than those described here.
4. Following electroblotting, disconnect the power, disassemble the blotting chamber, and remove the PVDF membrane from the gel (*see* **Note 13**). The PVDF membrane can be processed for immunological analyses or placed in CBB in fixer/destainer to stain the transferred peptides. Remove excess stain by shaking the membrane in several changes of fixer/destainer until background is white. Peptide bands can be excised, rinsed in dH_2O, dried, and subjected to N-terminal sequencing.

3.4. Modifications for Peptide Sequencing

Peptides to be used in N-terminal sequence analyses must be protected from oxidation, which can block the N-terminus. Several simple precautions can help prevent this common problem.

1. Prepare the separation and spacer gel the day before electrophoresing the peptides. After pouring, overlay the spacer gel with several milliliters of dH_2O, and allow the gel to stand overnight at room temperature (*see* **Note 14**).
2. On the next day, pour off the water, and dry between the plates with filter paper. Do not touch the gel with the filter paper. Prepare the stacking gel, but use half the amount of 10% ammonium persulfate (*see* **Note 15**). Pipet the stacking gel solution between the plates as described above, and allow the stacking gel to polymerize for at least 1 h. Add running buffers as described above, adding 1–2 mg of dithiothreitol to both the upper and lower chambers to scavenge any oxidizers from the buffers and gel.
3. Pre-electrophorese the gel for 15 min. then turn off the power, and load the samples and molecular-mass markers.

4. Run the gel as described above.
5. Blot the peptides to a PVDF membrane as described above, but add 1–2 mg of dithiothreitol to the blot transfer buffer.
6. Fix and stain as above, again adding 1–2 mg of dithiothreitol to the fixer/destainer, CBB, and dH_2O used to rinse the peptide-containing PVDF membrane.

Acknowledgments

The author thanks Joan Strange for her assistance in developing this system, Pam Gannon for her assistance, and the Public Health Service, NIH, NIAID (grants RO1 AI21236) and UM Research Grant Program for their continued support.

4. Notes

1. Working range of separation about 40 kDa down to about 1 kDa.
2. Working range of separation about 20 kDa down to less than 500 Dalton.
3. Use electrophoresis grade SDS. If peptide bands remain diffuse, try SDS from BDH (Poole, Dorset, UK).
4. Degassing of gel reagents is **not** necessary.
5. Coomassie staining can generally visualize a band of 0.5 µg. This may vary considerably based on the properties of the particular peptide (some peptides stain poorly with Coomassie). Some peptides do not bind SDS well and may never migrate exactly right when compared to mol-wt markers. Fortunately, these situations are rare.
6. Protocols are designed for a standard 13 cm × 11 cm × 1.5 mm slab gel. Dimensions and reagent volumes can be proportionally adjusted to accommodate other gel dimensions.
7. Permanent marks with a diamond pencil can be made on the back of the back plate if the plate is dedicated to this gel system.
8. The depth of the spacer gel can be varied from 1 to 2 cm. Trial and error is the only way to determine the appropriate dimension for each system.
9. It is wise to feel the front plate several times during the electrophoresis to check for over-heating. The plate will become pleasantly warm as the run progresses. If it becomes too warm, the plates might break, so turn down the power!
10. Standard-sized gels can be fixed in as little as 4 h with shaking.
11. It is best to blot peptides to PVDF membranes rather than nitrocellulose membranes, since small peptides tend to pass through nitrocellulose without binding. Moreover, peptides immobilized on PVDF membranes can be directly sequenced in automated instrumentation equipped with a "blot cartridge" ***(6)***.
12. The pH of the transfer buffer can be varied from 5.7 to 8.0 if transfer is inefficient at pH 8.0 ***(7)***.
13. Wear disposable gloves when handling membranes.

14. Do not refrigerate the gel. It will contract and pull away from the plates, resulting in leaks and poor resolution.
15. Do not pour the stacking gel the day before electrophoresis. It will shrink, allowing the samples to leak from the wells.

Separation of Proteins by Blue Native Electrophoresis (BN-PAGE)

Elke A. Dian, Joachim Rassow, and Christian Motz

1. Introduction

Proteins often work together in protein complexes. For the analysis of the function as well as the structure of proteins it is often of interest to analyze the assembly of such complexes. While protein complexes normally dissociate into their subunits when analyzed by SDS-PAGE (**Fig. 1B**), nondenaturing electrophoresis (so called native electrophoresis) methods leave the complexes intact. Blue native polyacrylamide gel electrophoresis (BN-PAGE, **Fig. 1C**), a method developed by Schägger and Jagow ***(1)***, has proven to be a valuable tool to analyze the respiratory chain complexes of different organisms ***(2,3)*** to investigate the complexes of the import machinery of mitochondria ***(4–6)*** or chloroplasts ***(7)***, or to analyze the proteome of isolated organelles or whole cellular lysates ***(8,9)***.

Compared to other methods, BN-PAGE offers some major advantages: (1) It allows the determination of the molecular weight for both positively and negatively charged proteins as well as for membrane proteins. (2) In contrast to gel filtration, BN-PAGE offers the possibility of testing many samples on the same gel (i.e., under identical conditions). (3) Small samples (electrophoretic amounts down to 5 µg) are possible. (4) The electrophoresis can be performed using standard equipment for SDS-PAGE.

With other native electrophoresis methods, the mobility of the proteins is mainly determined by their intrinsic charge but also to some extend by their size. Therefore neither the pI nor the molecular weight of the proteins can be exactly determined. The BN-PAGE overcomes this difficulty by binding of the anionic dye Coomassie Blue G-250 and so inducing a charge shift to the proteins. Thus the electrophoretic mobility depends only on the molecular weight.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

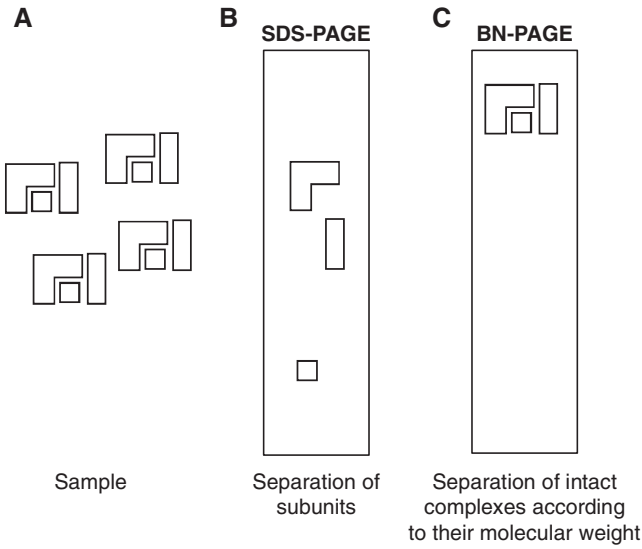

Fig. 1. Principle of the separation with different electrophoretic techniques. **(A)** The proteins to be separated. **(B)** SDS-PAGE: the subunits are separated according to their size. **(C)** The intact protein complexes are separated by size.

Schägger et al. ***(10)*** showed that the BN-PAGE allows the analysis of molecular masses of most soluble as well as most membrane proteins. Only a few proteins that do not bind the Coomassie dye and have no or almost no negative charge at pH 7.5 showed a significantly different behavior. As a side effect, the negatively charged dye also prevents aggregation of the proteins.

While in SDS-PAGE the SDS / protein ratio and thus the charge / mass ratio is constant for all proteins, the ratio of bound dye / protein shows some variation in BN-PAGE. Especially integral membrane proteins show an increase in their apparent molecular weights compared to soluble proteins due to differences in the affinity for detergent or dye molecules. Heuberger et al. ***(11)*** showed for different membrane proteins that bound detergents were replaced by dye molecules during electrophoresis. The apparent molecular weight was increased by the factor 1.8 compared to the molecular weight of soluble proteins that served as marker proteins.

2. Materials

Prepare all solutions in distilled H_2O unless otherwise stated.

1. Electrophoresis chamber: the gel has to be cooled during electrophoresis. Although running the gel in the cold room in a standard electrophoresis chamber may be

Table 1
Composition of Separating and Stacking Gels

	Separating gel: acrylamide concentration					
Components	*4 %*	*6 %*	*13 %*	*16 %*	*20 %*	Stacking gel
AB-mix	0.75 mL	1.15 mL	2.35 mL	3 mL	3.75 mL	0.3 mL
Gel buffer	3 mL	3 mL	3 mL	3 mL	3 mL	1.25 mL
Glycerol	-	-	1 mL	1 mL	1 mL	-
H_2O	Fill to 9 mL					2.2 mL
APS	38 µL	38 µL	30 µL	30 µL	30 µL	30 µL
TEMED	3.8 µL	3.8 µL	3 µL	3 µL	3 µL	3 µL

sufficient, best cooling is achieved using a system with cooling in a water bath, such as the Hoefer SE600 system (*see* **Note 1**).

2. A gradient mixer of the appropriate volume for a separating gel (*see* **Table 1** and **Note 7**).
3. Cathode buffer A: 50 m*M* Tricine, 15 m*M* Bis-Tris, 0.02 % coomassie brilliant blue G-250, pH 7.0 at 4°C, do not adjust the pH (*see* **Notes 1** and **2**).
4. Cathode buffer B: 50 m*M* Tricine, 15 m*M* Bis-Tris, pH 7.0 at 4°C (*see* **Note 1**).
5. Anode buffer: 50 m*M* Bis-Tris, adjust pH 7.0 with HCl (*see* **Note 1**).
6. Gel Buffer (3x): 1,5 *M* ε-aminocaproic acid, 150 m*M* Bis-Tris (*see* **Note 3**).
7. AB-Mix: 49.5 % acrylamide, 1,5 % bisacrylamide.
8. APS: 10 % (w/v) ammoniumpersulfate in H_2O.
9. TEMED: N,N,N',N'-tetrametylethylenediamine.
10. Lysis buffer: 20 m*M* Tris-HCl, 0.1 m*M* EDTA, 500 m*M* ε-aminocaproic acid, 10 % glycerol, pH 7.0 (HCl). Complete with the desired detergent (*see* **Notes 3 – 6**) and add PMSF to 1 m*M* just before use.
11. PMSF: phenylmethylsulfonylfluoride 200 m*M* in 2-propanol.
12. Sample buffer: 500 m*M* ε-aminocaproic acid, 100 m*M* Bis-Tris, 5 % Serva Blue G, pH 7.0 (HCl) (*see* **Note 2**).
13. 100 % methanol.
14. Blot buffer: 20 m*M* Tris, 150 m*M* glycine, 0.02 % SDS, 20 % methanol, do not adjust the pH.

3. Methods

3.1. General Experiment

3.1.1. Preparing the Gel

1. Prepare the gel assembly according to the manufacturers instructions,
2. Mix the separating gel solutions (**Table 1,** *see* **Notes 7** and **8**) without APS and fill them into a gradient mixer, filling the higher concentration in the exit chamber. Add the APS and TEMED, then pour the gel. Overlay with 2-propanol or 1-butanol.
3. After the separating gel has polymerized, discard the alcohol, then mix and pour the stacking gel **(Table 1).** Place a comb in the gel to form the wells.

3.1.2. Sample Preparation

The sample preparation depends on whether the proteins to be analyzed are soluble, or membrane proteins. For first experiments start with or twice the amount you would use for a normal SDS-PAGE (*see* **Note 9**). Soluble proteins can be used without further preparation by dilution with lysis buffer and addition of 10 % (v/v) sample buffer and proceed with the electrophoresis. Already solubilized membrane proteins can be treated in a similar manner if the detergent does not interfere with the electrophoresis (*see* **Note 10**).

Ideally, the proteins are precipitated or in membranes. Such samples are treated in the following way: Prior to the electrophoresis these samples are lysed in a buffer containing detergent. The choice of detergent is crucial because too harsh conditions will dissociate the complexes whereas too mild conditions may not be sufficient to solubilize the proteins (*see* **Fig. 2B** and **Notes 4–6**).

1. Reisolate the membranes (vesicles or organelles) or the protein precipitate by centrifugation. Discard the supernatant.
2. Resuspend the samples in 70 µL lysis buffer (i.e. 1 µL per µg protein) containing the detergent and 1 m*M* PMSF.

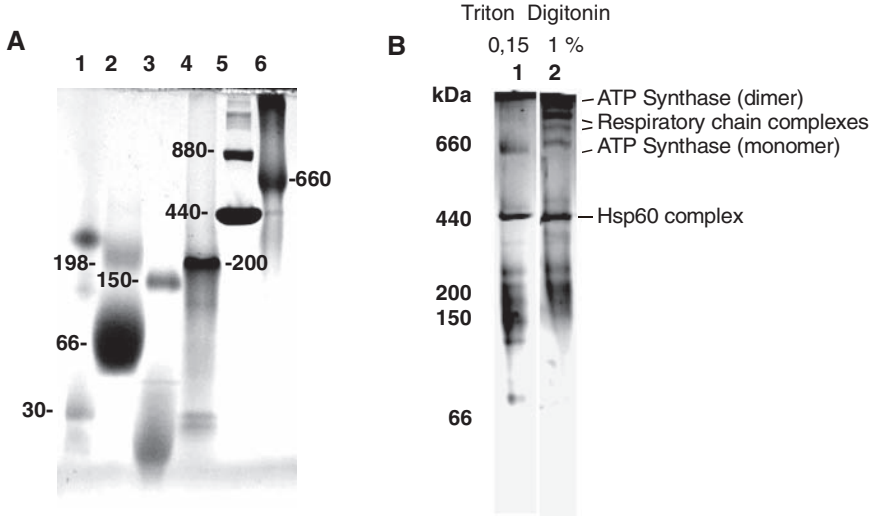

Fig. 2. Separation of protein complexes by BN-PAGE (4–16 % acrylamide gradient), staining with Coomassie. **(A)** Marker proteins: lane 1: carbonic anhydrase (30 kDa), 2: BSA (66 kDa), 3: alcohol dehydrogenase (150 kDa), 4: β-amylase (200 kDa), 5: apoferritin (440 kDa), 6: thyroglobulin (660 kDa). Note that some of the markers give more than one band; therefore it is not recommended to mix all the markers in one lane. **(B)** Separation of proteins from isolated yeast mitochondria in BN-PAGE (4–16 % gradient): lane 1: lysis of mitochondria with Triton X-100, lane 2: lysis with digitonin. Note that the large complexes of the respiratory chain are visible only when the mitochondria were lysed in digitonin. The ATP synthase dimer is only visible in digitonin.

3. Incubate 20 min on ice (*see* **Note 6**).
4. Centrifuge 20 min at 20000 g (minimum, use an ultracentrifuge if available) to pellet insoluble aggregates.
5. Discard the pellet (or keep it for lysis control using SDS-PAGE).
6. Add 7 µL of sample buffer (i.e. 10 % of the sample volume) to the supernatant.

3.1.3. Electrophoresis

1. Apply the samples to the gel.
2. Apply the markers solubilized in sample buffer (*see* **Note 11**).
3. Overlay the samples with cathode buffer A, assemble the precooled electrophoresis unit and fill the cathode buffer A in the upper buffer chamber.
4. Start the electrophoresis at 200 V until the blue front reaches the separating gel, then set the voltage to 500 V with the current limited to 15 mA per gel (*see* **Note 12**).
5. Removing excess dye can be achieved by changing the cathode buffer A to cathode buffer B after about one third of the run. This is recommended when blotting the gel but can be omitted if the gel will be stained after electrophoresis.

3.1.4. Staining

The Serva Blue G will not stain all proteins, so it will be necessary to stain the gel according to your standard procedures, e.g. staining with Coomassie Blue R-250 or silver staining.

3.1.5. Western Blotting

For western blotting it is best to use polyvinylidene (PVDF) membranes, which will allow removing the dye using organic solvents. Note that, unlike nitrocellulose, PVDF needs an extra preparation.

1. Prepare the PVDF membrane by immersing for a few seconds in 100 % methanol, until the membrane is translucent. Wash with water for another five min.
2. Incubate the membrane a few minutes in blot buffer. The membrane submerges when it is equilibrated.
3. Equilibrate the gel for a few seconds in transfer buffer.
4. Perform the western blotting according to your standard procedures.
5. After blotting, remove the blue dye by washing the membrane with methanol, then rinse with water.
6. The membrane can be stained or used for antibody detection following your standard procedures. Note that if the membrane once gets dry, you will have to repeat **step 1** before going on.

3.2. Two-Dimensional Gels

1. After running the native gel, disassemble the glass plates and remove the stacking gel.
2. Cut out the lanes of interest.
3. Place the lane on a glass plate at the usual position of the stacking gel. Leave some space at the side for a marker or a control (*see* **Fig. 3A** and **Note 13**).

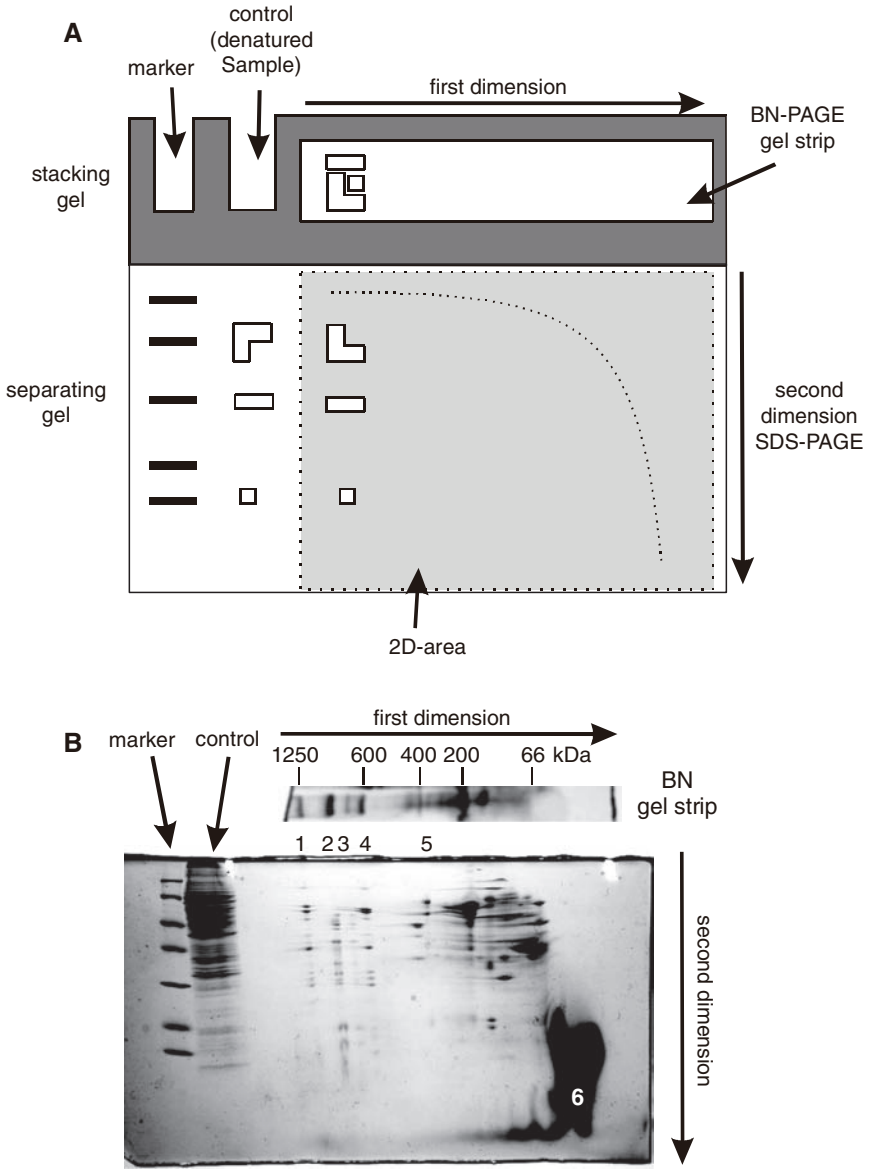

Fig. 3. Two-dimensional gel. **(A)** Principle; in the first dimension (BN-PAGE, left to right), the protein complexes are separated, in the second dimension (SDS-PAGE, top-down), the subunits and monomers are separated. The subunits of one complex can be found one below the other. Monomers will be found on the dotted hyperbolic line. **(B)** Example: mitochondria (70µg protein) lysed in digitonin: 1. ATP synthase (dimer), 2, 3: respiratory chain complexes, 4: ATP Synthase (monomer), 5: Hsp60 complex, 6: excess Coomassie dye

4. Assemble the glass plates for a standard SDS gel. The excised gel strip will be held in its position by friction.
5. Pour the separating gel. Leave about 0.5–1 cm below the gel strip. Overlay with 2-propanol or 1-butanol (according to your standard procedures).
6. After polymerization, decant the propanol and pour the stacking gel, avoiding air bubbles under the gel strip. This can be achieved by tilting the gel assembly and slowly straighten it while pouring the gel. Place a small comb for one or two wells for marker and control (*see* **Note 13**).
7. Place the gel into the electrophoresis apparatus. Apply the marker. If you need reducing conditions, overlay the blue native strip with reducing sample buffer.
8. Perform the electrophoresis according to your standard protocols. The blue dye in the native gel strip will form a thin line. After the line has reached the separating gel, remove the gel strip with a thin spatula. This will avoid an uneven run.
9. The gel can be stained, blotted, and so on, according to your standard procedures.

3.3. Analysis of Organelles or Cell Lysates

Blue Native electrophoresis offers the posibility to identify protein complexes in proteomic approaches. Camacho-Carvajal et al. ***(9)*** subjected whole cellular lysates to BN-PAGE with subsequent SDS-PAGE and identified various protein complexes using immunoblotting. Werhahn and Braun ***(8)*** used an elegant three-dimensional electrophoresis to identify the proteome of the mitochondrial complexes: in a first dimension they subjected mitochondria to BN-PAGE. The resulting bands of the protein complexes were cut out and each was subjected to first dimension isoelectric focusing and subsequent second dimension SDS-PAGE, resulting in a set of "classic" two dimensional gels, each representing the proteome of one complex of mitochondrial proteins.

3.4. Analysis of Isolated Protein Complexes

Figure 4A shows an assembly experiment with F_1 ATPase from *Escherichia coli* monitored by Blue Native electrophoresis: isolated α, β, and γ subunits were mixed in a stoichometric ratio without (lane 2) and with (lane 3) MgATP and then analyzed by BN-PAGE. Lane 1 shows intact ATPase as a control. Whereas in the absence of MgATP, only a mixture of the subunits can be detected (lane 2), in the presence of MgATP, a larger complex is detected (lane 3, arrow) which corresponds to $\alpha_3\beta_3\gamma$.

Arnold et al. ***(12)*** analyzed isolated ATP synthase from yeast with Blue Native electrophoresis. They could show the existence of two different complexes: one with the molecular weight of the ATP synthase, one with the double weight. Using a subsequent second dimension SDS-PAGE, they could identify both complexes as ATP synthase and further identify some proteins which are only present in the dimer.

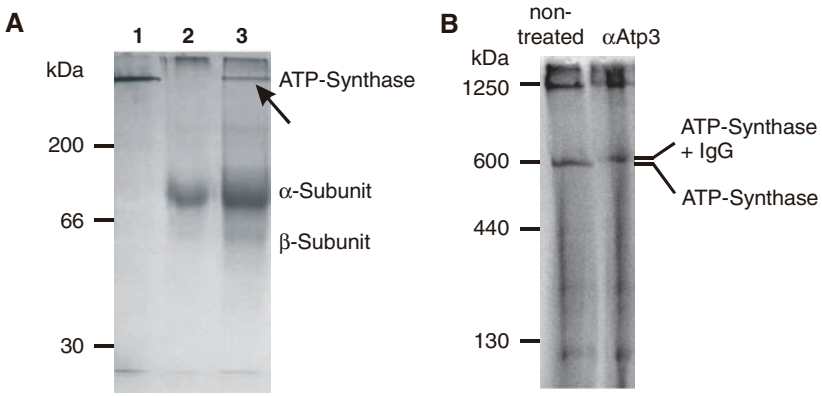

Fig. 4. Examples for applications of BN-PAGE: A: BN-PAGE of an assembly experiment with F_1 ATPase from *Escherichia coli*: 1: F1-ATPase, 2: isolated α, β und γ subunits (3:3:1) without MgATP, 3: isolated α, β und γ subunits (3:3:1) with MgATP. The arrow indicates the presence of a reconstituted $\alpha_3\beta_3\gamma$ complex. B: Autoradiogram of a BN-PAGE with mitochondria after the import of radiolabeled γ-subunit (Atp3) and lysis with digitonin. The right sample is treated with antiserum against Atp3. Due to binding of the IgG molecules to the ATP synthase complex, the corresponding bands are shifted from 600 kDa to 750 kDa.

3.5. Using an Antibody Shift to Determine Interaction Partners

Antibody binding is not affected by BN-PAGE and can thus be detected by a molecular mass shift of about 150 kDa (the molecular weight of a IgG molecule). Wiedemann et al. ***(13)*** used this method to identify components of the assembly intermediates of the TOM complex. This method can be used as an alternative to coimmune precipitation. Dissolve the samples in lysis buffer containing 1 % digitonin and add 1–5 µL polyclonal antiserum against potential interaction partners. Use a sample with the same amount of preimmune serum as control. Incubate 20 min on ice. Centrifuge, then run the blue native gel as described in **Subheading 3.1**.

Detect your protein of interest by western blotting or phosphor imager analysis. Protein bands showing an increase of the molecular weight by 150 or 300 kDa in comparison with the control indicate the binding of one or two IgG molecules and thus the presence of the protein the antibody was raised against in the protein complex of interest **(Fig. 4B)**.

4. Notes

1. The Hoefer SE600 system needs 400 mL of cathode buffer and 4 L of anode buffer, both can be reused up to five times
2. Coomassie Brilliant Blue R-250 cannot be used.

3. Schägger and Jagow ***(1)*** use a concentration of 500 m*M* ε-aminocaproic acid (EACA) in the gel and 750 m*M* in the lysis buffer. The concentration, however, can be varied in a wide range (100 m*M* to 1 *M*).
4. The choice of detergent is a critical step, as shown in **Fig. 2B**. For yeast mitochondria, 1 % digitonin will give a good lysis while keeping most protein complexes together. Also Triton X-100 in a range from 0,2 to 2 % may give good results. Any other detergent may be used; it should be selected to extract the proteins and preserve the protein complexes (*see* **Note 6**).
5. For determination of the protein pattern of the monomers, 1 % SDS or 8 *M* urea can be used.
6. The appropriate lysis conditions (lysis time, lysis buffer, detergent) should be determined in a pilot experiment: lyse the samples under different conditions, centrifuge at 20000 g (better: 100000 g) and analyze the pellet and supernatant on a SDS-gel for the protein of interest. Select conditions that keep the protein in the supernatant.
7. A linear gradient range from 4–16 % will give a good resolution from 1000 to 100 kDa, for other molecular weight ranges, gradients between 4 and 20% can be used. For separation of proteins in the range from 50 to 100 kDa, a homogenous gel with 10% acrylamide has proven suitable ***(14)***.
8. The volume of 18 mL for the separating gel is convenient for a gel with the dimensions 18 × 16 cm and 1 mm thickness, as purchased with the Hoefer SE600. For other gels, the appropriate volume has to be determined. The use of spacers with more than 1 mm thickness may result in broadening of the protein bands.
9. Protein amounts of 50 to 100 µg per sample for a heterogeneous mixture of proteins and 5 to 30 µg for purified protein are usually satisfactory detectable. For first experiments use twice the protein as you would for a normal experiment analyzed by SDS-PAGE. A high background or smearing on the gel, however, can be reduced by reducing the sample size.
10. It may be possible that some substances in the protein solution may interfere with the electrophoresis, so a precipitation or dialysis with lysis buffer may be necessary.
11. Molecular weight markers for gel filtration calibration (e.g. Sigma MW-GF-1000, *see* **Fig. 2A**) can be used as markers. Some of the markers may give more than one band, so it is best to run each marker in a separate lane first to see which may be mixed without confusing the bands (e.g., BSA and Apoferritin).
12. The Gel will run approximately five hours. Set the Voltage to 50 V if you want to run the gel overnight.
13. For analyzing protein mixtures with two-dimensional gels, it is good to apply an aliquot from the same experiment in Laemmli buffer (SDS-Buffer) as control on the side of the gel. A control of a SDS denatured sample that contains the protein of interest will make it easier to find the corresponding spots on the 2-D Gel. It will also facilitate troubleshooting.

Separation of Proteins by Gel Electrophoresis in the Tris-Taurine-HCl System

Sylvie Luche, Mireille Chevallet, Cécile Lelong, and Thierry Rabilloud

1. Introduction

SDS-PAGE (i.e., zone electrophoresis of proteins in the presence of SDS) is perhaps one of the most widely used protein separation tool. This is due to its relatively ease of setup, its robustness, in the sense that near all proteins are amenable to this type of separation, its compatibility with further protein analysis techniques (e.g., by blotting or by mass spectrometry), and its good resolution. The resolution of zone electrophoresis has been vastly improved by the use of discontinuous systems ***(1)***, so that almost only discontinuous systems are used nowadays, and the popular Laemmli system is just one of those ***(2)***.

However, there is no universal solution in protein separation, so that there is no single gel that is able to exhibit optimal protein separation for all studies. Quite often, the resolution must be adjusted to the experimental needs. These can vary from a rather low resolution over a wide range of molecular masses to a high resolution in a limited molecular mass range.

Most often, resolution is adjusted to the experimental needs by playing with the acrylamide concentration. By changing the pore size in the resulting gel, this results in changed sieving properties and thus to changed retardation of proteins in the gels. While very efficient, this way of adjusting resolution is not without practical drawbacks. Highly concentrated gels (15%acrylamide and over) are rather brittle, while low concentration gels (7.5% and lower) are very soft and tend to break. Moreover, highly concentrated gels pose often technical problems in the subsequent steps (e.g., in the mobilization of proteins for blotting or in the efficient penetration of trypsin in proteomics experiments).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

However, there is another way to adjust resolution in SDS-PAGE, which is to play with the electrophoresis buffer system. In discontinuous electrophoresis, the migration is stopped when the ion boundary (i.e., the zone materializing the migration of the fastest ions) has reached the bottom of the gels. This means in turn that the resolution of the proteins is the ratio between their mobility in the gel and the mobility of this ion boundary, and this gives another mechanism to tune protein resolution.

For example, at equal gel concentration, if the ion boundary mobility is slow, this means that all the small, fast-moving proteins will travel with the ion boundary with no resolution. Meanwhile, as the total electrophoretic process is slower and thus takes longer, the slow moving proteins will be given more time to travel in the gel and thus achieve greater resolution if the gel has adequate sieving properties. The overall result is an increased resolution of the high molecular weight proteins and a decreased resolution of low molecular weight proteins.

Conversely, if the ion boundary is fast, even the fast-moving, low molecular weight proteins will not be able to travel as fast as the ion boundary, mainly because of gel sieving. As a result, separation will show. However, as in this case the migration time is short, high molecular weight proteins travel minimally in the gel and are therefore poorly resolved. Of course, both acrylamide concentration and ion boundary can be adjusted independently to provide the optimal resolution.

While the Tris-glycine system originally described by Ornstein and Davis ***(1,3)*** is still by far the most popular, it is not a versatile system in resolution adjustment, and this illustrates how the adjustment of ion boundary speed works. Ion boundary mobilities can be calculated by using the system described by Jovin ***(4)***, but more intuitive rules can be used to understand what happens.

Ion boundary mobility is just a subcase of isotachophoresis, and a consequence is that the boundary speed is the speed of the slowest-moving ion. Quite often, the low mobility of this trailing ion is tuned by choosing a zwitterionic compound with basic and acidic pKs, so that changing the pH will change the mobility of the ion.

Going back to the example of a glycine-based anionic system, the basic pK of glycine is 9.7. This means at an operating pH of 9.7, the speed of the glycine ion wil be one half of its absolute mobility, as half of the molecules are charged. At 8.7, it will be one tenth of the absolute mobility, and 90% of the absolute mobility at 10.7.

While this is not a problem per se, these values pose practical problems. For example, at pH 10.7, the acrylamide gel will start to hydrolyze, giving rise to electroosmosis and mechanical problems. Furthermore, while the operating pH is not the gel pH (it is higher in anionic systems), the operating pH is dictated by the pH of the gel, which itself is governed by the other, cationic buffering

component—Tris in the case of Tris-glycine gels. As the pK of Tris is close to 8.1, this means that the buffering capacity becomes low at pH 9 and this alters the robustness of the system. It can be argued that other buffering components than Tris can be used. While this is in principle true, this buffer is the gel polymerization buffer. This means that this buffering component must not interfere with the acrylamide polymerization. As a result, choice of buffers that can be used is very limited. For example, only ammediol has been used to operate gels at high pH and thus allow for the resolution of low-molecular weight proteins in glycine systems ***(5)***.

At the other end of the spectrum, decreasing the pH below the classical 8.8 value of the Ornstein-Davis system enables better resolution in the high molecular mass range ***(6,7)***. Thus, alternate systems have been proposed for the resolution of low-molecular weight proteins. As a result of the high performance of Tris as a polymerization buffer, these systems have used zwitterionic compounds which a much lower pK than glycine, for example Tricine ***(8)***, Bicine ***(9)***, or even MES ***(10)***.

In addition, the use of high pH for gels electrophoresis is not without drawbacks. High pH gels have limited shelf-life because of slow hydrolysis of the acrylamide. Moreover, the reactivity of amino acids toward residual acrylamide monomer is increased at high pH, leading to modification of the side chains ***(11)***.

It has been therefore proposed to use a neutral pH system using Tricine as a trailing ion ***(12)***. However, here again, the required pH of 7 is far from the pK of Tris, leading to robustness problems.

The conclusion of these statements is that Tricine, pK 8, is well adapted to high velocity buffers while not adapted to low velocity buffers, while the reverse situation is encountered with glycine and its pK 9.7. We therefore reasoned that a system using a trailing ion of pK close to 8.8 should be adaptable to both high and low velocity buffers, while operating at moderately basic values and close to the pK of Tris—and therefore at maximal buffer capacity.

Additional constraints in the possible trailing ions, such as cost, or the presence of a primary amine to ensure compatibility with all types of silver staining, further limited the choice, and we selected taurine as a trailing ion ***(13)***. Once this choice was made, we could devise a double gel system (stacking-separating gel) to further optimize the resolution.

2. Materials

2.1. Stock Solutions (All Stored at Room Temperature)

1. Stock acrylamide solution: 30% acrylamide, 0.8% bis-acrylamide.
2. Buffers (*see* **Note 1**):
   a. Sample stock buffer: 120 g/l Tris, 0.8 M HCl.

   b. Stacking buffer: 90 g/l Tris, 0.6 M HCl.
   c. Separating buffer, low speed: 110 g/l Tris, 0.6 M HCl.
   d. Separating buffer, medium speed: 130 g/l Tris, 0.6 M HCl.
   e. Separating buffer, high speed: 150 g/l Tris, 0.6 M HCl.
3. 20% SDS.
4. 10% ammonium persulfate, made fresh every week.
5. Cathode buffer: 6.g/l Tris, 1.g/l SDS, 25.g/l taurine (*see* **Note 2**).
6. Anode buffer: 6 g/l Tris, 1 g/l SDS, 30 g/l glycine (*see* **Note 2**).
7. TEMED.
8. 60% glycerol.
9. Thioglycerol (*see* **Note 3**).
10. Saturated bromophenol blue in water.
11. Solid urea.
12. 2-butanol, saturated with an equal volume of water, and kept as a two-phase system.

2.2. Gel Recipes and Sample Buffers

1. Concentrated sample buffer for 1D electrophoresis: Mix 250 µl of stacking buffer, 250 µl of 20% SDS, 350µl of glycerol, 100 µl of thioglycerol, and 5 µl of saturated bromophenol blue. Add water up to 1 ml.
2. Gel equilibration buffer for 2D electrophoresis: Mix 25 ml of stacking buffer, 25 ml of 20% SDS and 100 ml of glycerol. Add 72 g of urea. This makes directly 200 ml of gel equlibration buffer.
3. Stacking gel: Mix 1 ml of stacking gel buffer, 1 ml of stock acrylamide solution, and 4 ml of water. Add 6 µl of TEMED, and finally 60 µl of 10% ammonium persulfate.
4. Separating gel (*see* **Note 4**): Mix 10 ml of the selected separating gel buffer, 20 ml of stock acrylamide solution and 30 m of water. Add 20 µl of TEMED and finally 400 µl of 10% ammonium persulfate.
5. Agarose gel for two-dimensional electrophoresis: To 1 g of agarose, add 12.5 ml of sample stock buffer, 2 ml of 20% SDS, 2 ml of saturated bromophenol blue solution. Add water to 100 ml, and dissolve the agarose by boiling. Store in 10 ml aliquots and let the gel set.

3. Methods

3.1. Gel Casting for One-Dimensional Gel Electrophoresis

3.1.1. Sample Solubilization

Mix an equal volume of sample with a volume of concentrated sample buffer. Incubate at 100°C (boiling water bath) for 5 min. Let cool at room temperature

3.1.2. Gel Casting and Loading

Clean the glass plates and spacers with water and ethanol. Assemble the glass plates and spacers assembly and let dry. To orient and identify the gel, cut a small piece of filter paper to any recognizable shape (triangle, square, diamond, rectangle, pentagon, etc.) and drop it to the bottom of the gel assembly.

Mix the components of the separating gel, and pour the mixture in the assembly, leaving adequate empty space at the top to cast the subsequent stacking gel (typically 2–5 cm, depending on the size of the gel and of the anticipated sample volume). Overlay with 2 mm of water-saturated butanol and let polymerize (*see* **Note 5**). Once the gel is polymerized (c. 30 min), remove the upper liquid layer (butanol plus gel exudate) and replace with 5 mm of water. Protect from evaporation with parafilm, or transfer in a closed humid box (*see* **Note 6**). When needed, remove the upper water layer, mix the components of the staking gel and pour the gel mixture in the gel assembly. Insert the sample comb and let polymerize for 30 min. Remove the comb, and remove the unpolymerized liquid with a needle. Add cathode buffer to fill the sample wells, and load the samples in each well with a syringe or with a sample loading micropipet tip.

3.2. Gel Casting for Two-Dimensional Gel Electrophoresis

Gel casting proceeds as for one-dimensional gels, except that no stacking gel is needed. The separating gel mixture can the be cast up to 5 mm from the top, and overlaid with water-saturated butanol. The gel is then kept until use as described for one-dimensional gels. The IEF gels are equilibrated in the gel equilibration buffer for 5 min (carrier ampholytes tube gels) to 20 min (immobilized pH gradient strips).

When ready to use, melt the agarose, remove the water layer from the top of the gel, remove the equilibration buffer from the IEF gel, and insert the IEF gel on the top of the second dimension gel. Seal in place with agarose and let the agarose gel set.

3.3. Gel Running

Place the loaded gel in the electrophoresis tank. Fill the chambers with the adequate electrode buffer. The taurine-containing buffer must be at least in the cathode chamber (connected to the “minus” lead of the power supply). When separate electrode chambers with no buffer recirculation are present, a cheaper, glycine-containing anode electrode buffer can be used in the anode chamber (connected to the “plus” electrode of the power supply).

Gels can be run at constant voltage, power or current. We recommend to run first the gels at 25 V constant voltage for 30 to 60 min to ensure slow and complete protein entry into the gel. The gels can then be run at the maximum power that does not lead to overheating. This depends on the gel size paramaters (length; width and thickness) as well as on the type of cooling used.

We run 200 × 160 × 1.5 mm gels in a thermostated chamber with recirculating cooling water at 12 W/gel in this step.

3.4. Subsequent Processing

The migration is stopped when the bromophenol blue front, materializing the moving boundary, reaches the bottom of the separating gel. Gel made in this taurine system can be processed exactly as standard SDS gels cast in the glycine system. This includes staining with coomassie blue, fluorescent stains, silver nitrate or silver-ammonia stains, or blotting. Typical examples of the resolution obtained with the taurine gels, together with the tuning of the resolution window by buffer change, are shown in **Figs. 1** and **2**.

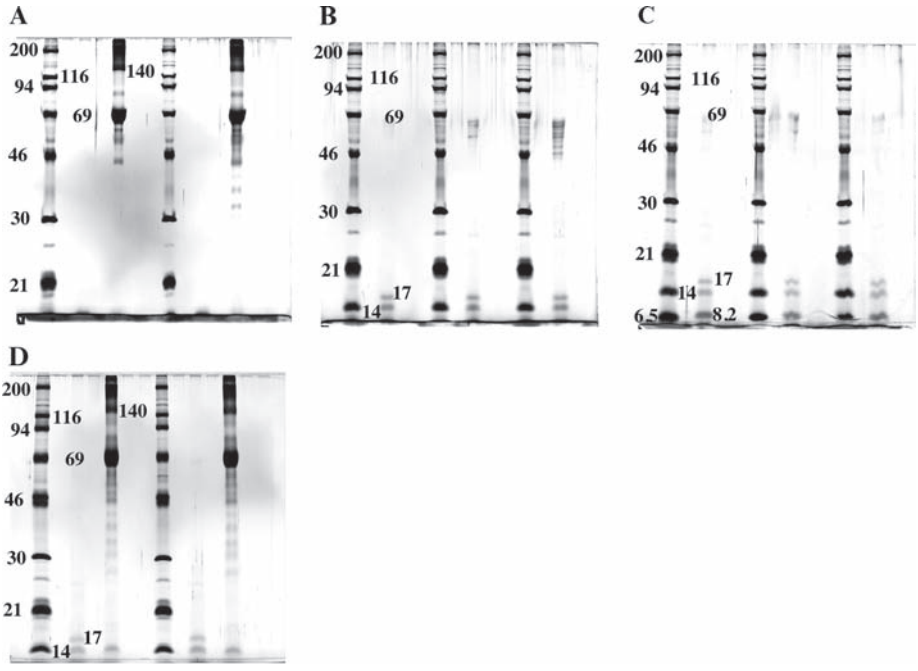

Fig. 1. Analysis of molecular weight markers. Molecular weight marker proteins were analysed by SDS-PAGE in various electrophoretic systems. The markers are: on the left lane, Bio-Rad wide range markers, in the middle lane, albumin + Myoglobin-CNBr peptides, and in the right lane, albumin crosslinked with pyromellitic dianhydride (on gels A and D only). The molecular weight is indicated close to the corresponding band. Proteins were detected by silver staining (nonammoniacal). **(A)** 10% gel, Tris taurine system (low speed). **(B)** 10% gel, Tris taurine system (medium speed). **(C)** 10% gel, Tris taurine system (high speed). **(D)** 10% gel, Tris glycine system pH 8.8.

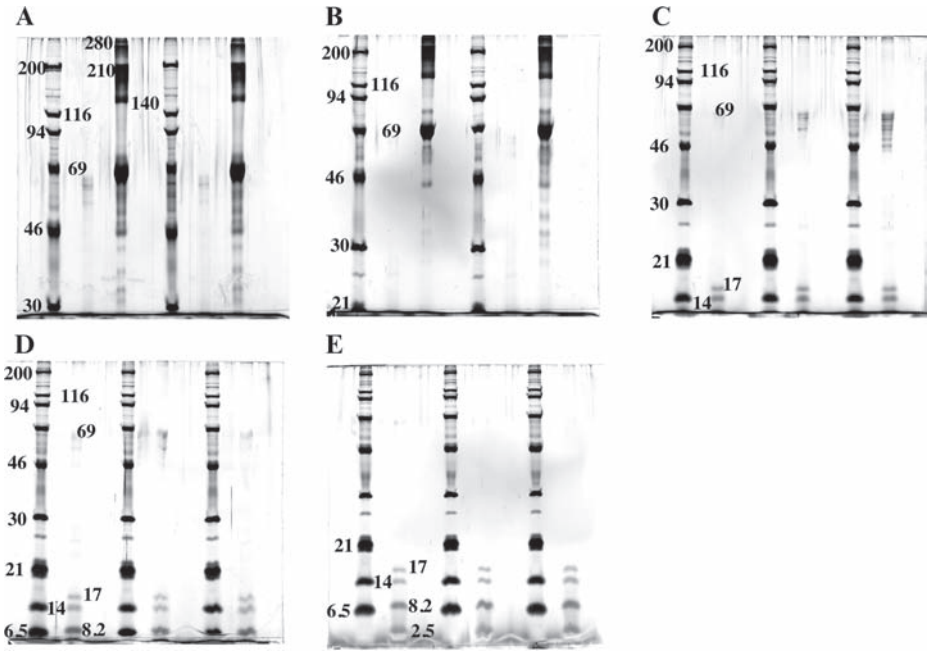

Fig. 2. Effect of double alteration of buffer and acrylamide concentration. The same molecular weight markers as in **Fig. 1** were used. **(A)** 7.5% gel, Tris taurine system (low speed). **(B)** 9% gel, Tris taurine system (low speed). **(C)** 10% gel, Tris taurine system (medium speed). **(D)** 10% gel, Tris taurine system (high speed). **(E)** 11.5% gel, Tris taurine system (high speed).

4. Notes

1. The versatility of the boundary speed means in turn that the pH of the gels buffers must be carefully controlled. This is especially difficult in the case of Tris buffers, because (i) many pH-meter electrodes have a sluggish response to Tris and (ii) Tris pK varies strongly with temperature (0.03 pH unit per °C). This means that the observed pH varies strongly with the laboratory temperature and/or the speed of addition of HCl. To avoid this variability, we recommend to make a buffer of constant composition, corresponding to the adequate pH. These buffers are most adequately made either by mixing Tris and Tris hydrochloride powders, or by mixing Tris powder with commercial titrated solutions of hydrochloric acid. The medium speed buffers has a moving boundary speed equivalent to the one of the Laemmli's buffer.

2. According to the theory of discontinuous electrophoresis, taurine is needed only in the cathode buffer, while Tris is required in the anode buffer. Thus, in an electrophoresis apparatus with separate buffer chambers, the cheaper glycine can replace taurine in the anode buffer. In an apparatus with a single chamber and/or with buffer recirculation, the taurine buffer must be used as electrode buffer. The electrode buffers are made the day of use, but can be stored for up to one week at room temperature
3. Thioglycerol is a substitute to the classical mercaptoethanol for disulfide reduction. Its efficiency is similar, but the odor is considerably weaker.
4. The recipe given yields a 10% separating gels. To adjust the acrylamide concentration, adjust the volume of stock acrylamide solution and complete to a total of 60ml (including the 10 ml of gel buffer) with water.
5. Polymerization is far from finished when the gel is set (i.e., converted from a liquid to a solid state). At this stage 50–70% of the monomer only is incorporated into the gel, depending on the temperature and time. Leaving the gel to "ripen" overnight at room temperature ensures >90% incorporation of monomers into the gel, leading to more consistent electrophoretic separations, less problems of reaction of proteins with acrylamide, and decreased safety problems with the toxic monomers
6. Once polymerized and "ripened," gels can be stored in a humid box for up to one week in the cold room.

Cetyltrimethylammonium Bromide Discontinuous Gel Electrophoresis of Proteins

M_r-Based Separation of Proteins with Retained Native Activity

Robert E. Akins and Rocky S. Tuan

1. Introduction

This chapter describes a novel method of electrophoresis that allows the fine separation of proteins to be carried out with the retention of native activity. The system combines discontinuous gel electrophoresis in an arginine/*N*-Tris (hydroxymethyl methylglycine) (Tricine) buffer with sample solubilization in cetyltrimethylammonium bromide (CTAB). Because the components that distinguish this system are **C**TAB, **a**rginine, and **T**ricine and because CTAB is a **cat**ionic detergent, we refer to this method as CAT gel electrophoresis ***(1,2)***. Proteins separated on CAT gels appear as discrete bands, and their mobility is a logarithmic function of M_r across a broad range of molecular weights. After CAT electrophoresis, many proteins retain high enough levels of native activity to be detected, and gel bands may be detected by both M_r and protein-specific activities. In this chapter, we provide a description of the procedures for preparing and running CAT gels. We also provide some technical background information on the basic principles of CAT gel operation and some points to keep in mind when considering the CAT system.

1.1. Technical Background

The electrophoretic method of Laemmli ***(3)*** is among the most common of laboratory procedures. It is based on observations made by Shapiro et al. ***(4)*** and Weber and Osborn ***(5)***, which showed that sodium dodecyl sulfate (SDS) could be used for the separation of many proteins based on molecular size. In Laemmli's method, SDS solubilization was combined with a discontinuous gel system using a glycine/Tris buffer, as detailed by Ornstein ***(6)*** and Davis ***(7)***

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

(*see* Chapter 21). Typically, SDS-discontinuous gel electrophoresis results in the dissociation of protein complexes into denatured subunits and separation of these subunits into discrete bands. Since the mobility of proteins on SDS gels is related to molecular size, many researchers have come to rely on SDS gels for the convenient assignment of protein subunit M_r.

Unfortunately, it is difficult to assess the biological activity of proteins treated with SDS: proteins prepared for SDS gel electrophoresis are dissociated from native complexes and are significantly denatured. Several proteins have been shown to renature to an active form after removal of SDS ***(8,9)***; however, this method is inconvenient and potentially unreliable. A preferred method for determining native protein activity after electrophoresis involves the use of nonionic detergents like Triton X 100 (Tx-100) ***(10)***; however, proteins do not separate based on molecular size. The assignment of M_r in the nonionic Tx-100 system requires the determination of mobilities at several different gel concentrations and "Ferguson analysis" ***(11–13)***. The CAT gel system combines the most useful aspects of the SDS and Tx-100 systems by allowing the separation of proteins based on M_r with the retention of native activity.

Previous studies have described the use of CTAB and the related detergent tetradecyltrimethylammonium bromide (TTAB), in electrophoretic procedures for the determination of M_r ***(14–18)***. In addition, as early as 1965, it was noted that certain proteins retained significant levels of enzymatic activity after solubilization in CTAB ***(19)***. A more recent report further demonstrated that some proteins even retained enzymatic activity after electrophoretic separation in CTAB ***(14)***. Based on the observed characteristics of CTAB and CTAB-based gel systems, we developed the CAT gel system.

In contrast to previous CTAB-based gel methods, the CAT system is discontinuous and allows proteins to be "stacked" prior to separation (*see* ***refs. 6*** and ***7***). CAT gel electrophoresis is a generally useful method for the separation of proteins with the retention of native activity. It is also an excellent alternative to SDS-based systems for the assignment of protein M_r (*see* **Note 1**).

1.2. Basic Principles of CAT Gel Operation

The CAT gel system is comprised of two gel matrices and several buffer components in sequence. A diagram of the CAT gel system is shown in **Fig. 1**. In an applied electric field, the positive charge of the CTAB–protein complexes causes them to migrate toward the negatively charged cathode at the bottom of the system. The arginine component of the tank buffer also migrates toward the cathode; however, arginine is a *zwitterion*, and its net charge is a function of pH. The arginine is positively charged at the pH values used in the tank buffer, but the pH values of the stacking gel and sample buffer are closer to the pI of arginine, and the arginine will have a correspondingly lower net

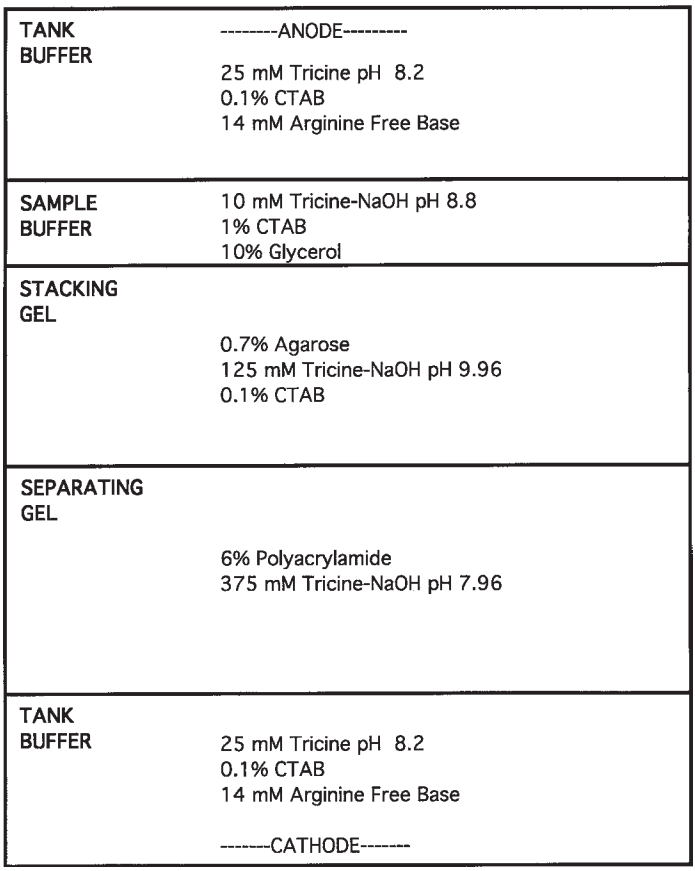

Fig. 1. Diagram of a CAT gel. CAT gels begin at the top with the anode immersed in tank buffer and end at the bottom with the cathode immersed in additional tank buffer. The tank buffer solution contains CTAB, Arginine, and Tricine. Between the tank buffers are the stacking gel and the separating gel. The gels are made up of acrylamide polymers in a Tricine-NaOH-buffered solution. Prior to electrophoresis, protein samples are solubilized in a sample buffer that contains CTAB, to solubilize the protein sample, Tricine-NaOH, to maintain pH, and carry current and glycerol, to increase specific gravity. Proteins solubilized in sample buffer are typically layered under the upper tank buffer and directly onto the stacking gel. *See* **Note 3** for a listing of some physical characteristics of the CAT gel components.

positive charge as it migrates from the tank buffer into these areas. Therefore, the interface zone between the upper tank buffer and the stacking gel/sample buffer contains a region of high electric field strength where the sodium ions in the stacking gel/sample buffer (Tricine-NaOH) move ahead of the reduced

mobility arginine ions (Tricine-arginine). In order to carry the electric current, the CTAB-coated proteins migrate more quickly in this interface zone than in the sodium-containing zone just below. As the interface advances, the proteins "stack," because the trailing edge of the applied sample catches up with the leading edge. When the cathodically migrating interface zone reaches the separating gel, the arginine once again becomes highly charged owing to a drop in the pH relative to the stacking gel. Because of the sieving action of the matrix, the compressed bands of stacked proteins differentially migrate through the separating gel based on size.

Two features of CTAB-based gels set them apart from standard SDS-based electrophoretic methods. First, proteins separated in CTAB gels migrate as a function of log M_r across a much broader range of molecular weights than do proteins separated in SDS gels. As shown in **Fig. 2**, a plot of relative migration distance, as a function of known log M_r of standard proteins, results in a straight line. Because of the consistent relationship between M_r and distance migrated,

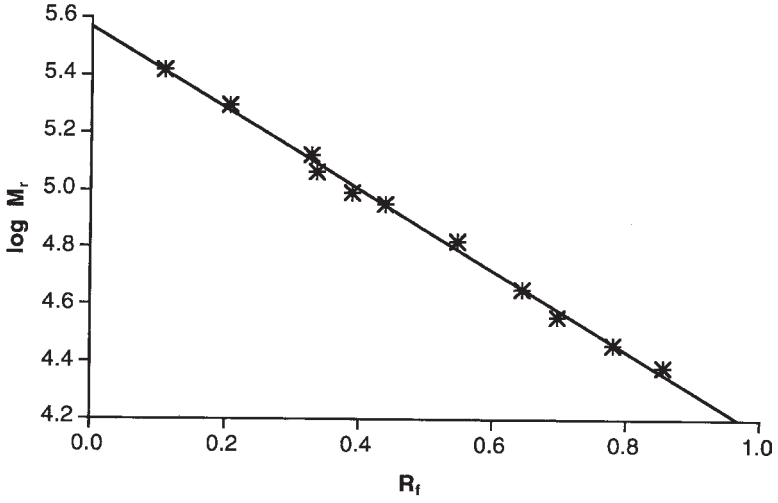

Fig. 2. Mobility of proteins in a CAT gel as a function of M_r. A mixture of proteins fractionated in a CAT gel with a 6% T acrylamide separator and a 0.7% agarose stacker was visualized by CBB R-250 staining. Relative mobilities (R_f) were calculated as distance, migrated divided by total distance to the salt/dye front and were plotted against the known M_r values for each protein band. The plot is linear across the entire range ($R^2 > 0.99$). Protein bands included trypsinogen (24 kDa), carbonic anhydrase (29 kDa), glyceraldehyde-3-phospate dehydrogenase (36 kDa), ovalbumin (45 kDa monomer and 90 kDa dimer), bovine serum albumin (66 kDa monomer and 132, 198, and 264 kDa multimers), phosphorylase-B (97.4 kDa), and β-galactosidase (116 kDa). *See* **Note 2** concerning the comparison of R_f values from different gels.

the relative molecular weights of unknown proteins can be determined. CAT gels may be especially useful for the assignment of M_r to small proteins or for the comparison of proteins with very different molecular weights. Second, the retention of significant levels of native activity in CAT gels allows electrophoretic profiles to be assessed *in situ* for native activities without additional steps to ensure protein renaturation (*see* **Note 2**). Taken together, these two characteristics of CAT gels make them an attractive alternative to standard electrophoretic systems.

2. Materials

1. CAT tank buffer: One liter of 5X tank buffer may be prepared using CTAB, Tricine, and arginine free base. First, prepare 80 mL of a 1 *M* arginine free base solution by dissolving 13.94 g in distilled water. Next, dissolve 22.40 g of Tricine in 900 mL of distilled water; add 5 g of CTAB, and stir until completely dissolved. Using the 1 *M* arginine solution, titrate the Tricine/CTAB solution until it reaches pH 8.2. Approx 75 mL of 1 *M* arginine solution will be required/L of CAT tank buffer. Since Tricine solutions change pH with changes in temperature, the tank buffer should be prepared at the expected temperature of use (typically 10–15°C). Finally, add distilled water to 1000 mL. Store the CAT tank buffer at room temperature. Prior to use, prepare 1X tank buffer by diluting 200 mL of the 5X stock to 1000 mL using distilled water of the appropriate temperature (usually 10–15°C); filter the 1X tank buffer through #1 Whatman filter paper to remove any particulate material. The 1X CAT tank buffer may be stored cold, but it should not be reused (*see* **Note 5**). Note that CTAB is corrosive, and care should be taken when handling CTAB powder or CTAB solutions: avoid inhalation or skin contact as advised by the supplier.
2. CAT stacking gel buffer: Prepare a 500 m*M* Tricine-NaOH by dissolving 22.4 g of Tricine in 200 mL of distilled water. Add NaOH until the pH of the solution reaches 10.0. Bring the solution to a total volume of 250 mL using distilled water. As with all Tricine solutions, the pH of CAT stacking gel buffer should be determined at the expected temperature of use. The CAT stacking gel buffer should be stored at room temperature to avoid any precipitation that may occur during long-term cold storage.
3. CAT separating gel buffer: Prepare a 1.5 *M* Tricine-NaOH solution by dissolving 134.4 g of Tricine in 400 mL of distilled water. Add NaOH until the pH of the solution reaches 8.0. Bring the solution to a total volume of 500 mL using distilled water. As with all Tricine solutions, the pH of CAT separating gel buffer should be determined at the expected temperature of use. The CAT separating gel buffer should be stored at room temperature to avoid any precipitation that may occur during long-term cold storage.
4. CAT sample buffer: Dilute 0.67 mL of CAT separating gel buffer to approx 80 mL with distilled water; to this add 10 mL of glycerol and 1 g of CTAB. Mix the solution until all the components are dissolved, and adjust the pH to 8.8 using NaOH.

Bring the solution to a final volume of 100 mL using distilled water. In some cases, it may be helpful to add a low-mol-wt cationic dye that will be visible during electrophoresis: 10 µL of a saturated aqueous solution of crystal violet may be added/mL of sample buffer. Note that CTAB is corrosive, and care should be taken when handling CTAB powder or CTAB solutions: avoid inhalation or skin contact as advised by the supplier. Store CAT sample buffer at room temperature to avoid precipitation of the components.

5. Acrylamide stock solution: A 40% acrylamide stock solution may be prepared by combining 38.93 g of ultrapure acrylamide with 1.07 g of *bis*-acrylamide in a total of 100 mL of distilled water. The final solution is 40%T (w/v) and 2.67%C (w/w). The "%T" and "%C" values indicate that the total amount of acrylamide in solution is 40 g/100 mL and that the amount of *bis*-acrylamide included is 2.67% of the total acrylamide by weight. The acrylamide stock solution should be stored in the refrigerator. Unpolymerized acrylamide is very toxic, and great care should be taken when handling acrylamide powders and solutions: Follow all precautions indicated by the supplier, including the wearing of gloves and a particle mask during preparation of acrylamide solutions.
6. Agarose stock solution: A ready-to-use agarose stacking gel solution may be prepared by combining 25 mL of CAT stacking gel buffer, 0.1 g CTAB, and 0.7 g of electrophoresis-grade agarose distilled to a final volume of 100 mL. Mix the components well, and, if necessary, adjust the pH to 10.0. Heat the solution in a microwave oven to melt the agarose, and swirl the solution to mix thoroughly. Divide the agarose stock solution into 10 aliquots, and store at 4°C until ready to use.
7. 10% Ammonium persulfate (AP): Dissolve 0.1 g of ammonium persulfate in 1 mL of distilled water. Make just prior to use.
8. Water saturated isobutanol: Combine equal volumes of isobutanol and distilled water. Mix well, and allow the two phases to separate: the water-saturated isobutanol will be the upper layer. Store at room temperature in a clear container so that the interface is visible.
9. CAT gel fixative: Combine 40 mL of distilled water, 10 mL of acetic acid, and 50 mL of methanol; mix well. Store CAT gel fixative in a tightly sealed container at room temperature.
10. Coomassie brilliant blue stain (CBB): Combine 40 mL of distilled water with 10 mL of acetic acid and 50 mL of methanol. Add 0.25 g of CBB R-250, and dissolve with stirring (usually overnight). Filter the solution through #1 Whatman paper to remove any particulate material. Store at room temperature in a tightly sealed container.
11. CBB Destain: Combine 437.5 mL of distilled water, 37.5 mL of acetic acid, and 25 mL of methanol. Mix well, and stored in a closed container at room temperature.
12. Electrophoresis apparatus: A suitable electrophoresis apparatus and power supply are required to run CAT gels. It is desirable to set aside combs, spacers, gel plates, and buffer tanks to use specifically with CAT gels; however, if the same apparatus

is to be used alternately for CAT gels and SDS gels, it is necessary to clean it thoroughly between each use. Often, the first CAT gel run in an apparatus dedicated to SDS gels will have a smeared appearance with indistinct bands. This smearing is the result of residual SDS, and subsequent CAT electrophoretic runs will resolve protein bands distinctly. This smearing may be somewhat avoided by soaking the gel apparatus and gel plates in CAT tank buffer prior to a final rinse in distilled water at the final step in the cleaning process.

The selection of an electrophoresis apparatus to be used for CAT gels should be based on a consideration of the electrical configuration of the system. Because molecular bromine (Br_2) will form at the anode, the anode should be located away from the top of the gel (*see* **Note 5**). In addition, it is important to realize that CAT gels are "upside-down" relative to SDS gels: proteins migrate to opposite electrodes in the two systems. Some electrophoresis apparatus are intentionally designed for use with SDS, and the anode (usually the electrode with the red lead) may be fixed at the bottom of the gel, whereas the cathode (usually the electrode with the black lead) is fixed at the top of the gel. If such an apparatus is used, the red lead wire should be plugged into the black outlet on the power supply, and the black lead should be plugged into the red outlet on the power supply. Crossing the wires in this fashion ensures that the CTAB-coated proteins in the CAT system will run into the gel and not into the tank buffer.

3. Method

The methods for the preparation and running of CAT gels are similar to other familiar electrophoretic techniques. In this section, we will describe the basic methods for preparing samples, casting gels, loading and running gels, visualizing protein bands, and transferring proteins to nitrocellulose (or other) membranes. We will emphasize the differences between CAT gels and other systems. To provide the best results, the recommendations of the manufacturer should be followed concerning the assembly of the apparatus and the casting of discontinuous gels.

3.1. Preparing Samples

1. Protein samples should be prepared at room temperature immediately prior to loading the gel. Typically, tissue fragments, cells, or protein pellets are resuspended in 1.5-mL microfuge tubes using CAT sample buffer (*see* **Note 6**). CAT sample buffer may also be used to solubilize cultured cells or minced tissues directly. In each case, the samples should be spun in a microfuge for 0.5 min at 16,000 *g* to pellet any debris or insoluble material prior to loading the gel. Good results have been obtained when the final concentration of protein in CAT sample buffer is between 1 and 5 mg/mL; however, the preferred concentration of protein will vary depending on the sample and the particular protein of interest. A series of protein dilutions should be done to determine the optimal solubilization conditions for a particular application.

3.2. Casting CAT Separating Gels

1. Assemble the gel plates and spacers in the gel casting stand as described by the manufacturer.
2. Prepare a separating gel solution by combining the 40%T acrylamide, CAT Separating gel buffer, and distilled water in the ratios indicated in Table 1. Mix the solution by swirling with the introduction of as little air as possible (oxygen inhibits the reactions necessary to accomplish acrylamide polymerization, *see* **Note 7**).
3. Degas the solution by applying a moderate vacuum for 5–10 min: the vacuum generated by an aspirator is generally sufficient.
4. Add 10% AP and TEMED to the solution as indicated in **Table 1**, and swirl the solution gently to mix. Note that insufficient mixing will result in the formation of a nonhomogeneous gel, but that vigorous mixing will introduce oxygen into the mixture.
5. Carefully pour the gel mixture into the gel plates to the desired volume; remember to leave room for the stacking gel and comb.
6. Finally, layer a small amount of water-saturated isobutanol onto the top of the gel. The isobutanol layer reduces the penetration of atmospheric oxygen into the surface of the gel and causes the formation of an even gel surface. Allow polymerization of the separating gel to proceed for at least 60 min to assure complete crosslinking; then pour off the isobutanol, and rinse the surface of the separating gel with distilled water.

3.3. Casting CAT Stacking Gels

Two different types of gel stackers are routinely used with CAT gels. For gel histochemical analyses, or where subsequent protein activity assays will be performed, stacking gels made from agarose have provided the best results.

1. Slowly melt a tube of agarose stock solution in a microwave oven; avoid vigorous heating of the solution, since boiling will cause foaming to occur and may result in air pockets in the finished gel.

Table 1
Preparation of Acrylamide Solutions for CAT Gels

Regent	4%T,mL	6%T,mL	8%T, mL	10%T,mL
40%T Acrylamide	1.00	1.50	2.00	2.50
Tricine buffer	2.50	2.50	2.50	2.50
Distilled water	6.39	5.89	5.39	4.89
Degas solution 10% AP	0.10	0.10	0.10	0.10
TEMED	0.01	0.01	0.01	0.01

Volumes indicated are in milliliters required to prepare 10 mL of the desired solution. Solutions should be degassed prior to the addition of the crosslinking agents, AP and TEMED.

2. Insert the gel comb into the apparatus, and cast the stacking gel directly onto the surface of the acrylamide separating gel. Allow the agarose to cool thoroughly before removing the comb (*see* **Note 8**).
3. As an alternative to agarose stacking gels, low%T acrylamide stackers may also be used. To prepare an acrylamide stacking gel, combine the 40%T acrylamide stock, CAT separating gel buffer (0.5 *M* Tricine-NaOH, pH 10.0), and distilled water in the ratios indicated in **Table 1**. Typically, a 4%T stacking gel is used. Degas the solution by applying a moderate vacuum for 5–10 min. Next, add 10% AP and TEMED to the solution as indicated in **Table 1**, and swirl the solution gently to mix. Insert the gel comb and cast the stacking gel directly onto the surface of the acrylamide separating gel. Do not use water-saturated isobutanol with stacking gels! It will accumulate between the comb and the gel, and cause poorly defined wells to form. Allow the stacking gel to polymerize completely before removing the comb.

3.4. Loading and Running CAT Gels

1. After the stacking and separating gels are completely polymerized, add 1X CAT tank buffer to the gel apparatus so that the gel wells are filled with buffer prior to adding the samples.
2. Next, using a Hamilton syringe (or other appropriate loading device), carefully layer the samples into the wells. Add the samples slowly and smoothly to avoid mixing them with the tank buffer, and fill any unused wells with CAT sample buffer. The amount of sample to load on a given gel depends on several factors: the size of the well, the concentration of protein in the sample, staining or detection method, and so forth. It is generally useful to run several dilutions of each sample to ensure optimal loading. Check that the electrophoresis apparatus has been assembled to the manufacturer's specifications, and then attach the electrodes to a power supply. Remember that in CAT gels, proteins run toward the negative electrode, which is generally indicated by a black-colored receptacle on power supplies.
3. Turn the current on, and apply 100 V to the gel. For a single minigel (approx 80 mm across, 90 mm long, and 0.8 mm thick), 100 V will result in an initial current of approx 25 mA. Excessive current flow through the gel should be avoided, since it will cause heating.
4. When the front of the migrating system reaches the separating gel, turn the power supply up to 150 V until the front approaches the bottom of the gel. The total time to run a CAT gel should be around 45–60 min for minigels or 4–6 h for full-size gels.

3.5. Visualization of Proteins

1. As with any electrophoretic method, proteins run in CAT gels may be visualized by a variety of staining techniques. A simple method to stain for total protein may be carried out by first soaking the gel for 15 min in CAT gel fixative, followed by soaking the gel into CBB stain until it is thoroughly infiltrated. Infiltration can take

as little as 5 min for thin (0.8 mm), low-percentage (6%T) gels or as long as 1 h for thick (1.5 mm), high-percentage (12%T) gels. When the gel has a uniform deep blue appearance, it should be transferred to CBB destain.

2. Destain the gel until protein bands are clearly visible (*see* **Note 9**). It is necessary to observe the gel periodically during the destaining procedure, since the destain will eventually remove dye from the protein bands as well as the background. Optimally, CBB staining by this method will detect about 0.1–0.5 µg of protein/protein track; when necessary, gels containing low amounts of total protein may be silver-stained (*see* **Note 10**). Note that the CBB stain may be retained and stored in a closed container for reuse.
3. In addition to total protein staining by the CBB method, enzyme activities may be detected by a variety of histochemical methods. The individual protocol for protein or enzyme detection will, of course, vary depending on the selected assay (*see* **Note 11**). Generally, when CAT gels are to be stained for enzyme activity, they should be rinsed in the specific reaction buffer prior to the addition of substrate or detection reagent. The CAT gel system provides an extremely flexible method for the analysis of protein mixtures by a variety of direct and indirect gel staining methods.

3.6. Electrophoretic Transfer Blotting

Similar to other methods of electroblotting (e.g., *see* Chapters 57 and 58), proteins can be transferred from CAT gels to polyvinylidene difluoride (PVDF) membranes. Blotting CAT gels is similar to the standard methods used for SDS-based gels with the notable difference that the current flow is reversed. We have successfully transferred proteins using the method described in Chapter 58 with the following changes: 1) A solution of 80% CAT gel running buffer and 20% MeOH was used as the transfer buffer, 2) the transfer membrane was PVDF, and 3) the polarity of the apparatus was reversed to account for the cationic charge of the CTAB. ***(2)*** As with electrophoresis, the tank and apparatus used for electroblotting should be dedicated to CTAB gels (*see* **Note 9**).

3.7. Conclusion

Gel electrophoresis of proteins is a powerful and flexible technique. There are many excellent references for general information concerning the theory behind electrophoresis. One good source of information is Hames and Rickwood ***(25)***. The CAT gel electrophoresis system presented here efficiently stacks and separates a wide range of proteins as a function of M_r and preserves native enzymatic activity to such a degree that it allows the identification of protein bands based on native activity. The nature of the interaction between CTAB and native proteins allows the formation of complexes in which the amount of CTAB present is related to the size of the protein moiety. Based on characterizations of detergent/protein interactions that indicate consistent levels of detergent binding without

massive denaturation ***(10,26–28)***, the retention of activity in certain detergent/protein complexes is expected, and CTAB is likely to represent a class of ionic detergents that allow the electrophoretic separation of native proteins by M_r. Since the level of retained activity after solubilization in CTAB varies depending on the protein of interest, and a given protein will retain varying amounts of measurable activity depending on the detergent used (*see* **ref. 1**, for example), a battery of detergents may be tried prior to selecting the desired electrophoresis system. In general, cationic detergents (e.g., the quartenary ammoniums like CTAB, TTAB, and so forth) may be used in the arginine/Tricine buffer system described above; anionic detergents (e.g., alkyl sulfates and sulfonates) may be substituted for SDS in the familiar glycine/Tris buffer system ***(29)***.

The CAT gel system and its related cationic and anionic gel systems provide useful adjuncts to existing biochemical techniques. These systems allow the electrophoretic separation of proteins based on log M_r with the retention of native activity. The ability to detect native protein activities, binding characteristics, or associations and to assign accurate M_r values in a single procedure greatly enhances the ability of researchers to analyze proteins and protein mixtures.

4. Notes

1. SDS vs CTAB: CTAB and SDS are very different detergents. CTAB is a cationic detergent, and proteins solubilized in CTAB are positively charged; SDS is an anionic detergent, and proteins solubilized in SDS are negatively charged. In terms of electrophoretic migration, proteins in CTAB gels migrate toward the cathode (black electrode), and proteins in SDS gels run toward the anode (red electrode). SDS is not compatible with the CAT gel system, and samples previously prepared for SDS-PAGE are not suitable for subsequent CAT gel electrophoresis. Also, the buffer components of the typical SDS-PAGE system, Tris and glycine, are not compatible with the CAT system: Tricine and arginine should be used with CAT gels.

   Although the detergents are different, protein banding patterns seen in CAT gels are generally similar to those seen when using SDS-PAGE. R_f values of proteins fractionated by CAT electrophoresis are consistently lower than R_f values determined on the same%T SDS-PAGE, i.e., a particular protein will run nearer the top of a CAT gel than it does in a similar

%T SDS gel. As a rule of thumb, a CAT gel with a 4%T stacker and a 6%T separator results in electrophoretograms similar to an SDS gel with a 4%T stacker and 8%T separator. Differences between the protein banding patterns seen in CAT gels and SDS gels are usually attributable to subunit associations: multisubunit or self-associating proteins are dissociated to a higher degree in SDS than in CTAB, and multimeric forms are more commonly seen in CAT gels than in SDS gels.

2. Detergent solubilization and protein activity: Many proteins separated on CAT gels may be subsequently identified based on native activity, and under the conditions presented here, CTAB may be considered a nondenaturing detergent. Denaturants generally alter the native conformation of proteins to such an extent that activity is abolished; such is the case when using high levels of SDS. Sample preparation for SDS-based gels typically results in a binding of 1.4 g of SDS/1 g of denatured protein across many types of proteins ***(20)***, and it is this consistent ratio that allows proteins to be electrophoretically separated by log M_r. Interestingly, at lower concentrations of SDS, another stable protein binding state also exists (0.4 g/1 g of protein) which reportedly does not cause massive protein denaturation ***(20)***. In fact, Tyagi et al. ***(21)*** have shown that low amounts of SDS (0.02%) combined with pore-limit electrophoresis could be used for the simultaneous determination of M_r and native activity. The existence of detergent–protein complexes, which exhibit consistent binding ratios without protein denaturation, represents an exciting prospect for the development of new electrophoretic techniques: protein M_r and activity may be identified by any of a variety of methods selected for applicability to a specific system.
3. Comparing CAT gels: The comparison of different CAT gel electrophoretograms depends on using the same separating gel, stacking gel, and sample buffer for each determination. An increase in the acrylamide%T in the separating gel will cause bands to shift toward the top of the gel, and high%T gels are more suitable for the separation of low M_r proteins. In addition, the use of acrylamide or high-percentage agarose stackers will lead to the determination of R_f values that are internally consistent, but uniformly lower than those determined in an identical gel with a low-percentage agarose stacker. This effect is likely owing to some separation of proteins in the stacking gel, but, nonetheless, to compare R_f values among CAT gels, the stacker of each gel should be the same. Similarly, any changes in sample preparation (for example, heating the sample before loading to dissociate protein subunits) or the sample buffer used (for example, the addition of salt or urea to increase sample solubilization) often precludes direct comparisons to standard CAT gel electrophoretograms.
4. Characteristics of system components: The CAT gel system is designed around the detergent CTAB. The other system components were selected

based on the cationic charge of CTAB and the desire to operate the gel near neutral pH. Some of the important physical characteristics of system components are summarized here; the values reported are from information supplied by manufacturers and *Data for Biochemical Research* ***(22)***.

In solution, CTAB exists in both monomer and micelle forms. CTAB has a monomer mol wt of 365 Dalton. At room temperature and in low-ionic-strength solutions (<0.05 *M* Na^+), CTAB has a critical micelle concentration (CMC) of about 0.04% (≈1 m*M*). The CMC may be defined as the concentration of detergent monomer that may be achieved in solution before micellization occurs; it depends on temperature, ionic strength, pH, and the presence of other solutes. The actual CMC of CTAB in the solutions used in the CAT gel system is not known. In low-ionic-strength solutions (< 0.1 *M* Na^+), the mol wt of CTAB micelles is approx 62 kDa with about 170 monomers/micelle. The solubility of CTAB is also a function of ionic conditions and solution temperature, and CTAB will precipitate from CAT sample buffer at temperatures below 10–15°C.

Arginine is an amino acid used in CAT tank buffer to carry current toward the cathode. Arginine is a zwitterion. It has a mol wt of 174.2 Dalton and contains three pH-sensitive charge groups (pK_a =1.8, 9.0, 12.5) with an isoelectric point (pI) near pH 10.8. Arginine was selected as the zwitterionic stacking agent because of its basic pI: at near-neutral pH levels, arginine will be positively charged and will migrate toward the cathode when an electric current is applied. Arginine free base is used in CAT tank buffer, and the proper pH of the CAT tank buffer is arrived at by mixing an acidic solution of Tricine with a basic solution of arginine.

Tricine functions to maintain the desired pH levels throughout the system. Tricine has a mol wt of 179.2 Dalton, and a pK_a of 8.15 (there is also a second $pK_a \approx 3$). During electrophoresis, Tricine also functions as a counterion to carry current toward the anode during electrophoresis. Tricine-buffered solutions will tend to change pH as temperature changes (a drop in temperature from 25 to 4°C will result in a shift in pH of about 0.5 U). Also, at the pH used in CAT stacking gels and CAT sample buffer, Tricine has a relatively low buffering capacity; therefore, the pH of the stacker and sample buffer should be confirmed, especially when any additions or alterations are made to the standard recipes.

5. Bromine drip: CTAB is an ionic compound comprised of both cetyltrimethylammonium cations and bromide anions. During electrophoresis, bromide anions migrate toward the anode at the top of the CAT system. Since electrons are removed at the anode, molecular bromine (Br_2) is formed at the anode. Under standard conditions, Br_2 is a dense, highly reactive liquid. While running CAT gels, a small amount of Br_2 will drip from the anode, and, if the anode is located directly above the top of the gel, Br_2 may drip

onto the samples. The "bromine drip" problem may be avoided if the apparatus used in CAT gel electrophoresis is configured so that the anode is away from (or even below) the top of the gel. Substitution of the bromide anion during CTAB preparation (perhaps with chloride to make CTACl) would be useful; however, the authors know of no high-quality commercial source. It should also be noted that the accumulation of reactive Br_2 during electrophoresis may preclude the reuse of tank buffer.

6. CAT sample buffer: The CTAB component of CAT sample buffer precipitates at low temperature (below 10–15°C). Samples should be prepared at room temperature immediately prior to use. Protease inhibitors, for example, phenylmethylsulfonyl fluoride (PMSF), may be added to the sample buffer to inhibit endogenous protease activity. The potential effects of any sample buffer additives (including PMSF) on the enzyme of interest should be assessed in solution before using the additive. Also, to avoid contaminating samples with "finger proteins" from the experimenter's hands, gloves should be worn when handling samples or sample buffer.
7. Acrylamide CAT gels: The polymerization of acrylamide generally involves the production of acrylamide free radicals by the combined action of ammonium persulfate and TEMED. Oxygen inhibits acrylamide polymerization by acting as a trap for the ammonium persulfate and TEMED intermediate free radicals that are necessary to accomplish chemical crosslinking. It is important to degas acrylamide solutions prior to the addition of crosslinking agents. CTAB itself interferes with gel polymerization as well and should not be included with acrylamide solutions; in the case of agarose stacking gels, however, CTAB may be included. Also, we have noticed a slight increase in the time required for acrylamide polymerization in the presence of Tricine buffer, but Tricine does not apparently affect gel performance. Although gelation will occur in about 10–20 min, polymerization should be allowed to go to completion (1–2 h) before running the gel. Finally, to optimize gel performance and reproducibility, both degassing and polymerization should be done at room temperature: cooling a polymerizing gel does not accelerate gel formation, and warming a polymerizing gel may cause brittle matrices to form.

   The presence of residual crosslinking agents in the acrylamide matrix may result in the inhibition of some protein activities. An alternative method of gel formation that avoids the use of reactive chemical crosslinkers involves photoactivation of riboflavin to initiate acrylamide polymerization (*see* **ref. 23**). We have had success using acrylamide separating gels polymerized with ammonium persulfate and TEMED in combination with agarose stacking gels; however, in some instances, riboflavin polymerized gels may be useful.

8. Agarose CAT gels: When using agarose stackers, remove the comb carefully to avoid creating a partial vacuum in the wells. To avoid pulling the agarose stacker away from the underlying acrylamide separating gel, wiggle the comb so that air or liquid fills the sample wells as the comb is lifted out.
9. Smeared gels: During electrophoresis, proteins run as mixed micelles combined with CTAB and other solution components. The presence of other detergents or high levels of lipid in the sample solution may result in a heterogenous population of protein-containing micelles. In such cases, protein bands may appear indistinct or smeared. Samples that have been previously solubilized in another detergent or that contain high levels of lipid may not be suitable for subsequent CAT gel analysis. Also, precipitation may occur when CTAB is mixed with polyanions (e.g., SDS micelles or nucleic acids). Samples containing high levels of nucleic acid or SDS may not be suitable for CAT gel analysis owing to precipitation in the sample buffer. Furthermore, if the gel apparatus to be used for CAT gels is also routinely used for SDS-based gels, the apparatus should be thoroughly cleaned to remove traces of SDS prior to CAT gel analysis, especially from the gel plates. Interaction between SDS and CTAB during electrophoresis may cause the formation of heterogenous mixed micelles or the precipitation of the components, and will invariably result in smeared gels. Although it is not always possible, it is preferable to have a separate apparatus dedicated to CAT gel use in order to avoid this problem.
10. Staining gels and transfer membranes: In addition to the basic CBB staining of protein bands, CAT gels may be stained by a variety of other techniques. Silver staining ***(24)*** allows the detection of even trace amounts of proteins (1–10 ng), including any fingerprints or smudges that would be otherwise undetected. In silver staining it is, therefore, essential to wear gloves throughout the procedure, even when cleaning the glassware prior to assembly of the apparatus. When the CAT gel is done, stain it with CBB to visualize proteins. (It is a good idea to take a photograph of the gel at this point, but be careful when handling it to avoid smudging the surface.) Next, place the gel into a 10% glutaraldehyde solution and soak in a fume hood for 30 min with gentle shaking. Rinse the gel well with distilled water for at least 2 h (preferably overnight) changing the water frequently; the gel will swell and become soft and somewhat difficult to handle while it is in the water. Combine 1.4 mL NH_4OH (concentrated solution ≈ 14.8 *M*) and 21.0 mL 0.36% NaOH (made fresh); add approx 4.0 mL of 19.4% $AgNO_3$ (made fresh) with constant swirling. A brown precipitate will form as the $AgNO_3$ is added, but it will quickly disappear; if it does not, a small amount of additional NH_4OH (just enough to dissolve the precipitate) may be added. Soak the gel in the ammoniacal/silver

solution for 10 min with shaking. Pour off the ammoniacal/silver solution and precipitate the silver with HCl. Transfer the gel to a fresh dish of distilled water and rinse for 5 min with two or three changes of water. Decant the water and add a freshly prepared solution of 0.005% citric acid and 0.019% formaldehyde (commercial preparations of formaldehyde are 37% solutions); bands will become visible at this point. Stop the silver-staining reaction by quickly rinsing the gel in water followed by soaking in a solution of 10% acetic acid and 20% methanol. Silver-staining takes a little practice to do well.

Transfer blots may be stained by a variety of conventional techniques. Two rapid and simple procedures are as follows: **Step (1)** Rinse the membrane briefly in phosphate-buffered saline containing 0.1% Tween 20 (PBS/Tw); soak the membrane in 0.1% solution of India ink in PBS/Tw until bands are detected (10 to 15 min.); rinse the blot in PBS/Tw. **Step (2)** Rinse the membrane briefly in phosphate-buffered saline (PBS); soak the blot in 0.2% Ponceau-S (3-hydroxy-4-(2-sulfo-4(sulfo-phenylazo) phenylazo)-2,7-naphthalene disulfonic acid) in 3% trichloroacetic acid and 3% sulfosalicylic acid for 10 min.; rinse the blot in PBS until bands appear. Ponceau S can be stored as a 10X stock solution and diluted with distilled water just prior to use. Staining with Ponceau-S is reversible, so blots should be marked at the position of mol-wt markers before continuing. When higher sensitivity is required to visualize bands, transfer membranes may be stained with ISS Gold Blot (Integrated Separation Systems, Natick, MA.

11. Enzyme activities and protein banding patterns: The histochemical detection of proteins in CAT gels is generally a straightforward process of soaking the gel in reaction buffer, so that the necessary compounds penetrate the gel, followed by the addition of substrate; however, not all enzymes retain detectable levels of activity when solubilized in CTAB or when they are run on CAT gels. It is a good idea to check the relative activity of the protein of interest in a CTAB-containing solution vs standard reaction buffer prior to investing time and effort into running a CAT gel. Of the proteins that do retain detectable the levels of activity, there are substantial differences in the level of retained activity after solubilization in CTAB. There is also the possibility that the protein of interest will run anomalously in CAT gels. Anomalous migration may occur owing to differential CTAB binding, conformational differences in the protein/CTAB mixed micelle, or the presence of previously unrecognized subunits or associated proteins. Unexpected enzyme histochemistry patterns in samples with the expected CBB protein staining pattern may reflect the presence of cofactors or other protein/protein interactions that are necessary for activity and should be interpreted accordingly.

It should also be pointed out that the intensity of a histochemical or binding assay does not necessarily reflect the actual level of enzyme in the sample. The rate of histochemical reaction within the gel matrix is not necessarily linear with respect to the amount of enzyme present: measured product also depends on the amount of substrate present and the ratio of product to substrate over time as well as the response of the detection apparatus. Reactions should be performed with an excess of substrate at the outset and should preferably be calibrated based on the varying level of a standard activity. Also, as with all detergents, CTAB may differentially solubilize proteins in a given sample, depending on the overall solution conditions. The detergent/protein solution is a complex equilibrium that may be shifted, depending on the level of other materials (proteins, lipids, salts, and so on) in the solution. When seeking to compare protein profiles on CAT gels, it is advisable to prepare samples from the same initial buffer and to solubilize at a uniform CTAB-to-protein ratio.

Acetic Acid–Urea Polyacrylamide Gel Electrophoresis of Basic Proteins

Jakob H. Waterborg

1. Introduction

Panyim and Chalkley described in 1969 a continuous acetic acid–urea (AU) gel system that could separate very similar basic proteins based on differences in size and effective charge ***(1)***. For instance, unmodified histone H4 can be separated from its monoacetylated or monophosphorylated forms ***(2)***. At the acidic pH 3 of this gel system, basic proteins with a high isoelectric point will clearly have a net positive charge that will be the major determinant of electrophoretic mobility. If a single of these positive charges is removed, for example, by in vivo acetylation of one of the positively charged ε-amino lysine side chain residues in the small histone H4 protein (102 residues), a significant decrease in effective gel mobility is observed. Similarly, addition of a phosphate moiety decreases the net positive charge of the protein during gel electrophoresis by one. Separation between similarly sized and charged proteins, for example, the partially acetylated H2A, H2B, and H3 histones of most organisms, can typically be achieved only by inclusion of a nonionic detergent such as Triton X-100 (*see* Chapter 28).

In 1980, Bonner and co-workers introduced a discontinuous acetic acid–urea–Triton (AUT) variation that avoids the necessity for exhaustive preelectrophoresis ***(3)***, prevents deformation of sample wells ***(4)*** and generally produces much sharper, straighter bands. Omission of Triton from this method creates the high capacity and high resolution AU gel electrophoresis protocol described in **Subheading 3**. **Figure 1** shows an example of the possibilities and limitations of the AU gel system. Yeast histones were extracted from four parallel cultures using a novel method that preserves all postsynthetic modifications ***(5)***. The separation of single-charge differences, proven to be caused by acetylation of

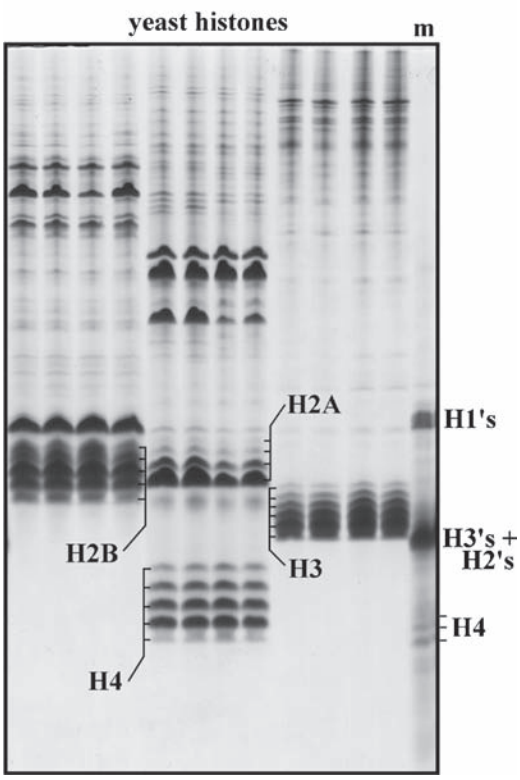

Fig. 1. Histones of the yeast *Saccharomyces cerevisiae* were extracted from crude nuclei, prepared in such a way that protein integrity and postsynthetic modifications were maintained ***(5)***. Histones from four parallel cultures (approx 2×10^{10} cells) were extracted, fractionated by reversed-phase HPLC into pools containing histone H2B (*left four lanes*), coeluting histone H2A and H4 (*center four lanes*) and histone H3 (*right four lanes*). In each histone species, the fastest mobility band represents nonacetylated histone. In each slower moving species one more lysine has been acetylated, neutralizing the positive charge of the lysine side chain, reducing the protein gel mobility by one charge. Virtually all low-mobility nonhistone proteins in this gel can be removed from yeast histone preparations by 100,000 mol wt ultrafiltration ***(5)***. The "m" indicates a marker lane with total calf thymus histones. Calf histone species are marked along the side. Note the closely overlapping pattern of H2A, H2B, and H3 histones. The long AU separating gel was 1 mm thick, 19 cm wide, and 27 cm long. The top of the gel is visible at the top of the figure. Electrophoresis was at 250 V constant voltage for 20 h with electrical current decreasing from 22 mA to 6 mA. The electrophoretic front, visualized using methylene blue, was below the lower edge of the figure, close to the lower margin of the gel. The gel was stained overnight in Coomassie, destained in 4 h with two aliquots of polyurethane foam, and digitized under standard conditions on a UMAX Powerlook II flatbed scanner with transilluminator.

lysines, is clearly demonstrated for each histone species (**Fig. 1**). It is clear that, without fractionation, the patterns of H2B, H2A, and H3 histones would overlap, preventing quantitation of each protein and its acetylation. Protein band shapes are generally sharp and straight. Compression of band shapes, visible for some high-abundance nonhistone proteins with lower gel mobilities shown in **Fig. 1**, can be minimized by decreasing the protein concentration during gel stacking by increasing gel thickness.

AU gels are currently used for very dissimilar proteins with isoelectric points lower than those of histones but sufficiently above pH 3 to be positively charged during gel electrophoresis. Examples include neutrophil defensins ***(6)***, antimicrobiol nasal secretions ***(7)***, enzymes like tyrosinase ***(8)***, serum isoenzymes ***(9)***, chemokines ***(10)*** and basic protamines ***(11)***. Typically curved, somewhat diffuse protein bands, characteristic for native, non-stacking electrophoretic gel separations are obtained. The superior discontinuous gel system described here has only been used for histones, producing clearer bands in a shorter period of time than achievable in continuous AU gel modes ***(1–2)***.

2. Materials

1. Vertical gel apparatus for short (15 cm) or long (30 cm) slab gels. A gel electrophoresis apparatus that allows gel polymerization between the glass plates with spacers, without necessarily being assembled in the apparatus, is preferable. This facilitates the even and complete photopolymerization of the acrylamide gel. In this type of apparatus the glass–gel sandwich is typically clamped to the lower buffer reservoir, which acts as a stand, after which the upper buffer reservoir is clamped to the top of the gel assembly.

   Details of the procedure are described for a fairly standard and flexible gel apparatus that uses two rectangular glass plates (4 mm thick standard plate glass with sanded edges), 21 cm wide and 32.5 and 35.5 cm long, respectively. The Plexiglas bottom buffer reservoir with platinum electrode is 22.5 cm wide with three sides 5 cm high and one of the long sides 12.5 cm high. The glass plates are clamped to this side. The upper buffer reservoir with platinum electrode and a similar buffer capacity is 18 cm wide with one long side enlarged to measure 21 cm wide by 10 cm high. It contains a cutout of 18 cm wide and 3.5 cm high that allows access of the upper reservoir buffer to the top of the gel. The 21-cm-wide Plexiglas plate is masked with 5-mm-thick closed-cell neoprene tape (weather strip) and provides a clamping ridge for attachment to the top of the glass-gel sandwich.
2. Spacers and combs are cut from 1-mm Teflon sheeting. High-efficiency fluorography may benefit from 0.5-mm spacers. Teflon up to 3 mm thick is less easy to cut but yields very high capacity gels (*see* **Note 1**).

   Two side spacers (1.5 × 35 cm) and one bottom spacer (0.5 × 24 cm) are required. Added to the top of the side spacers is 3 cm adhesive, closed-cell neoprene tape (weather strip, 14 mm wide and 5 mm thick). This is not required if a more expensive glass plate with "rabbit ears" is used instead of the rectangular shorter plate.

Combs have teeth 5–10 mm wide and 25–50 mm long, separated by gaps of at least 2.5 mm. For the detailed protocol described, a 15-cm-wide comb with 20 teeth of 5 × 30 mm is used.

3. Vaseline pure petroleum jelly.
4. Acrylamide stock solution: 60% (w/v) acrylamide, highest quality available, in water (*see* **Note 2**). The acrylamide is dissolved by stirring. Application of heat should be avoided, if possible, to prevent generating acrylic acid. The solution can be kept at least for 3 mo on the laboratory shelf at room temperature. Storage at 4°C can exceed 2 yr without detectable effects.
5. *N,N′* -methylene bis-acrylamide stock solution: 2.5% (w/v) in water (*see* **Note 2**).
6. Glacial acetic acid (HAc): 17.5 *M*.
7. Concentrated ammonium hydroxide: NH_4OH, 28–30%, approx 15 *M*.
8. *N, N, N′*, *N′* -Tetramethylenediamine (TEMED), stored at 4°C.
9. Riboflavin-5′ -phosphate (R5P) solution: 0.006% (w/v) in water. This solution is stable for more than 6 mo if kept dark and stored at 4°C.
10. Urea, ultrapure quality.
11. Side-arm suction flasks with stoppers, magnetic stirrer, stirrer bar, and water-aspirator vacuum; measuring cylinders with silicon-rubber stoppers; pipets, and pipetting bulbs or mechanical pipetting aids; 1- and 5-mL plastic syringes, with 20-gauge needles.
12. Fluorescent light box with diffuser for even light output and with the possibility to stand vertically. Light intensity should equal or exceed 5 klx at a distance of 5–10 cm. A high-quality X-ray viewing light box with three 40-W bulbs typically will meet this specification.
13. Aluminum foil.
14. Electrophoresis power supply with constant voltage mode at 300–500 V with up to 50 mA current, preferably with a constant power mode option.
15. Urea stock solution: 8 *M* urea in water. An aliquot of 40 mL with 1 g of mixed-bed resin (Bio-Rad [Hercules, CA] AG 501-X8) can be used repeatedly over a period of months if refrozen and stored between use at −20°C (*see* **Note 3**).
16. Phenolphthalein indicator solution: 1% (w/v) in 95% ethanol, stored indefinitely at room temperature in a closed tube.
17. Dithiothreitol (DTT, Cleland's reagent) is stored at 4°C and is weighed freshly for each use.
18. Methylene blue running front indicator dye solution: 2% (w/v) in sample buffer (*see* **Subheading 3.1., step 22**).
19. Reference histones: Total calf thymus histones (Worthington, Freehold, NJ), stored dry at 4°C indefinitely or in solution at −80°C in 50-µL aliquots of 5 mg/mL in water for more than 1 yr (*see* **Subheading 3.1., step 23**).
20. Glass Hamilton microsyringe (100 µL) with Teflon-tipped plunger.
21. Electrophoresis buffer: 1 *M* acetic acid, 0.1 *M* glycine (*see* **Note 4**). This solution can be made in bulk and stored indefinitely at room temperature.
22. Destaining solution: 20% (v/v) methanol, 7% (v/v) acetic acid in water.
23. Staining solution: Dissolve a fresh 0.5 g of Coomassie Brilliant Blue R250 in 500 mL of destaining solution for overnight gel staining (*see* **Note 5**). For rapid

staining within the hour the dye concentration should be increased to 1% (w/v). If the dye dissolves incompletely, the solution should be filtered through Whatman no. 1 paper to prevent staining artifacts.

24. Glass tray for gel staining and destaining.
25. Rotary or alternating table top shaker.
26. Destaining aids: Polyurethane foam for Coomassie-stained gels or Bio-Rad ion-exchange resin AG1-X8 (20–50-mesh) for Amido Black-stained gels.

3. Method

1. Assemble a sandwich of two clean glass plates with two side spacers and a bottom spacer, lightly greased with Vaseline to obtain a good seal, clamped along all sides with 2-in binder clamps. The triangular shape of these clamps facilitates the vertical, freestanding position of the gel assembly a few centimeters in front of the vertical light box.
2. Separating gel solution: Pipet into a 100-mL measuring cylinder 17.5 mL of acrylamide stock solution, 2.8 mL of *bis*-acrylamide stock solution, 4.2 mL of glacial acetic acid, and 0.23 mL of concentrated ammonium hydroxide (*see* **Notes 2** and **6**).
3. Add 33.6 g of urea and add distilled water to a total volume of 65 mL.
4. Stopper the measuring cylinder, and place on a rotary mixer until all urea has dissolved. Add water to 65 mL, if necessary.
5. Transfer this solution to a 200-mL sidearm flask with magnetic stir bar on a magnetic stirrer. While stirring vigorously, stopper the flask and apply water-aspirator vacuum. Initially, a cloud of small bubbles of dissolved gas arises, which clears after just a few seconds. Terminate vacuum immediately to prevent excessive loss of ammonia.
6. Add 0.35 mL of TEMED and 4.67 mL of R5P (*see* **Note 7**), mix, and pipet immediately between the glass plates to a marking line 5 cm below the top of the shorter plate (*see* **Notes 2** and **8**).
7. Carefully apply 1 mL of distilled water from a 1-mL syringe with needle along one of the glass plates to the top of the separating gel solution to obtain a flat separation surface.
8. Switch the light box on, and place a reflective layer of aluminum foil behind the gel to increase light intensity and homogeneity (*see* **Note 1**). Gel polymerization becomes detectable within 2 min and is complete in 15–30 min.
9. Switch the light box off, completely drain the water from between the plates, and insert the comb 2.5 cm between the glass plates. The tops of the teeth should always remain above the top of the short glass plate.
10. Stacking gel solution, made in parallel to **steps 2–4**: Into a 25-mL measuring cylinder, pipet 1.34 mL of acrylamide stock solution, 1.28 mL of *bis*-acrylamide stock solution, 1.14 mL of glacial acetic acid, and 0.07 mL of concentrated ammonium hydroxide (*see* **Notes 2** and **6**).
11. Add 9.6 g of urea, and add distilled water to a total volume of 18.6 mL.
12. Stopper the measuring cylinder, and place on a rotary mixer until all urea has dissolved. Add water to 18.6 mL, if necessary.

13. Once the separating gel has polymerized, transfer the stacking gel solution to a 50-mL sidearm flask with stir bar and degas as described under **step 5**.
14. Add 0.1 mL of TEMED and 1.3 mL of R5P, mix, and pipet between the plates between the comb teeth. Displace air bubbles.
15. Switch the light box on, and allow complete gel polymerization in 30–60 min.
16. Prepare sample buffer freshly when the separation gel is polymerizing (**step 8**). The preferred protein sample is a salt-free lyophilisate (*see* **Note 9**). Determine the approximate volume of sample buffer required, depending on the number of samples.
17. Weigh DTT into a sample buffer preparation tube for a final concentration of 1 *M*, that is, 7.7 mg/mL.
18. Per 7.7 mg of DTT add 0.9 mL of 8 *M* urea stock solution, 0.05 mL of phenolphtalein, and 0.05 mL of NH_4OH to the tube to obtain the intensely pink sample buffer.
19. Add 0.05 mL of sample buffer/sample tube with lyophilized protein to be analyzed in one gel lane (*see* **Note 10**). To ensure full reduction of all proteins by DTT, the pH must be above 8.0. If the pink phenolphtalein color disappears owing to residual acid in the sample, a few microliters of concentrated ammonium hydroxide should be added to reach an alkaline pH.
20. Limit the time for sample solubilization and reduction to 5 min at room temperature to minimize the possibility of protein modification at alkaline pH by reactive urea side reactions, for example, by modification of cysteine residues by cyanate.
21. Acidify the sample by adding 1/20 volume of glacial acetic acid.
22. To each sample add 2 µL of methylene blue running front dye (*see* **Note 11**).
23. Prepare appropriate reference protein samples: To 2 and 6 µL of reference histone solution with 10 and 30 µg total calf thymus histones, add 40 µL of sample buffer (**step 18**), 2.5 µL of glacial acetic acid, and 2 µL of methylene blue.
24. When stacking gel polymerization is complete, remove the comb. Drain the wells completely, using a paper tissue as wick, to remove residual unpolymerized gel solution. At comb and spacer surfaces, gel polymerization is typically incomplete. The high urea concentration of unpolymerized gel solution interferes with the tight application of samples.
25. Remove the bottom spacer from the bottom of the gel assembly and use it to remove any residual Vaseline from the lower surface of the gel.
26. Clamp the gel assembly into the electrophoresis apparatus and fill the lower buffer reservoir with electrophoresis buffer.
27. Use a 5-mL syringe with a bent syringe needle to displace any air bubbles from the bottom of the gel.
28. Samples are applied deep into individual sample wells using a Hamilton microsyringe (rinsed with water between samples) (*see* **Note 12**). For the combination of comb and gel dimensions listed, 50-µL sample will reach a height of 1 cm (*see* **Note 8**). Samples can also be applied to sample wells by any micropipetter with plastic disposable tip. Pipet each sample solution against the long glass plate and let it run to the bottom of the well.

29. Apply reference samples in the outer lanes, which frequently show a slight loss of resolution due to edge effects. The threefold difference in reference protein amounts facilitates correct orientation of the gel following staining and destaining and obviates the need for additional markings. Optionally, apply 50 µL of acidified sample buffer to unused lanes.
30. Gently overlayer the samples with electrophoresis buffer, dispensed from a 5-mL syringe fitted with a 21-gauge needle until all wells are full.
31. Fill the upper buffer reservoir with electrophoresis buffer.
32. Attach the electrical leads between power supply and electrophoresis system: the + lead to the upper and the – lead to the lower reservoir. Note that this is opposite to the SDS gel electrophoresis configuration. Remember, basic proteins such as histones are positively charged and will move toward the cathode (negative electrode).
33. Long (30-cm) gels require 15–20 h of electrophoresis at 300 V in constant voltage mode. They are most easily run overnight. For maximum resolution and stacking capacity, the initial current through a 1-mm thick and 18-cm-wide gel should not exceed 25 mA. Gel electrophoresis is completed in the shortest amount of time in constant power mode with limits of 300 V, 25 mA, and 5 W. The current will drop towards completion of electrophoresis to 6 mA at 300 V.

    Short (15-cm) gels are run at 250 V in constant voltage mode with a similar maximal current, or in constant power mode starting at 25 mA. In the latter example, electrophoresis starts at 25 mA and 135 V, and is complete in 5.5 h at 13 mA and 290 V (*see* **Note 13**).
34. Electrophoresis is complete just before the methylene blue dye exits the gel. Obviously, electrophoresis may be terminated if lesser band resolution is acceptable, or may be prolonged to enhance separation of basic proteins with low gel mobilities, for example, histone H1 variants or phosphorylated forms of histone H1.
35. Open the glass–gel sandwich, and place the separating gel into staining solution, which is gently agitated continuously overnight on a shaker (*see* **Note 14**).
36. Decant the staining solution. The gel can be given a very short rinse in water to remove all residual staining solution.
37. Place the gel in ample destaining solution (*see* **Note 15**). Diffusion of unbound Coomassie dye from the gel is facilitated by the addition of polyurethane foam as an absorbent for free Coomassie dye. To avoid overdestaining and potential loss of protein from the gel (*see* **Note 14**), destaining aids in limited amounts are added to only the first and second destaining solutions. Final destaining is done in the absence of any destaining aids.
38. Record the protein pattern of the gel on film or on a flatbed digital scanner (*see* **Note 16**), possibly with quantitative densitometry ***(12)***. Subsequently the gel may be discarded, dried, eluted, blotted ***(6)***, or prepared for autoradiography or fluorography as required.

4. Notes

1. Owing to absorbance of the light that initiates gel polymerization, gels thicker than 1.5 mm tend to polymerize better near the light source and produce protein bands that are not perpendicular to the gel surface. For very thick gels, two high-intensity light boxes, placed at either side of the gel assembly, may be required for optimal gel polymerization and resolution.
2. All acrylamide and *bis*-acrylamide solutions are potent neurotoxins and should be dispensed by mechanical pipetting devices.
3. Storage of urea solutions at −20°C minimizes creation of ionic contaminants such as cyanate. The mixed-bed resin ensures that any ions formed are removed. Care should be taken to exclude resin beads from solution taken, for example, by filtration through Whatman no. 1 paper.
4. The stacking ions between which the positively charged proteins and peptides are compressed within the stacking gel during the initial phase of gel electrophoresis are NH_4^+ within the gel compartment and glycine$^+$ in the electrophoresis buffer. Chloride ions interfere with the discontinuous stacking system (*see* **Note 7**). This requires that protein samples should (preferably) be free of chloride salts, and that glycine base rather than glycine salt should be used in the electrophoresis buffer.
5. Amido Black is an alternate staining dye which stains less intensely and destains much slower than Coomassie, but is the better stain for peptides shorter than 30–50 residues.
6. The separating and stacking gels contain 15 vs 4% acrylamide and 0.1 vs 0.16% *N,N′* -methylene (*bis*-acrylamide), respectively, in 1 *M* acetic acid, 0.5% TEMED, 50 m*M* NH_4OH, 8 *M* urea, and 0.0004 % riboflavin-5′-phosphate.

   We have observed that 8 M urea produces the highest resolution of histones in these gels when Triton X-100 is present (*see* Chapter 28). Equal or superior resolution of basic proteins has been reported for AU gels when the urea concentration is reduced to 5 *M*.
7. Acrylamide is photopolymerized with riboflavin or riboflavin 5 -phosphate as initiator, because the ions generated by ammonium persulfate initiated gel polymerization, as used for SDS polyacrylamide gels, interfere with stacking (*see* **Note 4**).
8. The height of stacking gel below the comb determines the volume of samples that can be applied and fully stacked before destacking at the surface of the separating gel occurs. In our experience, 2.5-cm stacking gel height suffices for samples that almost completely fill equally long sample wells. In general, the single blue line of completely stacked proteins and methylene blue dye should be established 1 cm above the separating gel surface. Thus, a 1–1.5 cm stacking gel height will suffice for small-volume samples.
9. Salt-free samples are routinely prepared by exhaustive dialysis against 2.5% (v/v) acetic acid in 3500 molecular weight cutoff dialysis membranes,

followed by freezing at −70°C and lyophilization in conical polypropylene tubes (1.5-, 15-, or 50-mL, filled up to half of nominal capacity) with caps punctured by 21-gauge needle stabs. This method gives essentially quantitative recovery of histones, even if very dilute.

Alternatively, basic proteins can be precipitated with trichloroacetic acid or acetone, acidified by hydrochloric acid to 0.02 *N*, provided that excess salt and acidity is removed by multiple washes with acetone.

Solutions of basic proteins can be used directly, provided that the solution is free of salts that interfere with gel electrophoresis (*see* **Note 11**) and that the concentration of protein is high enough to compensate for the 1.8-fold dilution that occurs during sample preparation. Add 480 mg of urea, 0.05 mL of phenolphthalein, 0.05 mL of concentrated ammonium hydroxide, and 0.05 mL of 1 *M* DTT (freshly prepared) per milliliter sample. If not pink, add more ammonium hydroxide. Leave for 5 min at room temperature. Add 0.05 mL of glacial acetic acid. Measure an aliquot for one gel lane and continue at **step 22**.

10. The amount of protein that can be analyzed in one gel lane depends highly on the complexity of the protein composition. As a guideline, 5–50 µg of total calf thymus histones with five major proteins (modified to varying extent) represents the range between very lightly to heavily Coomassie-stained individual protein bands in 1-mm-thick, 30-cm-long gels using 5-mm-wide comb teeth.
11. Methylene blue is a single blue dye that remains in the gel discontinuity stack of 15% acrylamide separating gels (*see* **Note 4**). Methyl green is an alternate dye marker that contains methylene blue together with yellow and green dye components that remain together in discontinuous mode but that in continuous gel electrophoresis show progressively slower gel mobilities (*see* **Note 17**).
12. As an alternative to **step 28,** electrophoresis buffer is added to the upper buffer reservoir, and all sample wells are filled. Samples are layered under the buffer when dispensed by a Hamilton microsyringe near the bottom of each well. The standard procedure tends to prevent mixing of sample with buffer and thus retains all potential stacking capability.
13. Long gels used in overnight electrophoresis are made on the day that electrophoresis is started. The time for preparation of short gels may prevent electrophoresis on the same day. The nature of the stacking system of the gel (*see* **Note 4**) allows one to prepare a gel on day 1, to store it at room temperature overnight and to initiate electrophoresis on the morning of day 2. To prevent precipitation of urea, gels should not be stored in a refrigerator. The gels should not be stored under electrophoresis buffer as glycine would start to diffuse into the gel and destroy the stacking capability of the system. We routinely store short gels overnight once polymerization is complete

(*see* **step 15**) and before bottom spacer and comb are removed. Saran Wrap® is used to prevent exposed gel surfaces from drying.

14. Be warned that small and strongly basic proteins such as histones are not fixed effectively inside 15% acrylamide gels in methanol–acetic acid without Coomassie. Comparison of identical gels, one fixed and stained as described and the other placed first in destain solution alone for several hours, followed by regular staining by Coomassie, reveals that 90% or more of core histones are lost from the gel. We speculate that the Coomassie dye helps to retain histones within the gel matrix. This is consistent with the observation that gradual loss of Coomassie intensity of histone bands is observed upon exhaustive removal of soluble dye.
15. Note that the gel increases significantly in size when transferred from the gel plates into the staining solution. The compositions of staining and detaining solvent mixtures are identical and changes in gel size are not observed upon destaining.
16. A standard method to record the protein staining pattern in Coomassie-stained polyacrylamide gels has been Polaroid photography, using an orange filter to increase contrast, with the gel placed on the fluorescent light box, covered by a glass plate to prevent Coomassie staining of the typical plastic surface. Polaroid negatives can be scanned but suffer from a nonlinear response of density, even within the range in which careful Coomassie staining leads to near-linear intensity of protein band staining.

    With the advent of 24+ bit color flatbed scanners with transmitted light capabilities and linear density capabilities in excess of three optical densities, it has become easy to record, and quantitate, intensity of protein staining patterns. Care should be taken to develop a standard scanning setup, using the full dynamic range (typically all three colors used at their full range, 0–255 for a 24-bit scanner, excluding automatic adjustments for density and contrast). A standard gamma correction value should be determined, using an optical density wedge (Kodak), to ensure that the density response is linear. Placing a detained polyacrylamide gel on the gel scanner, one should cover the top of the gel with an acetate film to prevent surface reflection abnormalities and prevent touching of the transilluminating light source surface to the film, avoiding moiré interference patterns. Recording gel patterns at 300 dpi in full color and saving loss-less tiff files facilitates faithful replication of experimental results (**Fig. 1**). Quantitative densitometry programs can use the image files.
17. Gel preelectrophoresis until the methylene blue dye, and thus all ammonium ions (*see* **Note 4**), have exited the separating gel converts this gel system into a continuous one. This option can be used to separate small proteins and peptides that do not destack at the boundary with the separating gel. Although this option is available, one should consider alternatives,

such as increasing the acrylamide concentration of the separating gel. West and co-workers have developed a system with 40–50% polyacrylamide gels that is similar to the one described here and that has been optimized for the separation of small basic peptides ***(13)***.

Acid–Urea–Triton Polyacrylamide Gel Electrophoresis of Histones

Jakob H. Waterborg

1. Introduction

Acid-urea polyacrylamide gels are capable of separating basic histone proteins provided they differ sufficiently in size and/or effective charge (*see* Chapter 27). Separation between similarly sized and charged molecules, such as the histones H2A, H2B, and the H3 forms of most organisms, can typically not be achieved. Zweidler discovered that core histones but not linker histones (*see* **Note 1**) bind the nonionic detergent Triton ***(1)***. Generally, Triton is added to an acetic acid-urea (AU) gel system to separate core histone sequence variants and histone species with overlapping AU gel patterns. This type of gel is known as an AUT or a TAU gel. To date, a single example is known where addition of Triton X-100 has allowed separation of a nonhistone primary sequence variation, the hydrophobic replacement variant of phenylalanine by leucine in fetal hemoglobin ***(2)***.

The binding of Triton to a core histone increases the effective mass of the protein within the gel without affecting its charge, and thus reduces its mobility during electrophoresis. Separation between most or all core histone proteins of diverse species can virtually always be obtained by adjusting concentrations of Triton and of urea, which appears to act as a counteracting, dissociating agent ***(3)***. Experimentally, an optimal balance can be determined by gradient gel electrophoresis with a gradient of urea ***(4)*** or Triton ***(5)***. The Triton gradient protocol in the discontinuous gel system, developed by Bonner and co-workers ***(6)***, is described in **Subheading 3**. It has a distinct advantage over the urea gradient protocol. Generally, it can identify a core histone protein band as belonging to histone H4, H2B, H3, or H2A. In this order the apparent affinities for Triton X-100 increase sharply ***(5,7,8)***. An example of such a separation of a crude

mixture of histones with nonhistone proteins from a tobacco callus culture is shown in **Fig. 1A**. In addition, a detailed working protocol for a long AUT gel at 9 m*M* Triton and 8 *M* urea is provided. It describes the protocol used extensively in my laboratory for the analysis of core histones, especially of histone H3, in dicot ***(7)*** and monocot plants ***(8)***, in the green alga *Chlamydomonas* ***(9)*** and in budding yeast *Saccharomyces cerevisiae* ***(10)***. **Figure 1B** shows an example of the differentially acetylated histone H3 variant proteins of tobacco, purified by reversed-phase high performance liquid chromatography (HPLC) ***(7)***. The protocol description parallels directly the acid-urea gel protocol described in Chapter 27 which also provides details for the use of different gel dimensions.

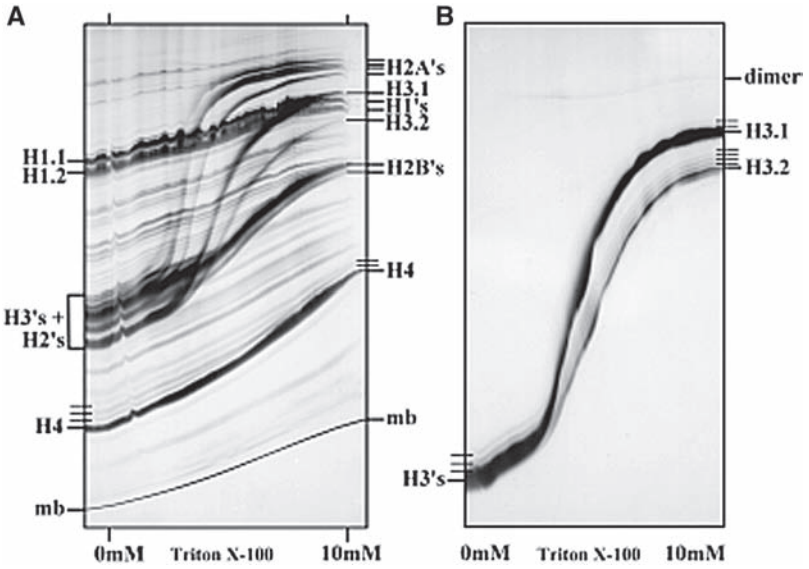

Fig. 1. Acid-urea gradient gel electrophoresis of tobacco histones. **(A)** A crude preparation of basic proteins, extracted from callus cultures of tobacco ***(7)***, was electrophoresed on the gradient AUT gel and stained with Coomassie, as described. Marks at top and bottom indicate the joints between the gel compartments, from left to right, 0 m*M* Triton, 0–10 m*M* Triton gradient, and 10 m*M* Triton. The buffer front is marked by the methylene blue dye (mb). The identified histone bands are marked: two variants for histone H1, histone H4 with detectable mono- through triacetylation, two histone H2B variants, two histone H3 variants (H3.1 and the more highly acetylated histone H3.2) and, at least four histone H2A variant forms. Note that the Triton affinity of the core histones increases in the typical order of H4, H2B, H3, and H_2A. **(B)** Tobacco histone H3, purified by reversed-phase HPLC as a mixture of low acetylated histone H3.1 and highly acetylated histone H3.2, on a gradient AUT gel. The 0 and 10 m*M* Triton concentrations coincide with the edge of the figure. The presence of a small amount of histone H3 dimer is indicated.

2. Materials

1. Vertical gel apparatus for long (30-cm) slab gels. A gel electrophoresis apparatus that allows gel polymerization between the glass plates with spacers, without being assembled in the apparatus, is required. This allows the even and complete photopolymerization of the acrylamide gel compartments in both orientations used. In this type of apparatus the glass-gel sandwich is typically clamped to the lower buffer reservoir, which acts as a stand, after which the upper buffer reservoir is clamped to the top of the gel assembly. Details of the procedure are described for a fairly standard and flexible gel apparatus that uses two rectangular glass plates (4-mm-thick standard plate glass with sanded edges), 21 cm wide and 32.5 and 35.5 cm long, respectively. The Plexiglas bottom buffer reservoir with platinum electrode is 22.5 wide with three sides 5 cm high and one of the long sides 12.5 cm high. To this side the glass plates are clamped. The upper buffer reservoir with platinum electrode and with a similar buffer capacity is 18 cm wide with one long side enlarged to measure 21 cm wide by 10 cm high. It contains a cutout of 18 cm wide and 3.5 cm high that allows access of the upper reservoir buffer to the top of the gel. The 21-cm wide Plexiglas plate is masked with 5-mm-thick closed-cell neoprene tape (weather strip), and provides a clamping ridge for attachment to the top of the glass–gel sandwich.
2. Spacers and combs are cut from 1 mm Teflon sheeting. Required are two side spacers (1.5 × 35 cm), one bottom spacer (0.5 × 24 cm) and, for the gradient gel, one temporary spacer (1.5 × 21 cm). Added to the top of the side spacers is 3-cm adhesive, closed-cell neoprene tape (weather strip, 14 mm wide and 5 mm thick). A 15-cm-wide comb with 20 teeth of 5 × 30 mm, cut from a rectangle of 15 × 5 cm Teflon, is used with the teeth pointing down for the regular gel and with the teeth pointing up as a block comb for the gradient gel.
3. Vaseline pure petroleum jelly.
4. Acrylamide stock solution: 60% (w/v) acrylamide, highest quality available, in water (*see* **Note 2**). The acrylamide is dissolved by stirring. Application of heat should be avoided, if possible, to prevent generating acrylic acid. The solution can be kept at least for 3 mo on the laboratory shelf at room temperature. Storage at 4°C can exceed 2 yr without detectable effects.
5. *N*,*N*′ -Methylene *bis*-acrylamide stock solution: 2.5% (w/v) in water (*see* **Note 2**).
6. Glacial acetic acid (HAc): 17.5 *M*.
7. Concentrated ammonium hydroxide: NH_4OH, 28–30%, approx 15 *M*.
8. Triton X-100 stock solution: 25% (w/v) in water (0.4 *M*) is used, as it is much easier to dispense accurately than 100%.
9. *N*,*N*,*N*′, *N*′ -Tetramethylenediamine (TEMED), stored at 4°C.
10. Riboflavin 5′-phosphate solutions: 0.006% (R5P) and 0.06% (R5P-hi) (w/v) in water. The lower concentration solution is used for the regular gel and for all stacking gels. It is stable for more than 6 mo if kept dark and stored at 4°C. Riboflavin 5′ -phosphate readily dissolves at the higher concentration, which is used for the gradient gel formulation, but it cannot be stored for more than 1 d at room temperature in the dark, as precipitates form readily upon storage at 4°C.

11. Glycerol.
12. Urea, ultrapure quality.
13. Side-arm suction flasks with stoppers, magnetic stirrer, stirrer bar, and water-aspirator vacuum. Measuring cylinders with silicon-rubber stoppers. Pipets and pipetting bulbs or mechanical pipetting aids. Plastic syringes, 1 and 5 mL, with 20-gauge needles.
14. Fluorescent light box with diffuser for even light output and with the possibility to stand vertically. Light intensity should equal or exceed 5 klx at a distance of 5–10 cm. A high-quality X-ray viewing light box with three 40-W bulbs typically will meet this specification.
15. Aluminum foil.
16. Gradient mixer to prepare a linear concentration gradient with a volume of 30 mL. We use with success the 50-mL Jule gradient maker (Research Products International, Mt. Prospect, IL) with two 25-mL reservoirs.
17. Electrophoresis power supply with constant voltage mode at 300–500 V with up to 50 mA current, preferably with a constant power mode option.
18. Urea stock solution: 8 *M* urea in water. An aliquot of 40 mL with 1 g of mixed-bed resin (Bio-Rad [Hercules, CA] AG 501-X8) can be used repeatedly over a period of months if refrozen and stored between uses at −20°C (*see* **Note 3**).
19. Phenolphthalein indicator solution: 1% (w/v) in 95% ethanol, stored indefinitely at room temperature in a closed tube.
20. Dithiothreitol (DTT, Cleland's reagent) is stored at 4°C and is weighed freshly for each use.
21. Methylene blue running front indicator dye solution: 2% (w/v) in sample buffer (*see* **Subheading 3.**, **step 16**).
22. Reference histones: Total calf thymus histones (Worthington, Freehold, NJ), stored dry at 4°C indefinitely or in solution at −80°C in 50-µL aliquots of 5 mg/mL in water for more than 1 yr (*see* **Subheading 3.**, **step 17**).
23. Glass Hamilton microsyringe (100 µL) with Teflon-tipped plunger.
24. Electrophoresis buffer: 1 *M* acetic acid, 0.1 *M* glycine (*see* **Note 4**). This solution can be made in bulk and stored indefinitely at room temperature.
25. Destaining solution: 20% (v/v) methanol, 7% (v/v) acetic acid in water.
26. Staining solution: Dissolve a fresh 0.5 g of Coomassie Brilliant Blue R250 in 500 mL of destaining solution. If the dye dissolves incompletely, the solution should be filtered through Whatman no. 1 paper to prevent staining artifacts.
27. Glass tray for gel staining and destaining.
28. Rotary or alternating table top shaker.
29. Destaining aid: Polyurethane foam.

3. Method

1. For the AUT regular gel, follow **steps a–i** and continue at **step 3**.
   a. Assemble a sandwich of two clean glass plates with two side spacers and a bottom spacer, lightly greased with Vaseline to obtain a good seal, clamped along all sides with 2-in binder clamps. The triangular shape of these clamps facilitates the vertical, freestanding position of the gel assembly a few centimeters in front of the vertical light box (**Fig. 2A**).

b. Separating gel solution: pipet into a 100-mL measuring cylinder 17.5 mL of acrylamide stock solution, 2.8 mL of *bis*-acrylamide stock solution, 4.2 mL of glacial acetic acid, and 0.23 mL of concentrated ammonium hydroxide solutions (*see* **Note 5**).
c. Add 33.6 g of urea and add distilled water to a total volume of 63.5 mL.
d. Stopper the measuring cylinder and place on a rotary mixer until all urea has dissolved. Add water to 63.5 mL, if necessary.
e. Transfer this solution to a 200-mL sidearm flask with magnetic stir bar on a magnetic stirrer. While stirring vigorously, stopper the flask and apply water-aspirator vacuum. Initially, a cloud of small bubbles of dissolved gas arises, which clears after just a few seconds. Terminate vacuum immediately to prevent excessive loss of ammonia.
f. Add 1.575 mL of Triton, 0.35 mL of TEMED and 4.67 mL of R5P (*see* **Note 6**), mix, and pipet immediately between the glass plates to a marking line 5 cm below the top of the shorter plate (*see* **Note 7**).
g. Carefully apply 1 mL of distilled water from a 1-mL syringe with needle along one of the glass plates to the top of the separating gel solution to obtain a flat separation surface.
h. Switch the light box on and place a reflective layer of aluminum foil behind the gel to increase light intensity and homogeneity. Gel polymerization becomes detectable within 2 min and is complete in 15–30 min.
i. Switch the light box off, completely drain the water from between the plates, and insert the comb 2.5 cm between the glass plates. The tops of the teeth should always remain above the top of the short glass plate.

2. For the Triton gradient gel, follow **steps a–q** and continue at **step 3**.
   a. Assemble a sandwich of two clean glass plates with one side spacer, a bottom spacer, and a temporary spacer, clamped with large binder clamps (Fig. 2B). The spacers are lightly greased with Vaseline to obtain a good seal but the amount of grease on the temporary spacer should be as low as possible. No grease should be present on the side of this spacer facing the buffer compartment to assure a flawless destacking surface. Place magic marker guidance lines at 4, 14, and 18 cm above the long side spacer (Fig. 2B). Place the assembly horizontally a few centimeters in front of the vertical light box and add a reflective layer of aluminum behind the gel.
   b. Heavy gel separating gel solution: Pipet into a 50-mL graduated, capped polypropylene tube, 4.0 mL of glycerol, 10 mL of acrylamide stock solution, 1.6 mL of bis-acrylamide stock solution, 2.4 mL of glacial acetic acid, and 0.13 mL of concentrated ammonium hydroxide. Add 19.2 g of urea. Add distilled water to a total volume of 38.5 mL (see Note 5).
   c. Light gel separating gel solution: Pipet into a 50-mL graduated, capped polypropylene tube, 10 mL of acrylamide stock solution, 1.6 mL of *bis*-acrylamide stock solution, 2.4 mL of glacial acetic acid, and 0.13 mL of concentrated ammonium hydroxide. Add 19.2 g of urea. Add distilled water to a total volume of 39.5 mL.

d. Place the closed tubes on a rotary mixer until all urea has dissolved. Add water to the required final volume, if necessary.
e. Transfer each solution to a 100-mL sidearm flask with magnetic stir bar on a magnetic stirrer. While stirring vigorously, stopper the flask and apply water-aspirator vacuum. Initially, a cloud of small bubbles of dissolved gas arises, which clears after just a few seconds. Terminate vacuum immediately to prevent excessive loss of ammonia.
f. Return the gel solutions after degassing to the capped tubes.
g. Add to the heavy gel solution 1.0 mL of Triton stock solution.
h. Wrap each tube into aluminum foil to protect the gel solution from light (*see* **Note 6**).
i. Prepare freshly concentrated (0.06%) riboflavin 5′ -phosphate (R5P-hi) solution (*see* **Subheading 2.**, **step 10**).
j. Add to each gel solution 0.20 mL of TEMED and 0.27 mL of R5P-hi, and mix.
k. Under conditions of darkness (or very reduced light levels), pipet approx 12 mL of heavy gel solution between the plates, up to the 4-cm heavy gel surface mark (Fig. 2B).
l. Turn the light box on for 2 min only. This allows the heavy gel to initiate polymerization and gelling, but retains sufficient unpolymerized acrylamide to fuse this gel partition completely into the gel layered on top.
m. In darkness, set up the gradient maker with 15 mL of heavy gel and 15 mL of light gel solutions and create slowly, over a period of at least several minutes, a linear gradient that flows slowly and carefully between the glass plates. Empirically, we have observed that a 10% increase over the calculated volume of the 27 × 10 × 0.1 cm gradient partition will create a gradient that is complete near the marker line between gradient and light partition (Fig. 2B).
n. Turn the light box on for 2 min only.
o. In darkness, slowly add light gel solution on top of the partially polymerized gradient gel until the upper marker line.
p. Switch the light box on for complete gel polymerization in 15–30 min.
q. Remove the temporary spacer from the assembly. Insert a slightly greased spacer along the polymerized light gel. Reclamp the assembly. Insert the 20-well comb in the middle and upside down as a block comb for 2.5 cm below the edge of the shorter glass plate. Reposition the assembly vertically between light box and aluminum foil (**Fig. 2A**).

3. Stacking gel solution, made in parallel to **steps 1b–d** or **steps 2b–d**: Pipet into a 25-mL measuring cylinder 1.34 mL of acrylamide stock solution, 1.28 mL of *bis*-acrylamide stock solution, 1.14 mL of glacial acetic acid, and 0.07 mL of concentrated ammonium hydroxide (*see* **Note 5**).
4. Add 9.6 g of urea and add distilled water to a total volume of 18.6 mL.
5. Stopper the measuring cylinder and place on a rotary mixer until all urea has dissolved. Add water to 18.6 mL, if necessary.
6. Once the separating gel has polymerized, transfer the stacking gel solution to a 50-mL sidearm flask with stir bar and degas as in **step 1e**.
7. Add 0.1 mL of TEMED and 1.3 mL of R5P, mix and pipet between the plates between the comb teeth.

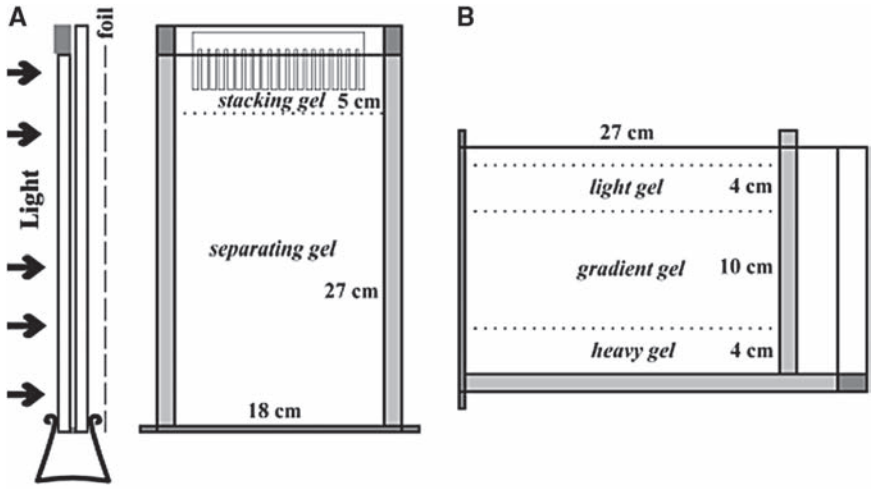

Fig. 2. **(A)** Side and front view of a long AUT gel assembly for 20 samples. The Teflon side spacers are shown in light gray, the bottom Teflon spacer and the neoprene blocks in dark gray. The fluorescent light source and reflecting aluminum foil are shown. One clamp is shown in the side view to demonstrate the independent vertical stand of this assembly and to represent the clamps all around the assembly at all spacer locations. **(B)** Front view of the AUT gradient assembly as used when the separation gel partitions are formed and polymerized.

8. Displace air bubbles, especially in the gradient assembly where residual Vaseline may interfere with gel solution flow. In this case, all (mini) bubbles should be carefully removed from the separation gel surface that will act as the destacking boundary.
9. Switch the light box on and allow complete gel polymerization in 30–60 min.
10. Sample buffer is freshly prepared when the separation gel is polymerizing. The preferred protein sample is a salt-free lyophilisate (*see* **Note 8**). For regular gels, determine the approximate volume of sample buffer required, depending on the number of samples. For a gradient gel 0.5–1.5 mL sample buffer appears optimal.
11. Weigh DTT into a sample buffer preparation tube for a final concentration of 1 *M*, that is, 7.7 mg/mL.
12. Per 7.7 mg of DTT, add 0.9 mL of 8 *M* urea stock solution, 0.05 mL of phenolphthalein, and 0.05 mL of concentrated ammonium hydroxide to the tube to obtain the intensely pink sample buffer.
13. Add 0.05 mL of sample buffer per sample tube with lyophilized protein to be analyzed in one gel lane (*see* **Note 9**). Add 1 mL of sample buffer to sample for one gradient gel. To assure full reduction of all proteins by DTT, the pH must be above 8.0. If the pink phenolphthalein color disappears because of residual acid in the sample, a few microliters of concentrated ammonium hydroxide should be added to reach an alkaline pH.

14. Limit the time for sample solubilization and reduction to 5 min at room temperature to minimize the possibility of protein modification at alkaline pH by reactive urea side reactions, for example, by modification of cysteine residues by cyanate.
15. Acidify the sample by addition of 1/20 volume of glacial acetic acid.
16. Add methylene blue running front dye: 2 µL per gel lane or 50 µL for a gradient gel.
17. For a regular AUT gel, prepare reference histone samples: To 2 and 6 µL reference histone solution with 10 and 30 µg of total calf thymus histones, one adds 40 µL sample buffer (**step 12**), 2.5 µL of glacial acetic acid, and 2 µL of methylene blue.
18. When stacking gel polymerization is complete, remove the comb. Drain the wells completely, using a paper tissue as wick, to remove residual unpolymerized gel solution. At comb and spacer surfaces, gel polymerization is typically incomplete. The high urea concentration of unpolymerized gel solution interferes with the tight application of samples.
19. Remove the bottom spacer from the gel assembly gel assembly and use it to remove any residual Vaseline from the lower surface of the gel.
20. Clamp the gel assembly into the electrophoresis apparatus and fill the lower buffer reservoir with electrophoresis buffer.
21. Use a 5-mL syringe with a bent syringe needle to displace any air bubbles from the bottom of the gel.
22. For regular gel, follow **steps a–c** and continue at **step 24**.
    a. Samples are applied deep into individual sample wells by Hamilton microsyringe (rinsed with water between samples) (*see* **Note 10**). For the combination of comb and gel dimensions listed, a 50-µL sample will reach a height of 1 cm (*see* **Note 7**). Samples can also be applied to sample wells by any micropipetter with plastic disposable tip. Pipet each sample solution against the long glass plate and let it run to the bottom of the well.
    b. Apply reference samples in the outer lanes, which frequently show a slight loss of resolution due to edge effects. The threefold difference in reference protein amounts facilitates correct orientation of the gel following staining and destaining and obviates the need for additional markings. Optionally, apply 50 µL of acidified sample buffer to unused lanes.
    c. Gently overlayer the samples with electrophoresis buffer, dispensed from a 5-mL syringe fitted with a 21-gauge needle until all wells are full.
23. For gradient gel, follow **steps a–c** and continue at **step 24**.
    a. Fill the block well with electrophoresis buffer.
    b. Use a level to confirm that the bottom of the preparative well is exactly horizontal.
    c. Distribute the total sample evenly across the width of the well using a 250-µL Hamilton microsyringe. Limited mixing of sample and electrophoresis buffer will facilitate even loading and is easily dealt with by the strong stacking capability of the gel system (*see* **Note 11**).
24. Fill the upper buffer reservoir with electrophoresis buffer.
25. Attach the electrical leads between power supply and electrophoresis system: the + lead to the upper and the – lead to the lower reservoir. Note that this is opposite to the SDS gel electrophoresis configuration. Remember, basic proteins such as histones are positively charged and will move toward the cathode (negative electrode).

26. Long (30-cm) gels require 15–20 h of electrophoresis at 300 V in constant voltage mode. They are most easily run overnight. For maximum resolution and stacking capacity the initial current through a 1 mm thick and 18 cm wide gel should not exceed 25 mA. Gel electrophoresis is completed in the shortest amount of time in constant power mode with limits of 300 V, 25 mA, and 5 W. The current will drop toward completion of electrophoresis to 6 mA at 300 V.
    Gradient gel electrophoresis typically takes a few more hours. At 300 V constant voltage the electrophoretic current is reduced, in particular at the heavy side of the gel due to the reduced water concentration caused by the inclusion of glycerol. The ion front with methylene blue dye reflects this in a distinct curvature (**Fig. 1A**).
27. Electrophoresis is complete just before the methylene blue dye exits the gel. Obviously, electrophoresis may be terminated earlier if lesser band resolution is acceptable, or may be prolonged to enhance separation of histones with low gel mobilities, for example, histone H3 variants (**Fig. 1B**).
28. Open the glass–gel sandwich and place the separating gel into staining solution, which is gently agitated continuously overnight on a shaker (*see* **Note 12**).
29. Decant the staining solution. The gel can be given a very short rinse in water to remove all residual staining solution.
30. Place the gel in ample destaining solution. Diffusion of unbound Coomassie dye from the gel is facilitated by the addition of polyurethane foam as an absorbent for free Coomassie dye. To avoid overdestaining and potential loss of protein from the gel, polyurethane foam in limited amounts is added to only the first and second destaining solutions. Final destaining is done in the absence of any foam.
31. Record the protein pattern of the gel on film (**Fig. 1**) or on a flatbed digital scanner (*see* **Note 13**). Subsequently the gel may be discarded, dried, or prepared for autoradiography or fluorography as required. Blotting of AUT gels requires removal of Triton to allow successful histone transfer (*see* **Note 14**).

4. Notes

1. Core histones share a 65-basepair helix-turn-helix-turn-helix histone-fold motif which is the basis of the hydrophobic pairwise interaction between histones H2A and H2B and between histones H3 and H4. Our studies of histone H3 variant proteins from HeLa, *Physarum* ***(11)***, Chlamydomonas ***(9)*** and several plant species ***(5, 7, 8)*** support the notion that the characteristic differences in Triton X-100 affinity—Triton affinity: H2A > H3 > H2B > H4 (**Fig. 1**)—depend on sequence differences at residues whose side chains are mapped to the inside of the histone fold ***(12, 13)***. To date, many proteins involved in DNA organization and transcription have been shown to share the histone fold, creating homo- and hetero-dimer complexes ***(14)***. However, none have yet been analyzed by AUT gradient gel electrophoresis to confirm the predicted interaction with Triton X-100.
2. All acrylamide and *bis*-acrylamide solutions are potent neurotoxins and should be dispensed by mechanical pipetting devices.

3. Storage of urea solutions at −20°C minimizes creation of ionic contaminants such as cyanate. The mixed-bed resin assures that any ions formed are removed. Care should be taken to exclude resin beads from solution taken, for example, by filtration through Whatman no. 1 paper.
4. The stacking ions between which the positively charged proteins and peptides are compressed within the stacking gel during the initial phase of gel electrophoresis are NH_4^+ within the gel compartment and glycine$^+$ in the electrophoresis buffer. Chloride ions interfere with the discontinuous stacking system. This requires that protein samples should (preferably) be free of chloride salts, and that glycine base rather than glycine salt should be used in the electrophoresis buffer.
5. The separating and stacking gels contain 15 vs 4% acrylamide and 0.1 vs 0.16% *N*,*N*′-methylene *bis*-acrylamide, respectively, in 1 *M* acetic acid, 0.5% TEMED, 50 m*M* NH_4OH, 8 *M* urea, and 0.0004% riboflavin 5 -phosphate. The concentration of Triton X-100 in the separating gel of the regular system is 9 m*M*, optimal for the separation desired in our research for histone H3 variant forms of plants and algae.
   In the gradient system, glycerol and Triton concentrations change in parallel: 10% (v/v) glycerol and 10 m*M* Triton in the heavy gel (**Fig. 2B**) and a gradient between 10 and 0% (v/v) glycerol and between 10 and 0 m*M* Triton in the gradient from heavy to light (**Fig. 2B**).
6. Acrylamide is photopolymerized with riboflavin or riboflavin 5′ -phosphate as initiator because the ions generated by ammonium persulfate initiated gel polymerization, as used for SDS polyacrylamide gels, interfere with stacking (*see* **Note 4**).
7. The height of stacking gel below the comb determines the volume of samples that can be applied and fully stacked before destacking at the surface of the separating gel occurs. In our experience, a 2.5 cm stacking gel height suffices for samples that almost completely fill equally long sample wells. In general, the single blue line of completely stacked proteins and methylene blue dye should be established 1 cm above the separating gel surface. Thus, 1–1.5 cm stacking gel height will suffice for small volume samples.
8. Salt-free samples are routinely prepared by exhaustive dialysis against 2.5% (v/v) acetic acid in 3500 mol wt cutoff dialysis membranes, followed by freezing at −70°C and lyophilization in conical polypropylene tubes (1.5-, 15-, or 50-mL, filled up to half of nominal capacity) with caps punctured by 21-gauge needle stabs. This method gives essentially quantitative recovery of histones, even if very dilute. (For alternative methods, *see* Chapter 27).
9. The amount of protein that can be analyzed in one gel lane depends highly on the complexity of the protein composition. As a guideline, 5–50 µg of total calf thymus histones with five major proteins (modified to varying extent) represents the range between very lightly to heavily

Coomassie-stained individual protein bands in 1-mm-thick, 30-cm-long gels using 5-mm-wide comb teeth.

The optimal amount of protein for a gradient gel also depends on the number of protein species that must be analyzed. In general, a gradient using the block comb used, equivalent to the width of 30 gel lanes, should be loaded with 30 times the sample for one lane.

10. As an alternative to **step 22**, electrophoresis buffer is added to the upper buffer reservoir and all sample wells are filled. Samples are layered under the buffer when dispensed by a Hamilton microsyringe near the bottom of each well.
11. The preparative well of a gradient gel should not be loaded with sample prior to the addition of electrophoresis buffer. Uneven distribution of sample cannot be avoided when buffer is added.
12. For unknown reasons, the polyacrylamide gel below the buffer front tends to stick tightly to the glass in an almost crystalline fashion. This may cause tearing of a gradient gel at the heavy gel side below the buffer front. Since attachment to one of the gel plates is typically much stronger, one can release the gel without problems by immersing the glass plate, with gel attached, in the staining solution.
13. A standard method to record the protein staining pattern in Coomassie-stained polyacrylamide gels has been Polaroid photography, using an orange filter to increase contrast, with the gel placed on the fluorescent light box, covered by a glass plate to prevent Coomassie staining of the typical plastic surface. Polaroid negatives can be scanned but suffer from a non-linear response of density, even within the range where careful Coomassie staining leads to near-linear intensity of protein band staining.

    With the advent of 24+ bit color flatbed scanners with transmitted light capabilities and linear density capabilities in excess of three optical densities, it has become easy to record, and quantitate, intensity of protein staining patterns. Care should be taken to develop a standard scanning setup, using the full dynamic range (typically all three colors used at their full range, 0–255 for a 24-bit scanner; excluding automatic adjustments for density and contrast). A standard gamma correction value should be determined, using an optical density wedge (Kodak), to assure that the density response is linear. Placing a destained polyacrylamide gel on the gel scanner, one should cover the top of the gel with an acetate film to prevent surface reflection abnormalities and prevent touching of the transilluminating light source surface to the film, avoiding moiré interference patterns. Recording gel patterns at 300 dpi in full color and saving loss-less tiff files facilitates faithful replication of experimental results (**Fig. 1**). Quantitative densitometry programs can use the image files.
14. Triton X-100 interferes with native-mode electrotransfer of histones to nitrocellulose ***(15)***. Exchange of Triton by SDS under acidic conditions allows Western blotting ***(16)*** (*see* Chapter 61).

Isoelectric Focusing of Proteins in Ultra-Thin Polyacrylamide Gels

John M. Walker

1. Introduction

Isoelectric focusing (IEF) is an electrophoretic method for the separation of proteins, according to their isoelectric points (pI), in a stabilized pH gradient. The method involves casting a layer of support media (usually a polyacrylamide gel but agarose can also be used) containing a mixture of carrier ampholytes (low-mol-wt synthetic polyamino-polycarboxylic acids). When using a polyacrylamide gel, a low percentage gel (4%) is used since this has a large pore size, which thus allows proteins to move freely under the applied electrical field without hindrance. When an electric field is applied across such a gel, the carrier ampholytes arrange themselves in order of increasing pI from the anode to the cathode. Each carrier ampholyte maintains a local pH corresponding to its pI and thus a uniform pH gradient is created across the gel. If a protein sample is applied to the surface of the gel, where it will diffuse into the gel, it will also migrate under the influence of the electric field until it reaches the region of the gradient where the pH corresponds to its isoelectric point. At this pH, the protein will have no net charge and will therefore become stationary at this point. Should the protein diffuse slightly toward the anode from this point, it will gain a weak positive charge and migrate back towards the cathode, to its position of zero charge. Similarly diffusion toward the cathode results in a weak negative charge that will direct the protein back to the same position. The protein is therefore trapped or "focused" at the pH value where it has zero overall charge. Proteins are therefore separated according to their charge, and not size as with SDS gel electrophoresis. In practice the protein samples are loaded onto the gel before the pH gradient is formed. When a voltage difference is applied, protein migration and pH gradient formation occur simultaneously.

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

Traditionally, 1–2 mm thick isoelectric focusing gels have been used by research workers, but the relatively high cost of ampholytes makes this a fairly expensive procedure if a number of gels are to be run. However, the introduction of thin-layer isoelectric focusing (where gels of only 0.15 mm thickness are prepared, using a layer of electrical insulation tape as the "spacer" between the gel plate) considerably reduced the cost of preparing IEF gels, and such gels are therefore described in this chapter. Additional advantages of the ultra-thin gels over the thicker traditional gels are the need for less material for analysis, and much quicker staining and destaining times. Also, a permanent record can be obtained by leaving the gel to dry in the air, i.e., there is no need for complex gel-drying facilities. The tremendous resolution obtained with IEF can be further enhanced by combinations with SDS gel electrophoresis in the form of 2D gel electrophoresis.

2. Materials

1. Stock acrylamide solution: acrylamide (3.88 g), bis-acrylamide (0.12 g), sucrose (10.0 g). Dissolve these components in 80 mL of water. This solution may be prepared some days before being required and stored at 4°C (*see* **Note 1**).
2. Riboflavin solution: This should be made fresh, as required. Stir 10 mg riboflavin in 100 mL water for 20 min. Stand to allow undissolved material to settle out (or briefly centrifuge) (*see* **Note 2**).
3. Ampholytes: pH range 3.5–9.5 (*see* **Note 3**).
4. Electrode wicks: 22 cm × 0.6 cm strips of Whatman No. 17 filter paper.
5. Sample loading strips: 0.5 cm square pieces of Whatman No. 1 filter paper, or similar.
6. Anolyte: 1.0 *M* H_3PO_4.
7. Catholyte: 1.0 *M* NaOH.
8. Fixing solution: Mix 150 mL of methanol and 350 mL of distilled water. Add 17.5 g sulfosalicylic acid and 57.5 g trichloroacetic acid.
9. Protein stain: 0.1% Coomassie brilliant blue R250 in 50% methanol, 10% glacial acetic acid. N.B. Dissolve the stain in the methanol component first.
10. Glass plates: 22 cm × 12 cm. These should preferably be of 1 mm glass (to facilitate cooling), but 2 mm glass will suffice.
11. PVC electric insulation tape: The thickness of this tape should be about 0.15 mm and can be checked with a micrometer. The tape we use is actually 0.135 mm.
12. A bright light source.

3. Methods

1. Thoroughly clean the surfaces of two glass plates, first with detergent and then methylated spirit. It is *essential* for this method that the glass plates are clean.
2. To prepare the gel mold, stick strips of insulation tape, 0.5 cm wide, along the four edges of one glass plate. Do not overlap the tape at any stage. Small gaps at the

join are acceptable, but do *not* overlap the tape at corners as this will effectively double the thickness of the spacer at this point.

3. To prepare the gel solution, mix the following: 9.0 mL acrylamide, 0.4 mL ampholyte solution, and 60.0 µL riboflavin solution.

   N.B. Since acrylamide monomer is believed to be neurotoxic, **steps 4–6** must be carried out wearing protective gloves.

4. Place the glass mold in a spillage tray and transfer ALL the gel solution with a Pasteur pipet along one of the short edges of the glass mold. The gel solution will be seen to spread slowly toward the middle of the plate.
5. Take the second glass plate and place one of its short edges on the taped edge of the mold, adjacent to the gel solution. Gradually lower the top plate and allow the solution to spread across the mold. Take care not to trap any air bubbles. If this happens, carefully raise the top plate to remove the bubble and lower it again.
6. When the two plates are together, press the edges firmly together (NOT the middle) and discard the excess acrylamide solution spilled in the tray. Place clips around the edges of the plate and thoroughly clean the plate to remove excess acrylamide solution using a wet tissue.
7 Place the gel mold on a light box (*see* **Note 4**) and leave for at least 3 h to allow polymerization (*see* **Note 5**). Gel molds may be stacked at least three deep on the light box during polymerization. Polymerized gels may then be stored at 4°C for at least 2 mo, or used immediately. If plates are to be used immediately they should be placed at 4°C for 15 min, since this makes the separation of the plates easier.
8. Place the gel mold on the bench and remove the top glass plate by inserting a scalpel blade between the two plates and *slowly* twisting to remove the top plate. (N.B. Protect eyes at this stage.) The gel will normally be stuck to the side that contains the insulation tape. Do *not* remove the tape. Adhesion of the gel to the tape helps fix the gel to the plate and prevents the gel coming off in the staining/destaining steps (*see* **Note 6**).
9. Carefully clean the underneath of the gel plate and place it on the cooling plate of the electrophoresis tank. Cooling water at 10°C should be passing through the cooling plate.
10. Down the full length of one of the longer sides of the gel lay electrode wicks, uniformly saturated with either 1.0 *M* phosphoric acid (anode) or 1.0 *M* NaOH (cathode) (*see* **Note 7**).
11. Samples are loaded by laying filter paper squares (Whatman No. 1, 0.5 cm × 0.5 cm), wetted with the protein sample, onto the gel surface. Leave 0.5 cm gaps between each sample. The filter papers are prewetted with 5–7 µL of sample and applied across the width of the gel (*see* **Notes 8–10**).
12. When all the samples are loaded, place a platinum electrode on each wick. Some commercial apparatus employ a small perspex plate along which the platinum electrodes are stretched and held taut. Good contact between the electrode and wick is maintained by applying a weight to the perspex plate.
13. Apply a potential difference of 500 V across the plate. This should give current of about 4–6 mA. After 10 min increase the current to 1000 V and then to 1500 V after

a further 10 min. A current of ~4–6 mA should be flowing in the gel at this stage, but this will slowly decrease with time as the gel focuses.

14. When the gel has been running for about 1 h, turn off the power and carefully remove the sample papers with a pair of tweezers. Most of the protein samples will have electrophoresed off the papers and be in the gel by now (*see* **Note 11**). Continue with a voltage of 1500 V for a further 1 h. During the period of electrophoresis, colored samples (myoglobin, cytochrome c, hemoglobin in any blood samples, and so on) will be seen to move through the gel and focus as sharp bands (*see* **Note 12**).
15. At the end of 2 h of electrophoresis, a current of about 0.5 mA will be detected (*see* **Note 13**). Remove the gel plate from the apparatus and *gently* wash it in fixing solution (200 mL) for 20 min (overvigorous washing can cause the gel to come away from the glass plate).

    Some precipitated protein bands should be observable in the gel at this stage (*see* **Note 14**). Pour off the fixing solution and wash the gel in destaining solution (100 mL) for 2 min and discard this solution (*see* **Note 15**). Add protein stain and gently agitate the gel for about 10 min. Pour off and discard the protein stain and wash the gel in destaining solution. Stained protein bands in the gel may be visualized on a light box and a permanent record may be obtained by simply leaving the gel to dry out on the glass plate overnight (*see* **Note 16**).
16. Should you wish to stain your gel for enzyme activity rather than staining for total protein, immediately following electrophoresis gently agitate the gel in an appropriate substrate solution (*see* **Note 7**, Chapter 20).

4. Notes

1. The sucrose is present to improve the mechanical stability of the gel. It also greatly reduces pH gradient drift.
2. The procedure described here uses photopolymerization to form the polyacrylamide gel. In the presence of light, riboflavin breaks down to give a free radical which initiates polymerization (Details of acrylamide polymerization are given in the introduction to Chapter 21). Ammonium persulphate /TEMED can be used to polymerize gels for IEF but there is always a danger that artefactual results can be produced by persulfate oxidation of proteins or ampholytes. Also, high levels of persulfate in the gel can cause distortion of protein bands (*see* **Note 10**).
3. This broad pH range is generally used because it allows one to look at the totality of proteins in a sample (but note that very basic proteins will run off the gel). However, ampholytes are available in a number of different pH ranges (e.g., 4–6, 5–7, 4–8, and so on) and can be used to expand the separation of proteins in a particular pH range. This is necessary when trying to resolve proteins with very similar pI values. Using the narrower ranges it is possible to separate proteins that differ in their pI values by as little as 0.01 of a pH unit.

4. Ensure that your light box does not generate much heat as this can dry out the gel quite easily by evaporation through any small gaps at the joints of the electrical insulation tape. If your light box is a warm one, stand it on its side and stand the gels adjacent to the box.
5. It is not at all obvious when a gel has set. However, if there are any small bubbles on the gel (these can occur particularly around the edges of the tape) polymerization can be observed by holding the gel up to the light and observing a "halo" around the bubble. This is caused by a region of unpolymerized acrylamide around the bubble that has been prevented from polymerizing by oxygen in the bubble. It is often convenient to introduce a small bubble at the end of the gel to help observe polymerization.
6. If the gel stays on the sheet of glass that does not contain the tape, discard the gel. Although usable for electrofocusing you will invariably find that the gel comes off the glass and rolls up into an unmanageable "scroll" during staining/destaining. To ensure that the gel adheres to the glass plate that has the tape on it, it is often useful to siliconize (e.g., with trimethyl silane) the upper glass plate before pouring the gel.
7. The strips must be fully wetted but must not leave a puddle of liquid when laid on the gel. (Note that in some apparatus designs application of the electrode applies pressure to the wicks, which can expel liquid.)
8. The filter paper must be fully wetted but should have no surplus liquid on the surface. When loaded on the gel this can lead to puddles of liquid on the gel surface which distorts electrophoresis in this region. The most appropriate volume depends on the absorbancy of the filter paper being used but about 5 µL is normally appropriate. For pure proteins load approx 0.5–1.0 µg of protein. The loading for complex mixtures will have to be done by trial and error.
9. Theoretically, samples can be loaded anywhere between the anode or cathode. However, if one knows approximately where the bands will focus it is best not to load the samples at this point since this can cause some distortion of the band. Similarly, protein stability is a consideration. For example, if a particular protein is easily denatured at acid pH values, then cathodal application would be appropriate.
10. The most common problem with IEF is distortions in the pH gradient. This produces wavy bands in the focused pattern. Causes are various, including poor electrical contact between electrode and electrode strips, variations in slab thickness, uneven wetting of electrode strips, and insufficient cooling leading to hot spots. However, the most common cause is excessive salt in the sample. If necessary, therefore, samples should be desalted by gel filtration or dialysis before running the gel.
11. Although not absolutely essential, removal of sample strips at this stage is encouraged since bands that focus in the region of these strips can be

distorted if strips are not removed. Take care not to make a hole in the gel when removing the strips. Use blunt tweezers (forceps) rather than pointed ones. When originally loading the samples it can be advantageous to leave one corner of the filter strip slightly raised from the surface to facilitate later removal with tweezers.

12. It is indeed good idea to include two or three blood samples in any run to act as markers and to confirm that electrophoresis is proceeding satisfactorily. Samples should be prepared by diluting a drop of blood approx 1:100 with distilled water to effect lysis of the erythrocytes. This solution should be pale cherry in color. During electrophoresis, the red hemoglobin will be seen to electrophorese off the filter paper into the gel and ultimately focus in the central region of the gel (pH 3.5–10 range). If samples are loaded from each end of the gel, when they have both focused in the sample place in the middle of the gel one can be fairly certain that isoelectrofocusing is occurring and indeed that the run is probably complete.
13. Theoretically, when the gel is fully focused, there should be no charged species to carry a current in the gel. In practice there is always a slow drift of buffer in the gel (electro-endomosis) resulting in a small (0.5 mA) current even when gels are fully focused. Blood samples (*see* **Note 9**) loaded as markers can provide additional confirmation that focusing is completed.
14. It is not possible to stain the IEF gel with protein stain immediately following electrophoresis since the ampholytes will stain giving a uniformly blue gel. The fixing step allows the separated proteins to be precipitated in the gel, while washing out the still soluble ampholytes.
15. This brief wash is important. If stain is added to the gel still wet with fixing solution, a certain amount of protein stain will precipitate out. This brief washing step prevents this.
16. If you wish to determine the isoelectric point of a protein in a sample, then the easiest way is to run a mixture of proteins of known pI in an adjacent track (such mixtures are commercially available). Some commercially available kits comprise totally colored compounds that also allows one to monitor the focusing as it occurs. However, it is just as easy to prepare ones own mixture from individual purified proteins. When stained, plot a graph of protein pI vs distance from an electrode to give a calibration graph. The distance moved by the unknown protein is also measured and its pI read from the graph. Alternatively, a blank track can be left adjacent to the sample. This is cut out prior to staining the gel and cut into 1 mm slices. Each slice is then homogenized in 1 mL of water and the pH of the resultant solution measured with a micro electrode. In this way a pH vs distance calibration graph is again produced.

1. Introduction

It has long been apparent that the separation capacity of conventional 18 cm IPGs as the first separation step in two dimensional polyacrylamide gel electrophoresis (2D-PAGE) was theoretically incapable of separating the complexity that is to be expected by the protein species of a mammalian cell line or tissue ***(1)***. We first attempted to improve the resolution of 2D-PAGE by developing IPGs of 54 cm in length ***(2).*** While this strategy was successful, it required the labor-intensive preparation and batchwise validation of own-caste IPGs for each experiment. Subsequently we found that qualitatively similar excellent results could be obtained by placing commercially available IPGs in series (end to end) during IEF. We submitted this method as a patent application on September 12, 2003 (WO2005026715, but since allowed to lapse in all countries but Germany) and published it in the scientific literature in August 2005 ***(3).*** The main advantage of this analytical strategy is that less sample is consumed per high resolution protein separation as compared to the alternative use of conventional combinations of individual narrow pH range IPGs for IEF. Thus, the system is well suited to the optimal analysis of samples that are limited in amount, as we have since demonstrated in a number of analytical investigations, including cases where samples from small human clinical biopsies were employed ***(4–6).*** Farhoud and colleagues independently published an essentially identical serial IEF method and device ***(7),*** also emphasizing the maximal resolution and yield of minimally consumed scarce samples. That paper was submitted for publication in July 2005, four months after the publication of our patent application.

2. Materials

2.1. Casting Polyacrylamide Bridges

1. Glass plates for casting polyacrylamide gels. 200 × 260 × 0.5 mm, U-frame and 200 × 260 × 4 mm glass plate (GE Healthcare 80-1106-87; 18-1102-47).
2. GelBond PAG film, 203 × 260 mm (GE Healthcare 80-1129-37).
3. PlusOne Acrylamide IEF (GE Healthcare 17-1300-01).
4. PlusOne N,N′-Methylene-bisacrylamide (GE Healthcare 17-1304-01).
5. PlusOne TEMED (GE Healthcare 17-1312-01).
6. PlusOne Ammonium Persulfate (GE Healthcare 17-1311-01).
7. PlusOne Repel-Silane ES (GE Healthcare 17-1332-01).
8. Kimtech Science Precision Wipes, Kimberly Clark Product Code: 75512.

2.2. Rehydration of IPG Strips

1. Immobiline DryStrip pH 4.0–5.0, 18 cm (GE Healthcare 17-6001-84).
2. Immobiline DryStrip pH 5.0–6.0, 18 cm (GE Healthcare 17-6001-86).
3. Immobiline DryStrip pH 6–9, 18 cm (GE Healthcare 17-6001-88).
4. IEF buffer: 7 M urea, 2 M thiourea, 1% Triton X-100, 10% glycerol, 4% CHAPS, 1% DTT.
5. IPG Buffer pH 3.5–5.0 (GE Healthcare 17-6002-02).
6. IPG Buffer pH 5.0–6.0 (GE Healthcare 17-6002-05).
7. Servalyte 6–9 (Serva Heidelberg 42913.01).
8. Immobiline DryStrip Reswelling Tray, for 7–18 cm IPG strips (GE Healthcare 80-6371-84).
9. Flat laboratory forceps suitable for IPG strip manipulation.
10. Sharp laboratory scissors (Stainless steel).

2.3. Assembly of Daisy Chain IPGs

1. Immobiline DryStrip Cover Fluid (GE Healthcare 17-1335-01).
2. Acrylamide bridges (*see* **Note 1**).

2.4. Isoelectric Focussing

1. Self-made IEF device (*see* **Note 2**).

3. Methods

In this methodical report only the serial IEF methodology is thoroughly described. We assume that the experimenter is already able to perform conventional 2D-PAGE using IPGs. Introductory material and references for this area can be found in the series of articles by Görg and colleagues (***8–10***); *see also* Chapter 35. The individual IPGs are best subsequently electrophoresed by SDS-PAGE and stained according to the protocols already established/optimized in your own laboratory for conventional single IPG-IEF.

3.1. Casting Polyacrylamide Bridges

1. Prior to use, wash the glass plates thoroughly with diluted detergent, followed by acetone, and then rinse with deionized water and air dry (*see* **Note 3**).
2. Siliconize glass plate bearing U-frame (*see* **Note 4**).
3. Wash Gel Bond PAG films 3 × 10 min with deionized water prior to use (*see* **Note 5**).
4. Assemble gel casting cassette prior to use and leave it in vertical position (*see* **Note 6**).
5. Prepare 4% acrylamide solution according to the given recipe (*see* **Note 7**). Fill the assembled casting cassette with approximately 23 mL (or less) of acrylamide solution and polymerize for 15 min at room temperature (*see* **Note 8**). Subsequently polymerize the gel for 1 hour at 50°C in a heating cabinet (*see* **Note 9**).
6. Cool down the gel (*see* **Note 10**) and cut them into 4 mm wide strips (*see* **Note 11**).
7. Store Acrylamide bridges at −20°C until use (*see* **Note 12**).

3.2. Rehydration of IPG Strips

1. Prepare IEF rehydration buffer or thaw from −20°C previously prepared buffer.
2. Rehydrate IPG strips pH 4–5, 5–6 and 6–9 according to standard protocol as you would for individual IPGs of these pH ranges (*see* **Note 13**).
3. Rehydrate bridges in IEF buffer with IPG buffer mixture (*see* **Note 14**).

3.3. Assembly of Daisy Chain IPGs

1. Assemble the IEF chamber as you routinely do with Multiphor IEF chamber **(Fig. 1).**
2. Fill the IEF chamber with Immobiline DryStrip Cover Fluid or Paraffin oil you use for standard IEF of IPG strips (*see* **Note 15**).
3. Assemble IPG strips from acidic to basic (from left to right) (*see* **Note 16**).
4. Cut bridges in 1 – 1.5 cm long pieces.
5. Gently apply the bridging gels to span between the IPG strips, briefly applying slight pressure to facilitate electrical contact between the aqueous zones **(Fig. 2).**

3.4. Isoelectric Focusing

1. Voltages employed for IEF are parameterized in **Table 1.**
2. After IEF the IPGs are handled identically to IPGs in conventional single gel 2D-PAGE.

4. Notes

1. Casting of "bridges" should be done at least one day before one plans to start daisy chain. The best is to cast bridges in advance, few days before, in sufficient amount and to store them at −20°C until use.
2. Our description of the self-made IEF device has been published (***3***). Farhoud and colleagues independently published an essentially identical serial IEF method and device (***7***). We recommend consulting both of these cited references before attempting to construct an own high voltage IEF device, and certainly not to even consider this without the assistance of suitably qualified

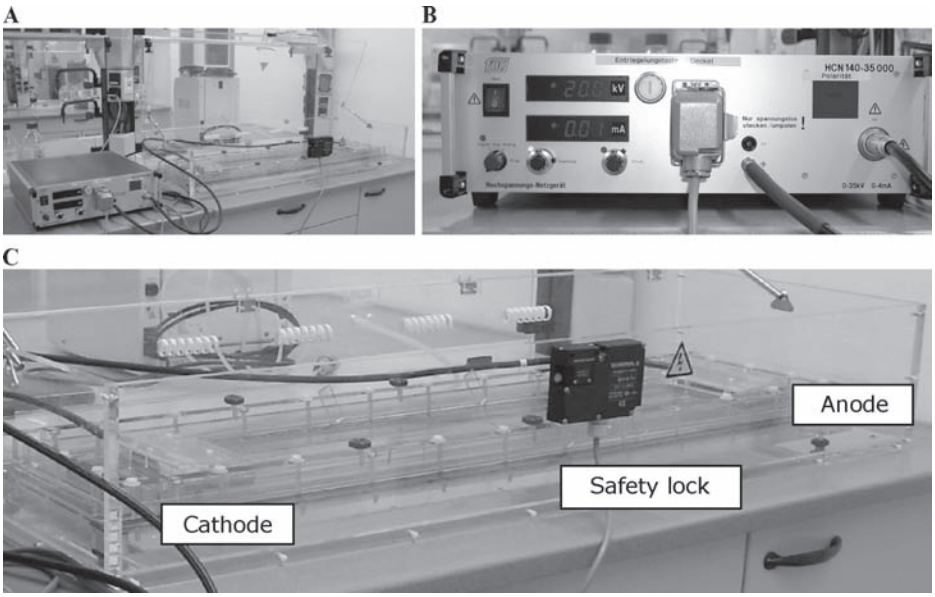

Fig.1. Working prototype long IEF chamber (for IEF up to 96 cm). **(A)** The IEF chamber and power supply. The safety lid is open and the temperature regulating water cooler is behind the device. **(B)** The power supply, running at 20 kV (for more rapid IEF, alternatively to Table 1)**. (C)** Detail view of the IEF chamber. The safety lock is connected via a time-delayed circuit to an unlocking mechanism on the power supply, and can be opened only 5 minutes after the power has been switched off. Other features include**:** variable IEF length: 18 – 100 cm, integrated cooling surface, silicon oil coolant is an electrical insulator, 35 kV power supply, 0.05 mA adjustable steps, high voltage cables for 35 kV, custom designed electrodes for 35 kV, and electrically insulating safety chamber surrounds IEF chamber.

electrical and/or engineering skill. All electrical circuitry in the self-made IEF chamber was configured according to German regulation VDE 0411 concerning the use of voltages over 10,000 V. The IEF chamber was based upon a water-cooled aluminum surface of about 1100 mm × 240 mm. A shallow glass tray was placed onto the metal surface, and cooled by application of mineral oil between metal and glass to permit heat transfer. The glass tray itself is 940 mm × 145 mm, and has walls that are 18 mm high, resembling a long Pharmacia Multiphore DryStrip tray. The IPGs are placed into this tray as described below and electrodes are placed at each end. These electrodes have cables rated >10,000 V and lead to a HCN 140–35000 power supply which is programmable at 0–4 mA in 50 µA steps (F.u.G. Elektronic, Rosenheim Germany). The cooled aluminum surface with glass tray and electrodes were completely contained in a large Plexiglas (acrylic glass/polymethyl methacrylate) case with a hinging top panel that serves as a locking lid. Plexiglas was

Molecular weight markers: kDa 220; 160; 120; 100; 90; 80; 70; 60; 50 (fat); 40; 30; 25; 20 (fat/double); 15.

chosen for its excellent properties of electrical insulation. The hinged lid was additionally fitted with an opening safety mechanism whose catch was electronically linked to the power supply. This had been internally custom modified during self-construction to prevent the lid from opening until voltage levels had dropped to safe levels. The joints of the Plexiglas case were also waterproofed with silicon and the case was of sufficient volume that any leakage from the water-cooling system would be retained inside the Plexiglas vessel, and would not come into contact with the electrodes. These aspects are mentioned to emphasize that the personal safety of the experimenter is dependent

Table 1.
Serial IEF Regime

150 V	30 min
300 V	30 min
600 V	60 min
3000 V	up to 10000 Vh
10000 V	up to 120000 Vh
1000 V	for 1440 min (stand by)

upon the technical design of the IEF device. Because commercially manufactured devices are not available, local governmental safety regulations (and common sense) should be strictly adhered to as the minimum standard in the manufacture of a suitable apparatus.

3. All glass plates must be absolutely clean and free of fat and detergents.
4. Treatment of plates with Repel-Silane enables an easier removal of glass plate from cast gels. Repel-Silane ES is a 2% solution of dimethyldichlorosilane dissolved in octamethyl cyclo-octasilane, a low toxicity, and environmentally safe solvent. Pipette 1–2 ml of repel silane on the glass plate with the U-frame and distribute it evenly over whole surface with a lint-free paper (e.g., Kimwipe). Let it dry for a few minutes, rinse with ethanol and repeat procedure once again. This procedure must be repeated occasionally in order to prevent the gels from sticking to the glass plates. Repel silane glass plates can be re-used, but never mix them with normal glass plates! When not in use siliconized glass plates should be stored separately from non-siliconized ones. Pack the plates face to face with a piece of tissue paper between them to avoid contamination or scratching of the glass. To facilitate efficient siliconization of the surface and thereby avoid sticking of gels to the glass plates, it is recommended that the procedure should be repeated at least twice in succession.
5. Always wash with the hydrophilic side upwards. Gel Bond PAG film is packed with the treated side up, with paper interleaving to protect the treated surface. If uncertain, the hydrophilic side can be confirmed by applying a drop of water and noting that it spreads on the hydrophilic side, but beads up on the hydrophobic side. Always handle Gel Bond PAG film by the edges and with gloves to avoid getting fingerprints on the treated surface. Note that PAG film is both light and heat sensitive. It should be stored under cool dark conditions, and you should be aware that after prolonged or inappropriate storage the acrylamide groups may be degraded, and your gels will not be able to polymerize to the surface satisfactorily.
6. Our casting cassette consists of two glass plates of 200 × 260 mm. One of these is covered with the Gel Bond PAG film and the other contains a 0.5 mm U-frame. The frame is made of silicon rubber enclosing 0.5 mm metal balls. The cassette is assembled as originally described by Görg and colleagues (http://www.weihenstephan.de/blm/deg/2D-Manual_06.pdf) (*8–10*). The cleaned glass plate without the U-frame is moistened with a few drops of water, and the Gel Bond PAG film, hydrophilic side upwards, is placed onto the wet glass surface. The surface of the Gel Bond PAG film is covered by a piece of Kimtech tissue paper and excess water is expelled with a roller as originally described by Görg and colleagues. Place the glass plate with the U-frame (0.5 mm thick) on top of the Gel Bond PAG film and clamp the cassette together.

7. Chemicals used for preparation of gel should be of the highest possible quality. We use IEF grade acrylamide purchased in powder form. A stock solution (30% T; 2,7% C) is always freshly prepared or occasionally stored at +4°C for a maximum of one week. We have found it unnecessary to use ion exchange resin for preparation of such stock solutions. Omission of ion exchange avoids potential contamination of the acrylamide solution with impurities from the resin preparations. Stock solution (30% T; 2,7% C): Dissolve 29,18 g of Acrylamide and 0,81 g of bisacrylamide in MilliQ water and fill up to 100 mL. Solution should be filtered and stored at +4 °C. To make the 4% gels add 4 ml acrylamide stock to 26 mL H_2O, then add 30 µL of freshly prepared 40% ammonium persulfate and 20 µL TEMED.
8. The gel can be caste using several different methods. The most important point is to fill slowly to avoid the formation of bubbles. We apply the acrylamide mixture slowly and steadily to one side of the casting chamber with a 10 mL pipette, initially tilting the cassette about 40° to run the gel down that side. This should obviously not be performed too slowly because of the advancing polymerization reaction itself.
9. Although the acrylamide mixture should have gelled by this stage, during polymerization in the oven the caste gel in its cassette should remain in the vertical position, this way avoiding any possible movement and leakage of the gel.
10. After polymerization at 50°C allow the gel to cool down to RT for at least 15 min. Disassemble the cassette by inserting a spatula between gel and glass plate and gently but firmly levering the plates apart. Remove the support film with attached gel carefully and wash the PAG film and gel 4 × 15 min with 500 ml MilliQ water to remove unpolymerized acrylamide monomers. Finally incubate the gel in 2% Glycerol for 30 min. Dry the gel overnight in a hood or with a fan or hair-dryer for a few hours. We prefer drying overnight, avoiding potential dust (and keratin) contamination which may occur by drying with a forced air flow, such as caused by a hair dryer or electric fan.
11. The gel can be cut into strips using an office paper cutter, as suggested by Görg. Cleaner edges can be achieved by scission with an industrial paper cutting machine.
12. The bridge gels, consisting only of polyacrylamide without buffers at this stage, are quite stable. We have used precast bridging gels stored sealed at –20°C for more than one year, after which the supply was exhausted.
13. Rehydration of strips should be done according to the instruction for the individual strips. There can be different methods of sample application for daisy chain experiments, e.g.:
    - sample application by in-gel rehydration.
    - sample application via wick- or cup-loading
    - sample application via bridge loading

Table 2
Buffers for IPG Rehydration

pH of IPG strip	Case A (in-gel rehydration)	Case B (wick application)
4–5	Sample + IEF buffer with 0.8% of IPG buffer pH 3.5–5.0	IEF buffer with 0.8 % of IPG buffer pH 3.5–5.0
5–6	IEF buffer with 0.8 % of IPG buffer pH 5.0–6.0	IEF buffer with 0.8 % of IPG buffer pH 5.0–6.0
6–9	IEF buffer with 0.8 % of Servalyte CA pH 6.0–9.0	IEF buffer with 0.8 % of Servalyte CA pH 6.0–9.0
Bridges	IEF buffer with 0.8% mix of IPG buffers 3.5–5.0; 5.0–6.0 and Servalyte 6.0–9.0, **1:1:1**	IEF buffer with 0.8% mix of IPG buffers 3.5–5.0; 5.0–6.0 and Servalyte 6.0–9.0, **1:1:1**

The best result depend upon the nature of the proteins in your sample. In the first case the sample is loaded by the rehydration method into the IPG strip pH 4–5 or 5–6 depending on the sample. The other IPG strips for the daisy chain are rehydrated with IEF buffer containing the appropriate corresponding IPG buffer.

The optimum method of loading the strips by rehydration will also be sample-specific, with better 2D-PAGE samples obtained by rehydration loading into the basic IPG, the acidic IPG, or all IPGs for different samples.

When we apply sample via the wick then all single gels are rehydrated in their appropriate IEF buffer with corresponding individual pH-specific IPG buffer. In all cases for each IPG strip pH gradient we used 0.8% of corresponding IPG buffer.

For specific samples better results can be obtained by bridge loading. The optimum position of the loading bridge is sample dependent and should be empirically determined.

A tabular presentation of appropriate conditions is depicted in Table 2.

14. Bridges were always rehydrated in IEF buffer containing 0.8% of mixture all used IPG buffers and Servalyte in relation 1:1:1. In all cases rehydration was done on the lab bench overnight at room temperature. Shorter rehydration steps can be employed, although we advise rehydration for more than 5 hours.
15. The IPG holding tray chamber should be filled with oil sufficiently that the IPG strips and paper wicks are submerged. It may be more convenient to first fill the IPG tray with oil and then lay the strips gently down into the oil.
16. To simplify assembling of a daisy chain in the IEF tray we use laminated grid paper positioned under the tray. Try to position the IPGs as closely as possible end-to-end, avoiding any overlap. To position the IPGs we suggest cutting the plastic ends of the IPG strips before alignment, according to the following schema:

- IPG strip pH 4–5: Cut the plastic end close to the gel at the cathodic ("–" or basic) end.
- IPG strip pH 5–6: Cut the plastic ends close to the gel at both the anodic ("+" or acidic) and cathodic ("–" or basic) ends.
- IPG strip pH 6–9: Cut the plastic end close to the gel at the anodic ("+" or acidic) end.

Radiolabeling of Eukaryotic Cells and Subsequent Preparation for 2-Dimensional Electrophoresis

Nick Bizios

1. Introduction

Two dimensional polyacrylamide gel electrophoresis (2-DE) provides not only the ability to resolve and quantify thousands of proteins, but it also gives those in research and industry the ability to monitor in-process protein purification, quickly and easily ***(1)***. It can become a valuable tool in process analytical technology (PAT) in which the goal is to understand and control a process in order to build in quality. 2-DE is also used to identify variability in protein expression in a variety of cell lines ***(2,3)***.

It is known that many parameters and laboratory conditions can influence the resolution of proteins on 2-DE, such as pH range of carrier ampholytes used, the quality of reagents and equipment used, temperature, voltage, and the skill of the researcher or technician. Even though there are a multitude of vendors that supply premade reagents, there is pride bestowed to the technician or researcher performing their work.

One of the biggest obstacles one may encounter prior to performing 2-DE is the proper documentation and validation of a Standard Operating Procedure, or SOP. This falls under the category of current Good Laboratory Practices (cGLPs) and or current Good Manufacturing Practices (cGMPs). Without the proper documentation of reagents used, such as Certificates of Analysis (readily supplied by the supplier's Quality Control/Assurance department), adherence to expiration dates of commercially prepared reagents, implementation of expiration dates of reagents prepared in the laboratory and the adherence of SOPs (*see* **Note 1**) the ability of generating repeatable and consistent results falls dramatically. However, the radiolabeling and preparation or eukaryotic cells for 2-D PAGE may be considered paramount in obtaining consistent results. Without proper

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

radiolabeling and preparation, how would one find subsequent spots of interest and perform quantitative analysis?

This chapter will describe a general and robust method for the labeling methionine-containing proteins, phosphorylation labeling, and subsequent lysate preparation for 2-DE that have been modified from Garrels ***(4)*** and Garrels and Franza ***(5)***. The Jurkat T-lymphoblast cell line is used as an example.

A larger number of protocols have been published for the solubilization and sample preparation of eukaryotic cell lines and tissues for 2-DE. One of the best places for additional protocols is found at the Geneva University Hospital's Electrophoresis laboratory, which can be accessed at http;//expasy.hcuge.ch/ch2d/technical-info.html.

2. Materials

2.1. Equpiment

1. 0.2µm filters (*see* **Note 2**)
2. Heat block or 100°C water bath

2.2. Reagents

1. Complete culture medium: 90% RPMI-1640, 10% fetal bovine serum (FBS), streptomycin-penicillin: Mix 990 mL of RPMI-1640 with 100 mL of FBS, and add 10 mL of streptomycin-penicillin (100X). Cold-filter-sterilize using a 0.2µm filter. Store at 4°C. Maintain the Jurkat T-lymphoblast at a concentration of 10^5–10^6 cells/mL (*see* **Note 3**).
2. Methionine-free medium: 90% methionine-free RPMI-1640, 10% dialyzed FBS (dFBS): Mix 990 mL of methionine-free RPMI-1640 with 100 mL of dFBS. Cold-filter-sterilize using 0.2µm filter. Store at 4°C.
3. Sodium phosphate-free medium: 90% sodium phosphate-free RPMI-1640, 10% FBS: Mix 90% sodium phosphate free RPMI with 10% FBS. Cold-filter-sterilize. Store at 4°C.
4. Redivue L-[^{35}S]methionine (cell labeling grade) (GE Healthcare)
5. ^{32}P-orthophospahte (GE Healthcare).
6. Phosphate buffered saline (PBS): Mix 8 g NaCl, 0.2 KCl, 1.44 g Na_2HPO_4, and 0.24 grams KH_2PO_4 in 800 mL of dH_2O) and adjust to 7.4 with HCl. Add dH_2O to a final volume of 1000 mL and autoclave. Store at room temperature.
7. Dilute SDS (dSDS): 0.3% SDS, 1% β-mercaptoethanol (β-ME), 0.05 M Tris-HCl, pH 8.0. In a cold room, mix 3.0 g of SDS, 4.44 g of Tris-HCl, 2.65 g Tris base, 10 mL of β-ME in dH_2O, and adjust the final to 1 L with dH_2O. Aliquot 500 mL into microcentrifuge tubes and store at -70°C.
8. DNase/RNase solution: 1 mg/mL DNase I, 0.5 mg/mL RNase A, 0.5 *M* Tris, 0.05 *M* $MgCl_2$, pH 7.0. Thaw RNase, Tris, and $MgCl_2$ stocks, and thoroughly mix 2.5 mg of RNase A (Worthington Enzymes), 1585 µL of 1.5 *M* Tris-HCl, 80 µL of 1.5 Tris base, 250 µL of 1.0 *M* $MgCl_2$, and 2960 µL of dH_2O. Mix the liquids, and add 5 mg

DNase I (Worthington Biochemical). Do not filter. Keep cool while dispensing into microcentrifuge tubes. Makes 50 µL aliquots, and store at −70°C.

9. 1.5 *M* Tris-HCl solution: Weigh out 11.8 g of desiccated Tris-HCl, and add 41.4 g dH_2O. Mix well and filter through 0.2 µm filter. Aliquot into microcentrifuge tubes, and store at −70°C.
10. 1.5 *M* Tris base solution: Weigh out 9.09 g of Tris base, and add 41.4 g of dH_2O. Mix and filter through 0.2 µm filter. Aliquot into microcentrifuge tubes, and store at −70°C.
11. 1.0 *M* $MgCl_2$ solution: Weigh out 30.3 g of $MgCl_2$, and add 85.9 g of dH_2O. Mix and filter through 0.2 µm filter. Aliquot into microcentrifuge tubes, and store at −70°C.
12. Sample buffer solution (SB): 9.95 M urea, 4.0% Igepal CA-630 (Sigma), 2% 6.0–8.0 ampholytes, 100 m*M* dithiothreitol (DTT). Mix 59.7 g urea, 44.9 g dH_2O, 4.0 g Igepal CA-630, 5.5 g of pH 5.0 to 8.0 ampholytes (GE Healthcare), 1.54 g of DTT (Calbiochem) in this order in a 30° to 37° water bath just long enough to dissolve the urea. Filter through a 0.2 µm filter, and aliquot 1 mL into microcentrifuge tubes. Snap-freeze in liquid nitrogen, and store at −70°C.
13. Sample buffer with SDS solution (SBS): 9.95 M urea, 4.0% Igepal CA-630 (Sigma), 0.3 % SDS, 2% 6.0–8.0 ampholytes, 100 m*M* dithiothreitol (DTT). Mix 59.7 g urea, 44.9 g dH_2O, 4.0 g Igepal CA-630, 0.3 g SDS, 5.5 g of pH 5.0 to 8.0 ampholytes, 1.54 g of DTT in this order in a 30° to 37° water bath just long enough to dissolve the urea. Filter through a 0.2 µm filter, and aliquot 1 mL into microcentrifuge tubes. Snap-freeze in liquid nitrogen, and store at −70°C.

3. Methods

3.1. ^{35}S-Labeling (see Note 4)

1. Jurkat T-lymphocytes are labeled for 3–24 h in methionine-free media containing 50–250 µCi/mL of ^{35}S.
2. Follow cell lysate protocol (**Subheading 3.3.,**).

3.2. ^{32}P-Labeling (see Note 3)

1. Add 100 µCi/mL of ^{32}P for up to 3 h to cells that are in phosphate-free medium (*see* **Note 5**).

3.3. Whole-Cell Lysate Preparation

1. Wash cells with PBS three times in a microcentrifuge tube.
2. Add an equal volume of hot (100°C) dSDS solution to the pellet.
3. Boil tube (100°C) for 1–3 min.
4. Cool in an ice bath (*see* **Note 6**).
5. Add one-tenth (1/10) volume of DNase/RNase solution.
6. Gently vortex for several minutes to avoid foaming. The sample should lose its viscosity, and the solution should look clear. If not, then add more dSDS and DNase/RNase solution (*see* **Note 7**).
7. Snap-freeze in liquid nitrogen, and store at −70°C. Samples may be kept for up to 6 mo at −70°C.

3.4. Preparing the Sample for 2D-PAGE: Vacuum Drying

1. Lyophilize sample (frozen at −70°C) in a Speed Vac using no or low heat until dry *see* **Note 8**).
2. Add SB solution to the sample equal to that of the original dSDS sample volume, and mix thoroughly.
3. Heat sample to 37°C for a short period if necessary (*see* **Note 9**).
4. Store at −70°C. Samples can be kept for up to 6 mo at −70°C.
5. Radioisotope incorporation in the sample may now be determined by TCA precipitation.
6. Recommended first-dimension load is 500,000 dpm for ^{35}S-labeled proteins and 200,000 dpm for ^{32}P-labeled proteins.
7. If necessary, the sample is diluted and mixed thoroughly with SBS solution before loading onto the first-dimension gel (*see* **Note 9**).

4. Notes

1. cGLPs and cGMPs will help with all aspects in a research facility. Industry will have Quality Assurance/Control departments to oversee the implementation of these practices. Smaller research labs may wish to assign or hire a person to oversee these practices and adhere to.
2. Small syringe type 0.2 µm filters are best acquired from Nalgene while larger scale filters requiring a pump are best supplied from Sartorius-Stedim Biotech, Pall or Millipore.
3. Maintain Jurkat T-lymphocytes in complete culture medium supplemented with streptomycin/penicillin, in a humidified incubator with 95% air and 5% CO_2 at 37°C at a concentration of 10^5-10^6 cells/mL.
4. It is extremely important that all radioactive work be performed with the utmost care, and according to your institutional and local guidelines.
5. It may be necessary to preincubate the cells. Preincubating the cells at a density of 1–10 × 10^6 cells/mL for 30 min in sodium-free, phosphate-free medium works well.
6. Sample preparation should be done quickly once to avoid degradation by proteases.
7. Keep salt concentrations as low as possible, high concentrations (>150 m*M*) of NaCl, KCl, and other salts cause streaking problems, as do lower concentrations of phosphate and charged buffers. Dialyzing samples to remove salts and other low-mol-wt substances is recommended.
8. Larger sample volumes may be prepared using a large scale commercial lyophilizer in order to prepare “internal standards” for each run.
9. After dissolving the sample in SB solution or diluting in SBS solution, it is imperative that the sample is not subjected to temperatures above 37°C. At extreme temperature (>40°C), the urea in SB and SBS will

cause carbamylation. Charged isoforms will be generated by isocyanates formed by the decomposition of urea.

Two-Dimensional Polyacrylamide Gel Electrophoresis of Proteins Using Carrier Ampholyte pH Gradients in the First Dimension

Patricia Gravel

1. Introduction

Two-dimensional polyacrylamide gel electrophoresis (2-D PAGE) is the only method currently available for the simultaneous separation of thousands of protein. This method separates individual proteins and polypeptide chains according to their isoelectric point and molecular weight. The 2-D PAGE technology can be used for several applications, from which; separation of complex protein mixture into their individual polypeptide components; comparison of protein expression profiles of sample pairs (normal versus transformed cells, cells at different stages of growth or differentiation, etc.).

This chapter describes the protocol for 2-D PAGE using carrier ampholyte pH gradient gel for the isoelectric focusing separation (pH gradient 3.5–10) and a polyacrylamide gradient gel for the second dimension ***(1,2)***.

For many years the 2-D PAGE technology relied on the use of carrier ampholytes to establish the pH gradient. This traditional technique has proven to be difficult in the hands of many because of the lack of reproducibility created by uncontrolable variations in the batches of ampholytes used to generate the pH gradients. This problem was solved by using immobilised pH gradients (IPG) (*see* Chapter 35), where the compounds used to set up the pH gradient are chemically immobilized and so the gradient is stable. Another advantage is that a larger amount of protein could be used in the separation for micropreparative runs. The availability of commercial precast IPG gels in a variety of narrow and broad pH ranges, as well as precast SDS-PAGE gels has lead also to major advances in protein separation, display and protein characterization ***(3).*** 2-D PAGE reference maps are now available over the World-Wide Web ***(4, 5)***.

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2. Materials

2.1. Preparation of Samples

1. Lysis solution A:10 % (w/v) SDS (sodium dodecyl sulfate) and 2.32 % (w/v) DTE (1,4- dithio-erythritol) in distilled water (dH_2O).
2. Lysis solution B:5.4 g urea (9.0 *M*) (must be solubilized in water at warm temperature, around 35°C), 0.1 g DTE (65 m*M*), 0.4 g CHAPS (cholamidopropyldimethylhydroxypropane sulfonate) (65 m*M*), 0.5 ml of Ampholines pH range 3.5–10 (5% v/v) made to 10 ml with dH_2O.

These solutions can be aliquoted and stored at −20°C for many months.

2.2. Isoelectric Focusing (IEF)

1. IEF is performed with the Tube Cell Model 175 (Bio-Rad) (see **Fig. 1**) and with glass capillary tubes (1.0 – 1.4 mm internal diameter and 210 mm long).

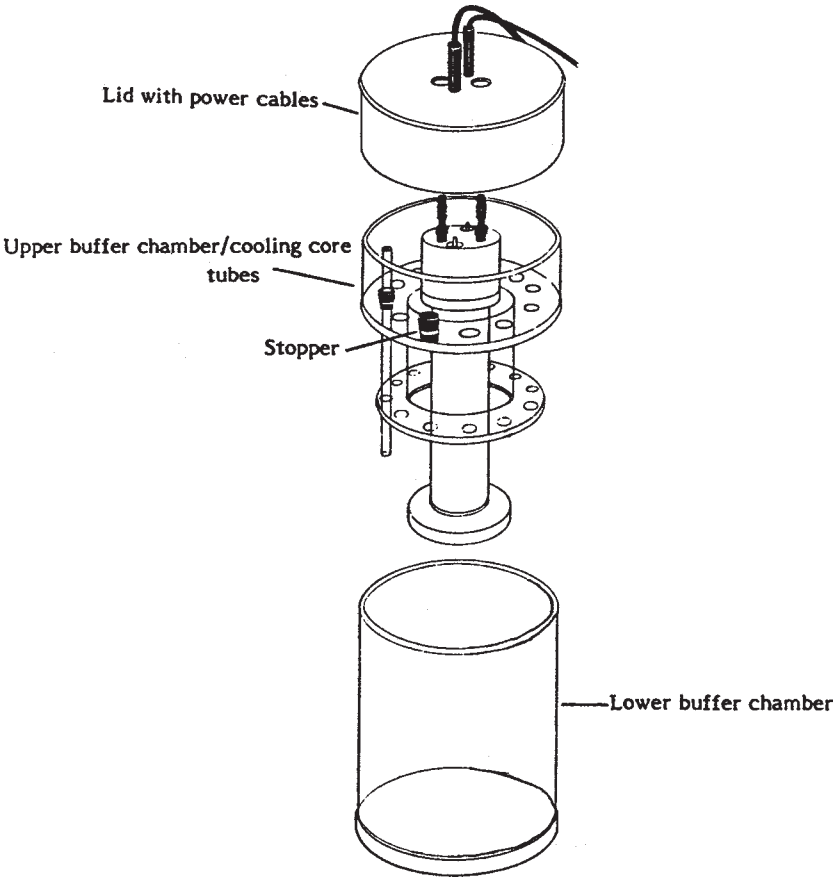

Fig. 1. Tube Cell Model 175 (Bio-Rad) for the isoelectric focusing with carrier ampholyte pH gradient capillary gels.

Ampholytes pH 4–8 and Ampholytes pH 3.5–10 are from BDH (Poole, England).

2. Stock solution of acrylamide: 30% (w/v) acrylamide, 0.8% (w/v) PDA (piperazine diacrylamide) in dH_2O. This solution should be stored in the dark at 4°C for 1 to 2 months.
3. Cathodic buffer: 20 m*M* NaOH in dH_2O. This solution should be made fresh.
4. Anodic buffer: 6 m*M* H_3PO_4 in dH_2O. This solution should be made fresh.
5. Ammonium persulfate (APS) stock solution: 10% (w/v) APS in dH_2O. This solution should be stored at 4°C, protected from light and made fresh every 2 to 3 weeks.
6. SDS stock solution: 10% (w/v) SDS in dH_2O. This solution can be stored at room temperature.
7. Bromophenol blue stock solution: 0.05% (w/v) bromophenol blue in dH_2O. This solution can be stored at room temperature.
8. Capillary gel equilibration buffer:
   20 ml 0.5 *M* Tris-HCl pH 6.8
   40 ml 10% (w/v) SDS stock solution
   8 ml 0.05% (w/v) bromophenol blue stock solution
   72 ml dH_2O

   This solution can be stored at room temperature for 2 to 3 months.

2.3. SDS Polyacrylamide Gel Electrophoresis (SDS-PAGE)

1. The Protean II chamber (Bio-Rad) is employed by us for SDS-PAGE. The gels (160 × 200 × 1.5 mm) are cast in the Protean II casting chamber (Bio-Rad). The gradient former is model 395 (Bio-Rad).
2. Running buffer: 50 m*M* Tris base, 384 m*M* glycine, 0.1% (w/v) SDS in dH_2O For 1 L: 6 g Tris base, 28.8 g glycine and 1 g SDS. Do not adjust pH. Fresh solution is made up for the upper tank. The lower tank running buffer can be retained for more than 6 months with the addition of 0.02% (w/v) sodium azide.
3. Sodium thiosulfate stock solution: 5% (w/v) sodium thiosulfate anhydrous in dH_2O. This solution should be stored at 4°C. (*See* **Note 1**.)
4. Silver staining: Proteins in the 2-D gel are stained with silver. We used the ammoniacal silver nitrate method modified by Hochstrasser et al. ***(6)*** and Rabilloud ***(7)***.

3. Method

3.1. Preparation of Protein Samples

Pellets of cells or tissue should be resuspended in 100 µl of 10 m*M* Tris-HCl pH 7.4 and sonicated on ice for 30 s. Add one volume of lysis solution B and mix. The mixed solution should not be warmed up above room temperature. Samples can be loaded directly onto the gels or stored at −80°C until needed. (*See* **Note 2** for plasma sample preparation and **Note 3** for optimal sample loading).

3.2. Isoelectric Focusing (IEF)

1. Draw a line at 16 cm on clean and dry glass capillary tubes (capillary should be cleaned with sulfochromic acid to eliminate all deposits). The remaining 0.5 cm of the capillary tubes is used to load the sample. Place each tube in a small glass test tube (tube of 5 ml) which will be filled with the isoelectric focusing gel solution. Connect the tops of each glass capillary tube to flexible plastic tubes joined together with a 1 ml plastic syringe.
2. At least twelve capillary gels can be cast with 11.5 ml of isoelectric focusing gel solution (800 µL of solution is needed per capillary).
   a. Prepare one milliliter of CHAPS 30% (w/v) and NP-40 (nonidet P-40) 10% (w/v) (0.3 g CHAPS and 0.1 g NP-40) and degase for 5 min.
   b. Separately, prepare a second solution: 10 g urea (7 ml of water is added to dissolve the urea at warm temperature, around 35°C), 2.5 ml of acrylamide stock solution, 0.6 ml of ampholytes pH 4–8, 0.4 ml of ampholytes pH 3.5–10 and 20 µL of TEMED.
   c. Mix the first solution (CHAPS, NP-40) with the second one. Degase the mixture and add 40 µL of APS 10% (w/v) stock solution. Pipette one ml of this isoelectric focusing gel solution into the glass test tubes (along the side walls in order to prevent the formation of air bubbles in the solution). Fill up the capillary tubes by slowly pulling the syringe (up to the height of 16 cm).
   d. After 2 h of polymerization at room temperature, pull the capillary tubes out of the glass test tubes. Clean and gently rub the bottom of each capillary gel with parafilm.
3. Fill the lower chamber with the anodic solution. Wet the external faces of the capillary tubes with water and insert them in the isoelectric focusing chamber. Load the samples on the top of the capillary (cathodic side). Generally, thirty to 40 µL of the final diluted sample is loaded using a 25 µL Hamilton syringe (*see* **Notes 3** and **4**).
4. Lay down the cathodic buffer solution at the top of the sample in the capillary tube and then fill the upper chamber. Connect the upper chamber to the cathode, and the lower chamber to the anode.
5. Electrical conditions for IEF are 200 V for 2 h, 500 V for 5 h and 1000 V overnight (16 h) at room temperature (*see* **Note 5**).
6. After IEF, remove the capillary tubes from the tank and force the gels out from the glass tube with a 1 ml syringe which is connected to a pipet tip and filled with water (*see* **Note 6**). Put the extruded capillary gels on the higher glass plate of the polyacrylamide gel (*see* **Subheading 3.3**). Residual water around the capillary gel should be soaked up with a filter paper. Put 140 µL of IEF equilibration buffer down on the capillary gel. Immediatly push the capillary gels between the glass plates of the polyacrylamide gel using a small spatula. Place the cathodic side (basic end) of the capillary gel at the right side of the polyacrylamide gel. Care should be taken to avoid the entrapment of air bubbles between the capillary and the polyacrylamide gels. It is not necessary to seal the capillary gels with agarose solution but the contact between the capillary gel and the 9–16% polyacrylamide gradient gel should be very tight.

3.3. SDS Polyacrylamide Gel Electrophoresis

1. In order to separate the majority of proteins, a 9–16% (w/v) polyacrylamide gradient gel is used for the second dimension. The gel is made as follows with 60 ml solution for a 9–16% (w/v) gel: 30 ml of 9% (w/v) acrylamide solution and 30 ml of 16% (w/v) acrylamide solution. Sixty milliliters are necessary to cast one gel of 1.5 mm × 200 mm × 160 mm (*see* **Note 7**).

Light solution:

9 ml of acrylamide stock solution (30% v/v)
7.5 ml 1.5 *M* Tris-HCl pH 8.8 (25% v/v)
150 µL 5% sodium thiosulfate solution (0.5% v/v)
15 µL TEMED (0.05% v/v)
13.2 ml water. This solution is degased and then 150 µL of 10% APS solution (0.5% v/v) is added.

Heavy solution:

16 ml of acrylamide stock solution (53% v/v)
7.5 ml 1.5 *M* Tris-HCl pH 8.8 (25% v/v)
150 µL of 5% sodium thiosulfate solution (0.5% v/v)
15 µL TEMED (0.05% v/v)
6.2 ml water. This solution is degased and then 150 µL of 10% APS solution (0.5% v/v) is added.

The gradient gel is formed using the Model 395 gradient Former (Bio-Rad) and a peristaltic pump. Immediately after the casting, the gels are gently over layered with a water-saturated 2-butanol solution using a 1 ml syringe. This procedure avoids the contact of the gel with air and allows to obtain a regular surface of the gel. Caution should be taken to avoid mixing the 2-butanol with the gel solution. The gels are stored overnight at room temperature to assure complete polymerization.

2. Prior to the second dimension separation, wash extensively the top of the gels with deionized water to remove any remaining 2-butanol. Remove the excess of water by suction with a syringe.
3. After the transfer of the capillary gel on top of the gradient polyacrylamide gel (see **Subheading 3.2.**, **step 6**), fill the upper and the lower reservoirs with the running buffer and apply a constant current of 40 mA per gel. The separation usually requires 5 h. The temperature in the lower tank buffer is maintained at 10°C during the run.
4. At the end of the run, turn off the power, rinse briefly the gel in distilled water for a few seconds and process for gel staining. A typical gel pattern of plasma proteins stained with the ammoniacal silver nitrate method is shown in **Fig. 2** ***(6, 7).***

4. Notes

1. The addition of thiosulfate to the gel delays the appearance of background staining with the ammoniacal silver nitrate method ***(6, 7).***
2. Human plasma proteins have been efficiently separated with the following sample preparation: 5 µL of plasma (containing approximately 400 µg

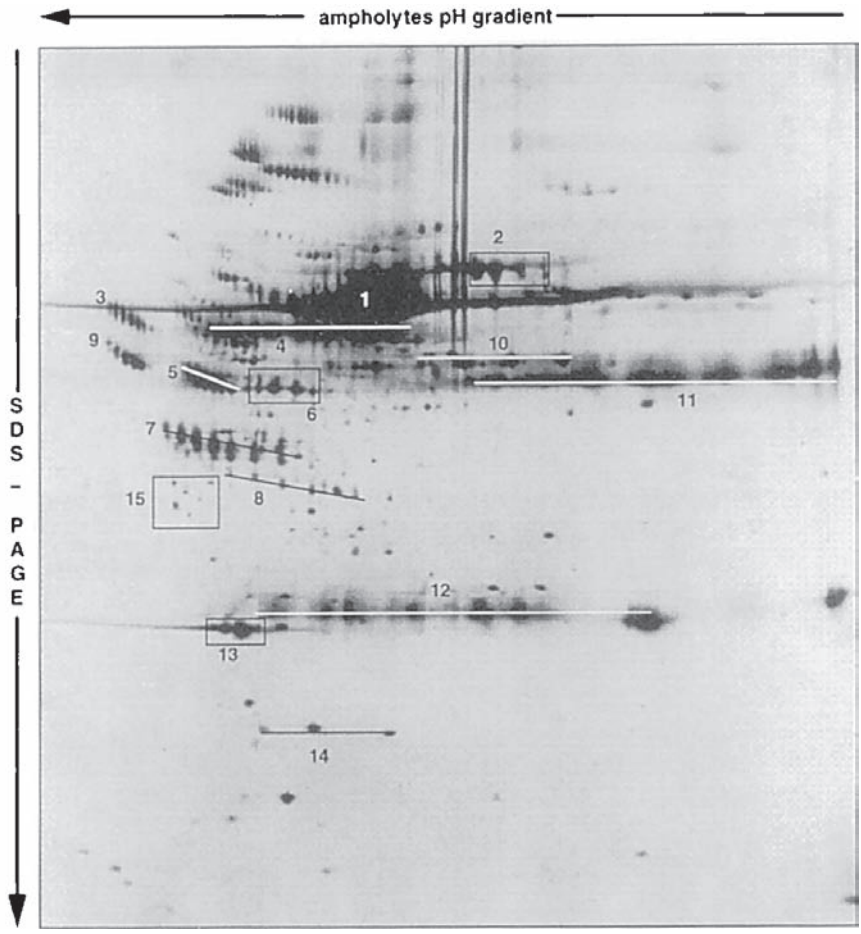

Fig. 2. Silver stained plasma proteins separated by two-dimensional polyacrylamide gel electrophoresis using carrier ampholyte pH gradient in the first dimension. *1,* albumin; *2,* transferrin; *3,* α_1-antichymotrypsin; *4,* IgA α-chain; *5,* α_1-antitrypsin; *6,* fibrinogen γ-chain; *7,* haptoglobin β-chain; *8,* haptoglobin cleaved β-chain; *9,* α_2-HS-glycoprotein; *10,* fibrinogen β-chain; *11,* IgG γ-chain; *12,* Ig light chain; *13,* Apolipoprotein A-1; *14,* haptoglobin α_2-chain; *15,* apolipoprotein J.

of proteins) are solubilized in 10 µL of lysis solution A (SDS-DTE) and heated in boiling water for 5 min. After cooling for 2 min at room temperature, 485 µL of lysis solution B is added. For silver stained gel, 30 to 40 µL of the final diluted sample is loaded on the top (cathodic side) of the capillary gel.

3. The best separation of complex protein mixtures is performed when less than 100 µg of proteins are loaded onto the capillary gel. Overloading may

cause streaking and inadequate resolution of spots. The use of a highly sensitive staining method (silver staining) allow to applied a low amount of proteins onto the IEF gel. For silver stained gel, concentrations up to 25–40 µg per gel are enough.

4. During the sample loading, it is very important to avoid the formation of air bubbles between the gel and the sample. After the loading, the Hamilton syringe should be withdrawn slowly along the side wall.
5. If more than 20 kVh is applied during the isoelectic focusing, more cathodic drift occurs and the protein pattern is not stationary.
6. Low pressure on the 1 ml syringe should be exerted to extrude the capillary gel. If too much pressure is applied, small lumps will be formed on the gel.
7. Precise determination of the volume of solution necessary to cast the gels should first be done by measuring the volume of distilled water required to fill one resolving gel or the casting chamber.

Vertical Agarose Electrophoresis and Electroblotting of High-Molecular-Weight Proteins

Marion L. Greaser and Chad M. Warren

1. Introduction

Very large molecular weight proteins are difficult to separate by electrophoresis because of their poor penetration into gels using the Laemmli SDS polyacrylamide system ***(1).*** Protein migration in SDS gels has been found to be linear with the log of the molecular weight ***(2),*** so the larger the protein, the more poorly it is resolved from other big proteins. Many workers have attempted to solve this problem by using very low concentration acrylamide gels ***(3),*** acrylamide mixed with agarose ***(4),*** or acrylamide gradients ***(5)*** to better separate large proteins. Low concentration acrylamide gels are difficult to use because of their mechanical fragility and distortion during handling; these problems are magnified when blotting is attempted. An additional difficulty in blotting very large proteins is their poor transfer to the membrane. Inclusion of 2-mercaptoethanol in the transfer buffer improves transfer efficiency, but acrylamide gels stained after transfer typically still contain most of the giant muscle protein titin ***(6)***.

A new electrophoresis system using SDS agarose for protein electrophoresis and blotting has been described ***(7).*** An example showing the resolution for several muscle samples containing large proteins is shown in **Fig. 1.** Migration distance shows a linear relationship with the log of the molecular weight ***(7)***. This system allows quantitative transfer of proteins from the gel with much higher reproducibility than can be achieved with methods using low percentage acrylamide.

2. Materials

2.1. Apparatus

1. SE 600 Slab Gel Unit with 16 × 18 cm glass plates (Hoefer) or a similar commercial gel unit (*see* **Note 1**).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

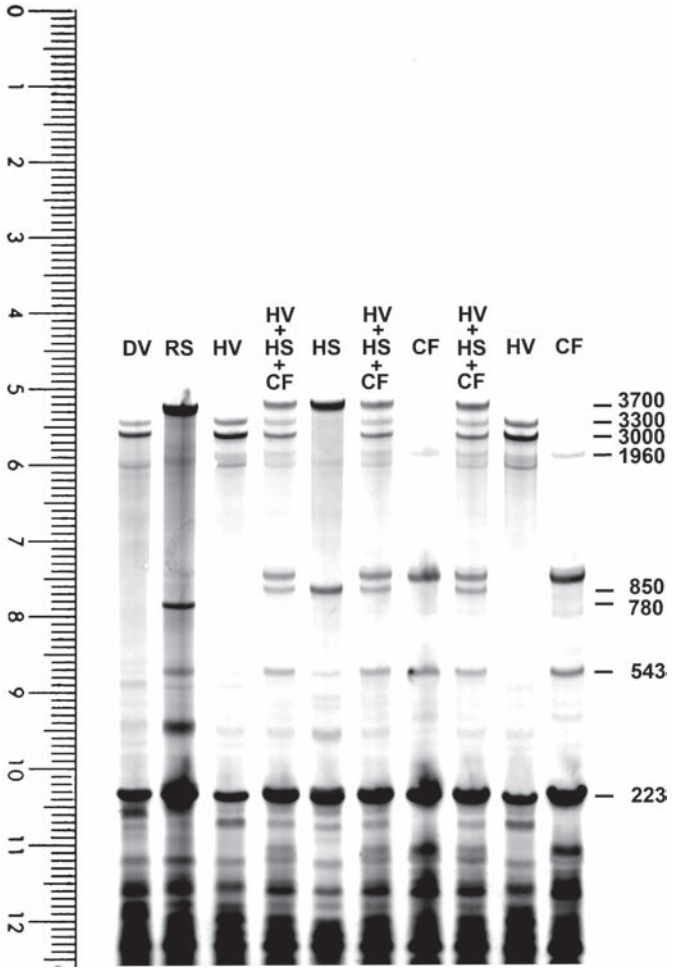

Fig. 1. SDS 1% agarose gel stained with silver. A centimeter ruler is shown on the left and the sizes of the various protein bands in KDa are listed on the right. DV, dog ventricle; RS, rat soleus; HV, human ventricle; HS, human soleus; CF, crayfish claw muscle. Human soleus titin is 3700 KDa and human ventricle has two titin bands of 3300 and 3000 KDa. The bands at 780 and 850 KDa are rat and human nebulin respectively. The myosin heavy chain is 223 KDa. Blotting proteins this size from acrylamide gels usually results in incomplete transfer, but full transfer can be achieved with agarose *(7)*.

2. 65°C oven.
3. A constant current power supply.
4. Circulating cooler.
5. TE62 Tank Blotting Unit, Hoefer.

2.2. Reagents

1. Acrylamide gel for plug; 38.5 % acrylamide. Weight 37.5 g of acrylamide (Biorad) and 1 g DATD (Biorad) into a beaker, add about 50 ml of water, stir till dissolved, dilute to 100 ml. Filter through a 0.45 micron filter (such as a Millex-HA, Millipore Corporation). Store in a brown bottle in the cold room (4°C). Danger! Avoid skin contact.
2. Reservoir and agarose gel buffer concentrate (5X); 0.25 *M* Tris, 1.92 *M* glycine, 0.5% SDS. Store at room temperature.
3. Ammonium persulfate; Prepare a 100 mg/ml solution in water; store frozen in 0.5 ml aliquots (stable indefinitely at −20°C).
4. Sample buffer; 8 *M* urea, 2 *M* thiourea, 0.05 *M* Tris-HCl (pH 6.8), 75 mM DTT, 3% SDS, 0.05% bromophenol blue (adapted from ***8***). (Dissolve urea and thiourea and treat with mixed bed resin to remove ionic constituents; then add remaining ingredients. Store at −20 °C).
5. 50% v/v glycerol.
6. Transfer buffer; 20 m*M* Tris, 150 m*M* glycine, 20% v/v methanol ***(7, 8)*** or 10 m*M* CAPS, pH 11 (Sigma Chemical Company) ***(9).*** For high molecular weight proteins, add SDS and 2-mercaptoethanol to 0.1% and 10 m*M* respectively to the transfer buffer.
7. SeaKem Gold agarose (Lonza Group Ltd.)

3. Methods

3.1. Gel Preparation

1. Volumes listed will provide enough solution for two 16 × 18 cm gels with 1.5 mm spacers. One is used for staining either with Coomassie blue or with silver with a special procedure for agarose ***(7),*** the other for blotting.
2. Clean plates and spacers with soap, rinse with distilled water and finally with ethanol.
3. Assemble gel plates. Place plate on clean bench top. Place spacers hanging half the way off each side of plate. Place second plate on top. Stand up plates and place one side into the clamp. Align spacer with side of plates and clamp and push spacer down so that bottom is flush with the glass plates (top buffer will leak if spacers are not flush with plates).
4. Pour acrylamide plugs in bottom of gel plate assembly (*see* **Note 2**): In a 15 ml plastic beaker add: 1.924 ml de-ionized water, 1.7 ml 50% glycerol, 2.12 ml 3 *M* Tris (pH 9.3), 2.72 ml acrylamide (40%), 24 µL 10% ammonium persulfate, and 13 µL TEMED. (*see* **Note 2**) Mix by pipeting a few times. Immediately add 2.5 ml to each gel assembly. Add a small amount of water on top of each plug to level the upper surface and provide an oxygen barrier. Allow gel to polymerize for 20–30 minutes. Drain off water layer by inverting gel plate assembly on a paper towel.
5. Place assembly, 20 lane sample combs, and 60 ml plastic syringe in a 65°C oven for 10 minutes (*see* **Note 3**).

6. Weigh 0.8 g of SeaKem Gold agarose (*see* **Note 4**) into a 600 ml beaker (*see* **Note 5**). To a 100 ml graduated cylinder add 48 ml of 50% v/v glycerol (*see* **Note 6**), 16 ml 5X electrophoresis buffer, and bring volume up to 80 ml with deionized water. Place parafilm over top of the graduated cylinder, mix by inverting a few times, and pour solution into the 600 ml beaker containing the agarose. Place saran wrap over top of beaker and poke a few holes in the saran wrap. Weigh beaker with contents. Place beaker in a microwave oven along with a separate beaker of de-ionized water. Heat for a total of 2 minutes (stop every 30 seconds to swirl – protect hand with an insulated glove) (*see* **Note 7**).
7. Allow agarose to cool for a few minutes at room temperature. Reweigh, and add sufficient heated de-ionized water to replace that lost by evaporation.
8. Draw up about 40 ml of agarose in the prewarmed 60 ml Luer-Lock syringe and pour each gel slowly until it just overflows the top of the plates. Try to avoid formation of bubbles (if bubbles present, bring them to the top of the gel and pinch them with the sample comb). Insert sample combs and allow unit to cool at room temperature for about 45 minutes (*see* **Note 8**),

3.2. Electrophoresis Setup and Sample Loading

1. Add 4 liters of buffer to lower chamber (3200 ml de-ionized water plus 800 ml 5X electrophoresis buffer). Start cooling unit and stir bar (gels run at 6°C).
2. Prepare 600 ml upper chamber electrophoresis buffer (same concentration as lower chamber buffer). Add 2-mercaptoethanol (final concentration of 10 m*M*). Buffer will be poured into top chamber after samples are loaded and assembly placed in unit.
3. Take combs out of gels by bending them back and forth to detach from gel and slowly pull them up. Pour a small amount of upper chamber buffer into a 15 ml beaker and pipette buffer into first and last wells (the rest will fill over). Add buffer to remove any trapped bubbles. Insert pipette tip to deposit sample in bottom of the sample well. Skip the first and last lanes (*see* **Note 9**).
4. Running gels. Once samples are loaded, put upper chamber on the assembly. Pour upper chamber buffer into upper chamber from corners (do not pour buffer directly over wells). Place lid on unit, and connect to power supply. Turn electrophoresis unit on and run at 30 mAmps (2 gels) for 3 hours.

3.3. Staining and Western Blotting

1. After tracking dye reaches the bottom of the acrylamide plug, turn off the power and disassemble the plates. Cut off sample wells and acrylamide plug and discard. Soak the remaining agarose gel in 10 m*M* CHAPS (pH 11.0), 0.1% SDS, and 10 m*M* 2-mercaptoethanol for 30 minutes with gentle shaking.
2. The gel is then placed on top of either a sheet of PVDF or nitrocellulose, assembled into the transfer unit, and the protein electrophoretically transferred using 40 V constant voltage for 2–3 hours (*see* **Note 10**).
3. Blotted proteins can then be treated using conventional procedures with either colorimetric (horseradish peroxidase or alkaline phosphatase substrates) or ECL (enhanced chemiluminescence) methods.

4. Notes

1. The agarose gel procedure works equally well with small format gels (i.e., 8 × 10 cm).
2. The acrylamide plug is used to prevent the agarose from slipping out of the vertical gel plate assembly. Use of DATD as the cross-linker provides a stickier bond of the acrylamide to the glass plates than if a conventional bisacrylamide cross-linker is used. Plugs can be poured a day before making the gel (place tape or parafilm over the top of the plates to prevent drying and store in cold room).
3. Preheating the glass plate assembly, well comb, and syringe prevents premature agarose gelling when the solution touches the colder surfaces. In addition the plates are less likely to crack during pouring if they are closer to the temperature of the hot agarose.
4. The supplier for SeaKem Gold agarose has changed twice since 2003. Biowhittaker was succeeded by Cambrex who was followed by Lonza Group Ltd, Muenchensteinerstrasse 38, CH-4002 Basel, Switzerland.
5. It is essential to use SeaKem Gold agarose for optimal migration of high molecular weight proteins. This type has large pore size and excellent mechanical stability. Other types of agarose may be used, but the protein mobility will be significantly reduced.
6. Glycerol is included in the mixture to increase the solution viscosity inside the gel and thus sharper protein bands.
7. Periodic swirling during the heating step eliminates non-hydrated agarose granules in the final gel.
8. Sample combs should extend no longer than 1 cm into agarose; otherwise they may be difficult to remove. Gels can be used right away or stored overnight in cold room.
9. Conventional sample buffers may not be dense enough for the sample to stay at the bottom of the well. If necessary add additional glycerol (up to 30% v/v final concentration) to increase sample density.
10. The disulfide bond formation of large proteins during electrophoresis also retards their migration out of the gel onto blots during transfer. Thus inclusion of 2-mercaptoethanol in the transfer buffer improves efficiency of transfer of high molecular weight proteins. The use of the agarose electrophoresis system with inclusion of 2-mercaptoethanol in the transfer buffer results in complete transfer of all high molecular weight proteins out the gel, including titin (Mr 3000 to 3700 KDa subunit size) ***(7).***

Two-Dimensional PAGE of High-Molecular-Mass Proteins

Masamichi Oh-Ishi and Tadakazu Maeda

1. Introduction

Many high-molecular-mass proteins (MW>100 kDa) are known to be involved in cytoskeleton, defense and immunity, transcription and translation in higher eukaryotic organisms. Though a variety of protein separation techniques have been described, at the moment purification of a high-molecular-mass protein remains a difficult task. O'Farrell ***(1)*** was the first to devise a two-dimensional gel electrophoresis (2-DE) technique which could detect more than 1000 spots in a gel. Though it is evident that this method was quite powerful in his days, the method is not particularly suitable in analyzing high-molecular-mass proteins larger than 200 kDa. When skeletal muscle, for example, is simultaneously analyzed by sodium dodecyl sulfite (SDS)-polyacrylamide gel electrophoresis (PAGE) and O'Farrell's 2-DE method, myosin heavy chain (approx 200 kDa) is clearly seen in the former gel, but not in the latter. Hirabayashi ***(2)*** was the first to develop a 2-DE method which could analyze high-molecular-mass proteins, including myosin heavy chain and dystrophin, as large as 500 kDa ***(3).*** His trick was the use of agarose gel instead of polyacrylamide gel for the first-dimensional isoelectric focusing (IEF). Agarose gel, when used for IEF, can analyze much larger proteins than the polyacrylamide gel can. Oh-Ishi and Hirabayashi ***(4)*** further improved the method by adding 1 *M* thiourea and 5 *M* urea in an agarose IEF medium. Thiourea is a potent protein solubilizing reagent especially effective for high-molecular-mass proteins that could enter the first-dimensional agarose IEF gel. Here, we describe the 2-DE method with agarose gels in the first dimension (agarose 2-DE) that is compatible with analyzing high-molecular-mass proteins.

2. Materials

2.1. Equipment

1. Apparatus for first-dimensional agarose IEF (AE-6300 electrophoresis unit) ATTO (Tokyo, Japan).
2. Glass tubes (260 mm × 3.4 mm ID) for agarose IEF (ATTO).
3. Dialysis membranes.
4. Rubber bands.
5. Syringe to fit thin 30-cm-long polyethylene tubing.
6. Electrophoresis power supply (Crosspower 3500) (ATTO).
7. Horizontal electrophoresis apparatus (Multiphor II, GE Healthcare).
8. Immobiline DryStrips pH 3–10 L (GE Healthcare).
9. Perista pump (SJ-1211) (ATTO).
10. Glass tubes (300 mm × 5 mm ID) for protein fixation on agarose IEF gels.
11. Polyvinyl chloride (PVC) tubing (400 mm × 2 mm ID).
12. Vertical type apparatus for second-dimensional SDS-PAGE (NA-1200 electrophoresis unit) Nihon Eido (Tokyo, Japan).
13. Glass plates with a 1.5-mm thick frame (size 165 mm × 240 mm) for second-dimensional SDS-PAGE (Nihon Eido).
14. Plain glass plates (size 165 mm × 240 mm) for second-dimensional SDS-PAGE (Nihon Eido).

2.2. Reagents

1. Agarose IEF gels: Agarose IEF and pharmalyte were purchased from GE Healthcare. D-sorbitol, urea, and thiourea were from Wako Pure Chemicals (Osaka, Japan). Agarose IEF gels were prepared according to the protocols in section 3.1.1 Gel preparation and in **Table 1**.
2. Extraction medium: 7 *M* urea, 2 *M* thiourea, 2% CHAPS, 0.1 *M* dithiothreitol (DTT), 2.5% Pharmalyte, and protease inhibitors (Complete Mini ethylenediaminetetraacetic acid [EDTA]-free; Roche).
3. Overlaying solution: 4 *M* urea, 1 *M* thiourea.
4. Cathode buffer: 0.2 *M* NaOH.
5. Anode buffer: 0.04 *M* DL-aspartic acid.
6. Protein fixing solution: 10% trichloroacetic acid, and 5% sulfosalycylic acid.
7. Incubation medium: 2% SDS, 10% glycerol, 5% 2-mercaptoethanol, 0.02% bromophenol blue, and 0.05 *M* Tris-HCl, pH 6.5.
8. Staining solution: 0.02% PhastGel Blue R (coomassie brilliant blue R-350; GE Healthcare), 30% methanol, and 10% acetic acid.
9. Destaining solution: 30% methanol, and 10% acetic acid.

3. Methods

3.1. Agarose Gels for IEF

3.1.1. Gel preparation

1. We prepared the first-dimensional agarose IEF gels following the same procedure as described in our former report ***(5)***, to which we added the modifications described

here. Three agarose IEF gels (180 mm in length and 3.4 mm in diameter) containing 1 *M* thiourea and 6 *M* urea were prepared by the present protocol.

2. Agarose IEF (0.10 g) and D-sorbitol (1.2 g) were put into a 50 mL beaker, and dissolved in 5.8 mL distilled water at room temperature (solution A) (*see* **Note 1**).
3. Solution A was boiled 10 times for 15 s in a microwave oven until the solution became clear, and was kept in a 70°C water bath for 5 min.
4. A mixture of urea (3.6 g) and thiourea (0.76 g) powder was put into the solution A at 70°C, which we shall call solution B hereafter (*see* **Note 2** and **Table 1**). The volume of solution B was then adjusted to 9.0 mL with distilled water, and was kept at room temperature.
5. Solution B was divided into three test tubes: 1.0 mL for acidic, 4.5 mL for neutral, and 2.5 mL for basic solutions.
6. Four kinds of Pharmalyte (pH 2.5–5 for acidic, pH 3–10 and pH 4–6.5 for neutral and pH 8–10.5 for basic solutions) were added to the respective tubes according to the protocol shown in **Table 1**.
7. A glass tube (standard size: 260 mm × 3.4 mm ID) was prepared beforehand, the bottom of which was covered with a piece of dialysis membrane and tied with a rubber band.
8. The glass tube was set to AE-6300 electrophoresis unit (apparatus for agarose IEF produced by ATTO).
9. The acidic, neutral, and basic solutions were sucked in with one syringe each through thin 30-cm-long polyethylene tubing. First, the acidic solution was softly injected into the glass tube until the meniscus reached a height of 20 mm from

Table 1
Protocols for Making Agarose Isoelectric Focusing (IEF) gels

the bottom of the tube. Next, the neutral solution was slowly injected until the meniscus reached a height of 135 mm from the bottom, and then the basic solution was carefully injected until the meniscus was 180 mm from the bottom. A 10 μL overlaying solution was gently layered on top of the agarose solution, which made it easier for proteins to enter the agarose IEF gel. The glass tube was filled with the chamber and kept there at least 6 h, until the agarose solution gelled (*see* **Note 3**).

3.1.2. Sample Preparation

1. Freshly obtained mammalian tissues were cut into small blocks, quickly frozen in liquid nitrogen, and stored at −80°C until use. Each frozen tissue piece (about 10 mg) was homogenized with a Teflon glass homogenizer in an extraction medium (20 times the volume of the tissue pieces) (e.g. brain, muscle, kidney, and liver). Homogenates of the tissues were centrifuged at 112,000 g for 20 min, and the clear supernatant was subjected to the agarose IEF gel.

3.1.3. Sample Application

1. We added 10–200 μL of protein sample solution at the cathodic end of the gel, and gently filled the overlaying solution above the sample solution to the top of the glass tube. We added anode buffer to the lower reservoir, and cathode buffer to the upper reservoir. First-dimensional IEF was conducted at 600 V for 18 h at 4°C.
2. Then the agarose gel was transferred onto the top of the second-dimensional SDS gel, either directly or after proteins in the gel were fixed (*see* **Note 4**).

3.2. Second-Dimensional SDS-PAGE

1. Slab gels for second-dimensional electrophoresis were 12% polyacrylamide gels (200 mm × 120 mm × 1.5 mm). Second-dimensional SDS-PAGE was carried out according to the stacking system of Laemmli ***(6)*** with the slight modification of adding 1% SDS both in the stacking and separation gels.
2. The first-dimensional agarose IEF gel was loaded on top of the stacking gel without SDS equilibration (*see* **Note 5**) and covered with 1% agar solution to keep the agarose IEF gel in place. An incubation medium was overlaid on the IEF gels.
3. The second-dimensional gel electrophoresis was started with a constant current at 40 mA for 1 h and continued at 70 mA until the end of the run.
4. The slab gels were first soaked and shaken overnight in a destaining solution, which removed Pharmalytes from the gel (*see* **Note 6**). The slab gels were then stained with a staining solution containing PhastGel Blue R and destained with the destaining solution.

3.3. Comparison of IPG-Dalt with Agarose 2-DE

1. In this study, we compared the agarose 2-DE system with IPG-Dalt (immobilized pH gradients for IEF in the first dimension, SDS-PAGE in the second dimension) to assess their capability of analyzing high-molecular-mass proteins.
2. The first-dimensional IEF with IPGs was performed essentially as described by Gorg *et al*. ***(7)***. IPG dry strips (Immobiline DryStrips pH 3–10 L) and Multiphor II (GE Healthcare) were used in this study.

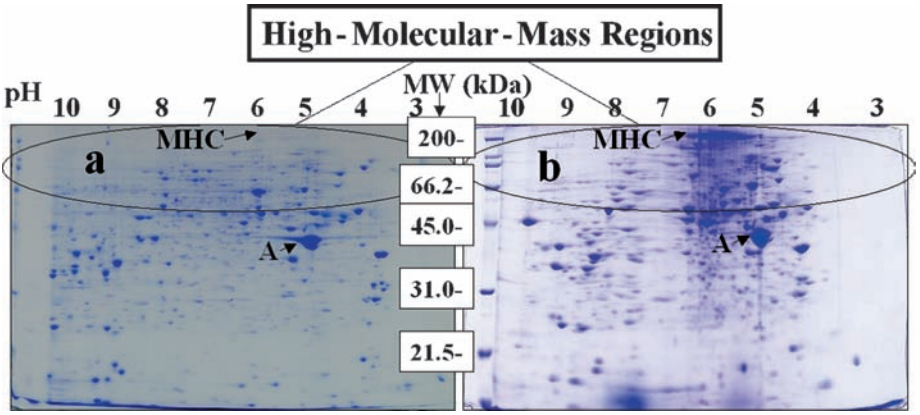

Fig.1. Comparison of IPG-Dalt and agarose two-dimensional gel electrophoresis (2-DE). Tissues used are rat duodenum. **(A)** A 2-DE gel with immobilized pH gradients (IPGs) in the first dimension. **(B)** A 2-DE gel with agarose gels in the first dimension. Proteins loaded on an agarose isoelectric focusing gel and an IPG gel were 740 μg. Note that spot densities are different in the high-molecular-mass regions. A, actin; MHC, myosin heavy chain. The gels were stained with PhastGel Blue R.

3. Coomassie-stained 2-DE patterns of rat duodenum (**Fig. 1**) revealed that high-molecular-mass proteins larger than 150 kDa could be analyzed with the agarose 2-DE but not with IPG-Dalt.

4. Notes

1. Shake the beaker gently until a mixture of agarose IEF and D-sorbitol powder is completely suspended.
2. Immediately after the mixture of urea and thiourea powder was put into the beaker, solution B was stirred with a magnetic stirrer until the urea and thiourea were completely dissolved.
3. As a side effect of thiourea, a thiourea-urea agarose IEF solution does not gel at room temperature but at 4°C, and the gel formed at 4°C does not melt even when the gel is returned to room temperature. From the practical point of view of an experimental scientist, the 1 *M* thiourea/5 *M* urea-agarose IEF gel was a tremendous improvement over the 7 *M* agarose IEF gel originally used ***(2)***, because the agarose solution temperature no longer needed to be kept above 40°C when preparing agarose IEF gels.
4. When proteins in the agarose gel were fixed prior to the second dimensional electrophoresis, the gel was extruded into a 300-mm-long, 5-mm-diameter glass tube filled with a protein fixing solution containing 10% trichloroacetic acid and 5% sulfosalycylic acid. Both ends of the 5 mm diameter tube were connected to a Perista pump with PVC tubing to form a closed

circuit filled with the fixing solution. When more than two gels were to be fixed, each of the gels was respectively extruded in a 5-mm-diameter glass tube, which was serially connected to one another to form a bigger closed circuit filled with the fixing solution. The proteins in the gel were fixed by 1 h circulation of the fixing solution in the 5-mm-diameter glass tube with a Perista pump, followed by 1 h circulation of 500 mL distilled water.

5. Avoid SDS equilibration step because the step easily spreads proteins out of the agarose gel.
6. Thorough removal of Pharmalytes from first-dimensional agarose IEF gel is useful in two respects: one is to reduce spot deformations by Pharmalyte pH 8–10.5 in the basic pI (>8) and low molecular mass (<30 kDa) region of a 2-DE gel and the other is to lower the background level of a Coomassie-stained 2-DE gel.

Casting Immobilized pH Gradients

Elisabetta Gianazza

1. Introduction

One of the main requirements for a 2-D protocol is reproducibility of spot position, and, indeed, the technique of isoelectric focusing on immobilized pH gradients (IPGs) is ideally suited to provide highly reproducible 1-d separations. IPGs are obtained through the copolymerization of acidic and basic acrylamido derivatives of different pKs within a polyacrylamide matrix ***(1, 2)*** (**Fig. 1**). The pH gradient may be devised by computer modeling either with a linear or with an exponential course. IPGs are cast from two limiting solutions containing the buffering chemicals at concentrations adjusted to give the required pH course upon linear mixing. For consistent results, gradient pouring and polymerization are carried out under controlled conditions. The covalent nature of the chemical bonds formed during the polymerization step results in a permanent stability of the pH gradient within the matrix. Conflicting requirements during the focusing procedure prevent any effective use of IPGs into capillary tubes ***(3)***: The need to buffer with carrier ampholytes (CAs) the pH extremes caused by the migration of the polymerization catalysts is contrasted by the adverse effects of the electroendosmotic flow brought about by the addition of CAs to the gel phase. The demand for the IPG gels to be backed by a binding support—they are usually cast on GelBond™ foils—results in dimensional stability between 1-D and 2-D as a further assistance to reproducibility.

Toward the aim of reproducibility, batch production and quality control as allowed by an industrial process give the commercially available IPG strips (e.g. Immobiline DryStrip™ from GE-Amersham, Uppsala, Sweden) obvious advantages over homemade slabs. Moreover, the pH course of the commercial product is being carefully characterized in chemicophysical terms, by assessing the dissociation constants of the acrylamido buffers under the experimental

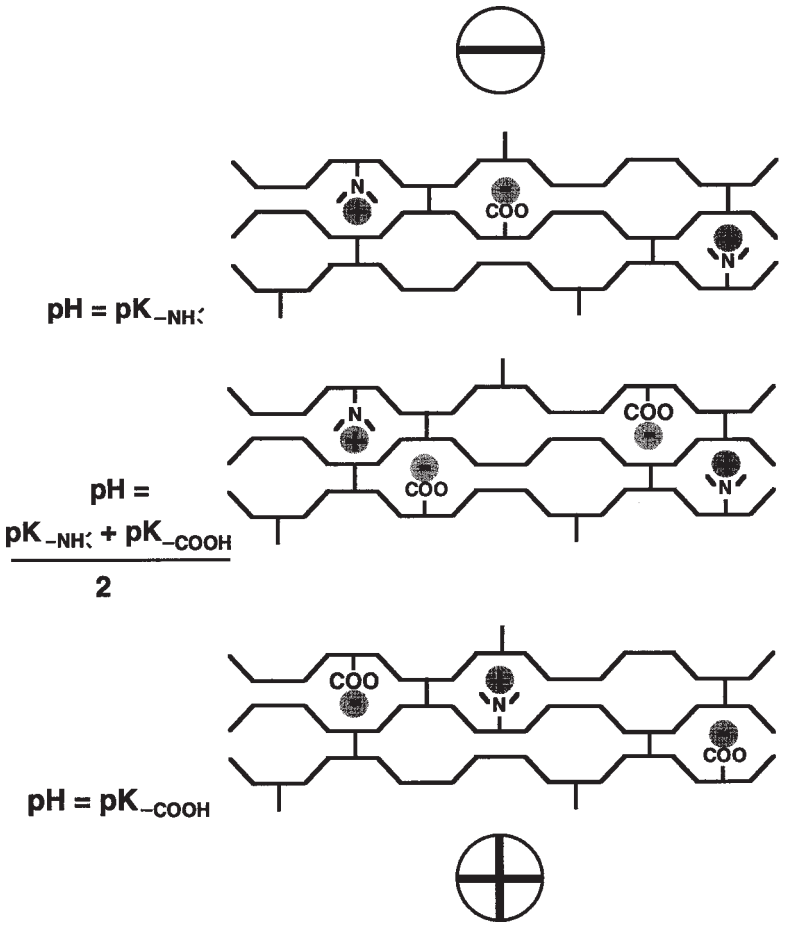

Fig. 1. Structure of the IPG matrix. Different regions of an IPG made up with a basic and an acidic Immobiline are schematically drawn, from cathode to anode. In each region, pH depends from the concentration ratio between the basic and the acidic dissociating groups. From the Henderson-Hasselbalch equation, where the concentration of the basic monomer is twice the concentration of the acidic monomer, pH equals the pK of the base, where the concentration of the basic monomer is one half the concentration of the acidic monomer pH equals pK of the acid, where the two concentrations are alike pH equals the mean between the two pKs.

conditions relevant to the 1-d run of an IPG-DALT ***(4)***. The aim of this effort is to connect focusing position reliably with p*I* ***(5)***; any discrepancy between computed and experimental values for known proteins would then hint at the occurrence of posttranslational modifications ***(6)***.

From the above it seems this chapter could shrink to the statement: Use the readymade IPG strips according to the manufacturer's instructions. However, there are reasons, and not only of economical order, for laboratories to cast their own slabs. The main one is the variability of the analytical needs. 2-D protocols usually aim at the resolution of all peptide components of a complex mixture. Although the proteins in cellular extracts and biological fluids have mostly mildly acidic p*I* values, this is not true of all samples, and the optimal pH course should be devised accordingly. Moreover, after specific qualitative or quantitative variations have been detected for some spots as the result of a given experimental treatment, it is usually worth investigating the area of interest under conditions of maximal resolution. This is especially true if the spots have to be identified or characterized (e.g., by mass spectrometry [MS] techniques) ***(7)***. IPGs allow the tailoring of wide, narrow, or ultranarrow pH gradients, whereas migration on continuous or gradient PAA slabs of different %T in 2-D may further improve resolution of the spots of interest. In order to optimize reproducibility and to increase throughput, laboratories handling a very large number of gels may consider a medium-scale production with gradient pouring through mechanical devices (computer-driven burettes) **(8, 9)**. In any event, even at the typical laboratory level, the procedure of IPG casting is reliable and allows a remarkable reproducibility of results ***(10)***. The following will try to convince the readers that it is also an easy one.

2. Materials

2.1. Equipment

1. Polymerization cassette:
   a. A molding plate with a 0.5-mm-thick permanent frame. Available in two sizes, either 12.5 *x* 25 cm, w *x* h (cat. no. C2418, from Sigma, St. Louis), or 25 *x* 12.5 cm, w *x* h (cat. no.80-1106-89, from GE-Amersham).
   b. Gel-supporting plate.
   c. Gel-binding foil, e.g., GelBond PAG™ (GE-Amersham, Sigma).
   d. Clamps.
2. Gradient-mixing device:
   a. A two-vessel chamber (e.g., gradient maker cat. no. Z340405 or Z340413, from Sigma).
   b. Magnetic bars.
   c. Outlet to the mold, either a one-way silicone tubing (od 3 mm, id 1.5 mm, ca. 12 cm long, equipped with a 2-cm teflon tip) or multiple inlets cast by adapting the tips, ca. 6 cm long, of butterfly needles gauge 21 to a T-connector, available from Cole-Parmer (cat. no. K6365–70).
   d. A stirrer providing constant and even operation at medium to low rpm rating with minimal overheating.
   e. Screw-jack rising table.
3. Electrophoresis apparatus:

for upside-up (IPG matrix up) runs:

a. Horizontal electrophoretic chamber with movable electrodes.
b. Power supply able to deliver >3000 V. We recommend using a power supply with an amperometer sensitive to <1-mA currents.
c. Thermostating unit.

for upside-down (IPG matrix down) runs:

a. Specialized IEF cells (e.g., IPG-Phor from GE-Amersham)

4. Forced-ventilation oven at 50°C.
5. Shaking platform.
6. Fan.

2.2. Reagents

1. Acrylamido buffers: 0.2-*M* solutions (*see* **Table 1**), prepared either in water with 5 ppm of hydroquinone methylether as polymerization inhibitor for the acidic monomers or in *n*-propanol for the basic monomers. The chemicals are available from GE-Amersham (as Immobiline™) or from Fluka (Buchs, Switzerland). Storage at 4 °C; the expiration date is given by the manufacturer. The products are defined as irritant, whereas *n*-propanol is classified as highly flammable.
2. Acrylamide monomers stock solution: 30% T, 4% C ***(11)***. Dissolve in water 1.2 g *bis*acrylamide and 28.8 g acrylamide/100 mL final volume. Filter the stock through 0.8-mm membranes and store at 4°C for about 2 mo. The chemicals should be of the highest purity. Acrylamide has been recognized as a neurotoxin.
3. 40% w/v Ammonium persulfate solution: Dissolve 200 mg of ammonium persulfate in 440 µL of water. Store up to a week at 4°C.
4. TEMED: Store at 4°C for several months.
5. 87% v/v Glycerol.
6. 1 *M* Acetic acid: Dilute 57.5 mL of glacial acetic acid to 1 L.
7. Dimethyldichlorosilane solution: 2% v/v solution of dimethyldichlorosilane in 1,1,1-trichloroethane. Both chemicals are available from Merck (Darmstadt, Germany), or a ready-made solution is marketed by GE-Amersham as RepelSilane™.
8. Glycerol washing solution: 1% v/v glycerol.

Table 1
pK values of Immobilines™

Chemicals	water solution, 25°[a]	PAA gel, 10°C[a]	8 M urea in PAA gel, 10°C[b]

3. Method

3.1. Selecting a pH Range and a Gradient Course

The formulations for narrow to wide-range IPGs have been reported in a series of papers ***(12–15)***, and the recipes for casting the gradients collected ***(2)***. Most of the formulations use the acrylamido buffers marketed as Immobiline™ by GE-Amersham, since the pK distribution in their set is even and broad enough for all applications in the 4.0–10.0 pH region. For specific purposes—increased hydrophilicity, narrow ranges, pH extremes—other chemicals are available as acrylamido derivatives ***(16)*** or have been custom-synthesized ***(17)***. These chemicals are available from Fluka. Computer programs for pH gradient modeling, with routines optimizing the concentrations of the acrylamido buffers required in the two limiting solutions in order to give the expected pH course, have been described in the literature ***(18–20)***. For most practical applications, a wide pH gradient is required for 2-D mapping in order to resolve all components of a complex biological sample. A statistical examination of the p*I* distribution across characterized proteins as well as the typical maps of most biological specimens show a prevalence of acidic to mildly alkaline values over basic proteins. A nonlinear pH course is then expected to give improved resolution of most proteins in a complex sample. An exponential gradient whose slope increases from pH 6.0 to 7.0 and to 8.0 optimally resolves most samples run in IPGs: one such recipe ***(14)*** is given in **Table 2** (I), whereas

3.2. Selecting Size and Shape of the Gel Strips

In all 2-D protocols involving IPGs samples are run on individual strips. Depending on the available equipment/strip handling and on the requirements of the sample, to be shortly discussed below, alternative procedures may be applied (summarized in **Table 4**).

3.2.1. Strip Handling

IPG strips are either run upside-up with sample applied 'on-gel', or the sample is rehydrated 'in-gel' (as part of the soaking solution) and the reswollen strips are run upside-down. The latter procedure is standard with ready-made commercial products; strips with comparable performance may be home-made along the protocols detailed in this chapter.

Table 4
Options in IPG strip geometry[a]

Custom geometry of the strips	Problem to be solved
A - optimal sample loading near either electrode, 'on gel application'	
1) 160[a] OR 80[c] x (between 10 and 20) mm^2, no plateau 	medium-high total protein load, higher sample volume; no spot distortion across sample loading area
2) (160+20) OR (80+20) x 7 mm^2, with plateau at either electrode 	proteins focusing at, or near to, optimal loading area
3) (160+20) OR (80+20) x 12 mm^2, with plateau at either electrode 	higher sample volume
4) (20+160+20) OR (20+80+20) x 12 mm^2, with plateau at both electrodes 	higher ionic concentration
B - optimal sample loading throughout the strip, 'in gel rehydration'	
(20+80+20) OR (40+80+40) x 3.5 mm^2, with plateau at both electrodes 	higher sample volume higher ionic concentration

(continued)

Table 4
(continued)

Custom geometry of the strips	Problem to be solved
C – special-purpose protocols	
1) Tall, wedge-shaped plateau 	<u>*extremely*</u> high sample volume (typically, as a result of problems / mistakes in dilution)
2) High-M_r ligands in plateau[d] 	*in situ* affinity subtraction

[a] from ***(23)***
[b] reference is made to medium size slabs for second dimension, 160 mm wide; similar concepts apply when rescaling the protocols to a different standard size
[c] two 80 mm-long strips can be mounted per second dimension slab, head-to-tail, after cutting the plateau area; this arrangement is valuable with low total protein load, or running a high number of routine samples
[d] from ***(30)***

3.2.2. Strip Shaping

Either the IPG slab is reswollen as a whole and grooves are then cut to leave parallel lanes on a continuous plastic backing (GelBond™), or the dry IPG is sliced together with its support and the strips independently reswollen.

The characteristics of the sample relevant for the choice of the loading procedure hence of the geometrical features of the IPG strips are (a) stability vs. pH, (b) volume and (c) salt content.

1. With some samples, only anodic or cathodic application performs well and avoid horizontal streaking of some proteins; this behavior disfavors in-gel rehydration.
2. When the strips are run upside-up, it is easy to cut strips several millimeters in width to arrange for higher protein loads and/or just larger sample volumes ***(21)*** (case A1 in **Table 4**). Sometimes however the optimal loading area (anodic, cathodic) overlaps the pI of relevant sample components, blurring/distorting their focusing pattern. Polymerizing an extension to the IPG, with constant pH, slightly higher at the cathode, slightly lower at the anode than the gradient bounds – polymerizing an immobilized pH (IP) plateau ***(21)*** – allows room for sample application without interference (A2). Increasing in addition the

width of the whole strip (A3), or wedge-shaping the plateau (C1) ***(22)***, lets higher and higher sample volumes to be loaded. With thin IPG strips to be run upside-down it is possible to use IP plateaus to increase the protein load. As an example, next to a pH gradient 8 cm in length anodic and cathodic plateaus may be cast to match electrode-to-electrode distances of 10.5 or 16 cm (B), typical of standard focusing trays, approximately doubling sample volume ***(23)***.

3. When it is known, or feared, that the samples contain higher amounts of salts, and dialysis is impractical, pH plateaus at both electrodes (A4) may collect the ionic ridges past the anodic or cathodic application point and allow for complete migration of the sample proteins ***(24)***. Using this procedure, up to 12.5 µmoles of KCl are compatible with an upside-down strip with 4 + 4 cm IP ***(23)***. With upside-up strips, changing the electrodic paper strips after some hours of run further helps easing the extremes of pH and conductivity beside the electrodes **(22, 25)**.

The recipe for a non-linear 4–10 IPG with IP plateaus in given in **Table 5.**

Table 5

3.3. Preparing the Working Solutions

As an equilibrium technique, IPG technology freezes within the structure of the amphoteric matrix the actual composition of the acrylamido buffer mix. Since there is no adjustment once the gradients are cast, all steps in liquid handling require the careful use of properly calibrated measuring devices.

1. On two calibrated test tubes or 10-mL cylinders, mark the pH and the volume of the solutions to be prepared with a felt-tip (*see* **Note 1**).
2. Add the acrylamide buffers. For reproducible measurements, all chemicals should be at room temperature (*see* **Note 2**).
3. After adding all the acrylamido buffers, fill the two solutions to one-half their final volume with water, and check their pH with a microelectrode. Refer to expected pH readings at 25°C in the liquid phase, not the values computed for 10°C in the gel phase (*see* **Tables 2** and **3**).
4. Add acetic acid to the basic solution to bring the pH to between 7.0 and 7.5 in order to prevent hydrolysis of the amide bonds during the polymerization step.
5. Add glycerol to the acidic solution to a final concentration of 15–20% v/v. Use a widemouth or a clipped pipet tip for dispensing the 87% glycerol stock.
6. The solutions are filled to their final volume with water and carefully mixed. Acrylamide is typically used at the final concentration of 4% T, 4% C. The concentration of TEMED is higher in the acidic than in the basic solution to counteract the effect of amine protonation. Ammonium persulfate is **not** added at this stage (*see* **Note 3**).

3.4. Assembling the Polymerization Cassette

To obtain a 16-cm high IPG slab that fits the 2-D SDS-PAGE gel (e.g., Protean™ from Bio-Rad [Hercules, CA]), the 12.5 *x* 25 cm w *x* h cassette is used (*see* **Note 4**).

1. When preparing slabs to be reswollen as a whole, mark a GelBond PAG™ foil for polarity using a felt-tip marker (anode at the bottom, cathode at 2/3 height); additional annotations (pH gradient, date, even short reminders) may help further identification. The felt-tip marking does not interfere with electrophoretic procedures (*see* **Note 5**). When preparing strips to be individually reswollen, a "code" for identifying gradient type and polarity may be devised, using felt-tip pens of different colors and a variable pattern of parallel lines.
2. Wet the gel-supporting plate with distilled water.
3. Lay the GelBond PAG™ foil—hydrophobic side down, hydrophilic side up, still covered with the protective paper foil—on a gel-supporting plate. Adhere the foil to the plate by rolling it onto the glass. Take care to align the foil flush with the plate.
4. Discard the protecting sheet. Blot any water on the hydrophilic side of the foil with a paper tissue.
5. Swab the inside of the molding plate with a paper towel moist with a dimethyldichlorosilane solution. It is recommended to wear gloves and to perform this treatment in a fume hood.

6. After the solvent has dried out, rinse the surface of the glass with distilled water, and dry with a paper towel. Inspect the rubber gasket for any break or any adherent material (driedout acrylamide, paper cuts, and so forth).
7. Invert the molding plate on the GelBond-glass assembly, and carefully align it. Check the marked polarity!
8. Fasten the cassette with clamps of adequate thickness and strength. If two strips from the 1-D IEF are to be aligned tail-to head for the 2-d SDS-PAGE run on the same gel, the procedure detailed above applies to the 25 *x* 12.5-cm w *x* h mold. Pouring a gradient of the stated volume **(Table 2)** will result in an 8-cm-high gel.

3.5. Pouring the Gradient

3.5.1. Pouring the Gradient without IPs

1. Add the magnetic bar to each chamber of the gradient mixer. Set both connections between the two vessels as well as to the outlet tubing in the closed position. Arrange the mixer on a stirrer, about 5 cm above the mouth of the polymerization cassette.
2. Stick the outlet(s) (*see* **Subheading 2.1., item 2**) in the cassette taking extreme care to not miss the opening to reach instead the gap between GelBond and supporting glass plate.
3. Transfer the acidic, heavy solution into the mixing chamber of the gradient mixer (i.e., the vessel next to the outlet).
4. Briefly open the connection to the reservoir in order to purge air bubbles from the solution; return the solution that flowed into the reservoir during the purging operation to the mixing chamber with a Pasteur pipet.
5. Add the basic light solution to the reservoir.
6. Start the mixing on the stirrer at high speed. Slowly move the gradient mixer around the active area of the mixer in order to find a position in which the magnetic bars in both chambers turn evenly and synchronously. Reduce the stirring speed.
7. Add ammonium persulfate solution in the stated amounts (*see* **Table 2**) to the solutions in both chambers.
8. Open the outlet to the polymerization chamber; the liquid should easily flow by gravity: in case it does not, a light pressure (the palm of your hand over the mouth of the vessel) might solve the problem.
9. When the heavy solution is about to enter the polymerization cassette, open the connection between the two chambers of the mixer.
10. The in-flowing light solution should mix promptly with its heavy counterpart; if not (streams of liquid of different density are distinctly seen in the mixing chamber), the stirring speed should be increased accordingly (*see* **Note 6**).
11. When all solution has flown by gravity, force the few drops remaining in the outlet tubing and in the mixing chamber to the cassette by applying pressure *(see above)* first on the reservoir and then on the mixing chamber, while raising the gradient mixer.
12. Inspect the liquid within the cassette: no air bubbles should be present. It is possible to remove them, with **great caution**, with the help of a thin hook cut from GelBond foil.

13. Leave the gradient to stabilize for 5–10 min at room temperature before moving the cassette into the oven to start the polymerization step.
14. After use, promptly fill the gradient mixer with distilled water and flow the water through the outlet tubing; repeat this procedure twice.
15. Set aside the stirring bars; disassemble the outlet tubing and dry by suction with a pump; and blow the liquid still remaining inside the gradient mixer with compressed air, before drying the outside with a paper tissue.
16. Let the equipment dry to completion with all connections in the open position. Rinsing and drying the gradient mixer, and pouring a new gradient takes 10 min, so no delay is actually required when processing a number of IPGs one after another.

3.5.2. Pouring the Gradient with IPs

1.-6. Same as in **Subheading 3.5.1.**

7.1. Add ammonium persulfate solution in the stated amounts (*see* **Table 5**) to the test tube containing the solution for the acidic IP; mix (inversion of the tube topped by Parafilm, or vortexing); transfer to the polymerization cassette with a Pasteur pipet.

7.2. Add ammonium persulfate solution in the stated amounts (*see* **Table 2**) to the gradient solutions in both mixer chambers.

8.-11. Same as in **Subheading 3.5.1.**

12. Add ammonium persulfate solution in the stated amounts (*see* **Table 5**) to the test tube containing the solution for the basic IP; transfer to the polymerization cassette with a Pasteur pipet.

13.-16. Same as in **Subheading 3.5.1.**

3.6. Polymerization Conditions

1. Let the IPGs polymerize for 1 h at 50°C (*see* **Note 7**).
2. Gel setting occurs within approx 10 min, whereas polymerization slowly proceeds to plateau in the next 50 min. It is critical during the early period that the polymerization cassette is kept in an upright position **on a level surface**. Moreover, the oven should not be opened in order to avoid both shaking the cassette and causing the temperature to drop.

3.7. Washing, Drying, and Storing IPGs

1. At the end of the polymerization period, disassemble the cassette by removing the clamps.
2. Insert a scalpel blade between GelBond and glass plate to loosen the foil from its support.
3. Fill a plastic box in which the gel may lay flat with 1 L of glycerol washing solution.
4. Gently peel the IPG from the mold, and transfer (upside up!) into the box containing the glycerol solution.
5. Gently shake for 1 h at room temperature.

6. Lay the gel (upside up!) on a supporting glass plate partially or completely submerged in the washing solution in order to avoid trapping air bubbles (*see* **Note 8**).
7. Set the assembly upright, approx 30 cm in front of a (cool) fan, operating at high speed. The whole area should be as dustless as possible; glycerol smudge is better collected on a tray.
8. Evaluate the progression of the drying by sensing the cooling from water evaporation on the back of the glass plate and by looking for an even and matt appearance on the front of the gel. Depending on the temperature and relative humidity, the drying step may take between 1 and 2 h, and should not be unnecessarily prolonged. It is acceptable, but not recommended to let the gels dry unattended (e.g., overnight, at room temperature).
9. For barely damp gels, the very last phase of drying may occur in the refrigerator, with the gel in an open box. If needed, the polymerized gels may be stored overnight in their cassettes at 4°C before washing.
10. The dry gels may be further processed right away or stored for later use. Dry IPGs may be kept in boxes at 4°C for few days. For longer periods of time ***(26)***, they are stored at −20°C. For use along the in-gel rehydration protocol, the dry IPG matrix is carefully covered with Parafilm, minimizing trapped air bubbles. The assembly is then sliced with a paper cutter to obtain 3.5 mm-wide strips, to be stored in ziplock bags at −20°C.

4. Notes

1. All required stock solutions are orderly aligned on the bench. It is most helpful if their sequence corresponds to the order in which they are called for by the recipe. This is especially important for the acrylamido buffers, whose bottles look necessarily alike, whereas the pK label is in a relatively small print. It may be advisable to duplicate the pK label on the bottle caps, in larger print, with felt-tip pens. It is strongly suggested that the recipe be marked with a ruler and that each chemical be put back in a box after its use. When a bottle is open, hold its cap upside down on a paper tissue. Make sure you are storing the open bottles on a flat, stable surface (like a tray): Expensive and not harmless Immobiline may be easily if inadvertently spilled.
2. Positive displacement measuring devices might be more accurate than air-displacement pipets. No liquid droplets must adhere to the outside of the pipet tips; for this purpose, it is usually sufficient to touch the neck of the bottle. For a quantitative transfer of the Immobiline chemicals, and especially of the basic monomers dissolved in an alcoholic solution, two precautions should be taken; namely, slow pipeting and rinsing the pipet tips twice with distilled water after each measurement.

3. It is not customary to prepare large batches of the limiting solutions—the storage conditions in the mixture are appropriate for none of the chemicals. However, leftover solutions might be used within a couple of days.
4. In the case where the commercial products were not available, an adequate substitution for the gel mold may be a plate of plain glass (polished and saturated with silane) together with a rubber gasket of approx 0.5-mm thickness. The latter may be cut from foils of *para*-, silicone, or nitrile rubber, should have a U-shape, and should be ~5 mm wide. Thick clamps from stationery stores may then be used, but care should be taken to apply the pressure on the gasket, not inside it.
5. A note of caution for 1-D experiments with radioactive samples. In some cases, the ink gives a strong positive signal; more commonly, the writing negatively interferes with film exposure. In these experiments, all marks should then be outside the area of sample application (where their disturbing appearance may turn into the definition of useful reference points).
6. The major points of caution will be stressed once more below. The flow between the different compartments must be unhindered by air bubbles between the two vessels of the mixer or by water droplets in the outlet. No backflow should occur. The pouring should not be too fast to allow proper mixing in the chamber and to avoid turbulence in the cassette (with a proper selection of the pressure drop). The solution should evenly flow along the hydrophilic wall of the cassette (lined with GelBond) and not fall dropwise along the hydrophobic one.
7. A forced ventilation is more appropriate to this purpose than a convection oven in order to provide even and controlled heating. It should be recalled that the selected temperature is the one allowing identical incorporation efficiency for all acrylamido buffers, which grafts into the gel matrix a pH gradient exactly matching the computed course ***(23)***.
8. It is sensible to set aside some containers only for this purpose, i.e., to avoid recycling between gel washing, protein staining, and blot immunodetection. Owing to its high viscosity, 100% glycerol should be avoided as stock reagent in favor of the 87% preparation; ~12 mL of the latter may be measured in a small plastic beaker instead of in a graduated cylinder. Failure to include glycerol as a humidity-conditioning agent results in slab curling and easy peeling and tearing of the gel from its support. On washing, IPGs reswell to a different extent, depending on the pH of the matrix and on the course of the glycerol gradient.

Acknowledgments

Part of the research reviewed in this chapter was supported by grants from MIUR (Grant RBNE03B8KK, Call 2003) and from AFM (Grant 11643, Call 2005).

A Modified Nonequilibrium pH Gradient Electrophoresis (NEPHGE) Technique for Protein Separation

James A. Carroll

1. Introduction

Membrane proteins, hydrophobic proteins, and proteins with alkaline isoelectric points (pIs) traditionally have been difficult to visualize by two-dimensional (2-D) gel electrophoresis. There are a multitude of reason as to why proteins with basic pIs (many of them membrane proteins) are difficult to resolve by standard IEF methods: (i) the lack of pH gradient formation above pH 7.6 due to the buffering effect of urea, (ii) precipitation of proteins when entering the gel and during focusing, (iii) cathodic drift during focusing resulting in the migration of basic proteins off the ends of the tube gels, or (iv) lack of solubility in particular nonionic detergents. O'Farrell et al. first reported in 1977 a novel protein separation technique termed Nonequilibrium pH Gradient Electrophoresis (NEPHGE) as a method to enhance the separation of proteins with significantly basic pIs ***(1),*** but this alternative technique had its limitations due to issues with reproducibility with the reagents of that era. With the advent of new compounds for the solubilization of recalcitrant proteins, my laboratory has made minor modifications to the original NEPHGE protocol reported by O'Farrell offering enhanced reproducibility with increased solubilization of alkaline and membrane proteins ***(2–4).***

When performing NEPHGE, the pH gradient does not reach steady-state (as is the case with IEF) and shorter focusing times are applied. Acidic proteins will focus to completion but the basic proteins do not, rather they are continually migrating in the electrical field towards their pI. The electrophoretic pattern will change depending on the accumulation of volt hours (Vhr) applied during focusing; therefore, it is necessary to empirically determine the optimal Vhr yielding the

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

desired resolution. Furthermore, it is important to note that the polarity of the focusing tank must be reversed in order to perform NEPHGE.

2. Materials

2.1. NEPHGE Reagents

1. C_4TT (CHAPS/Triton/Thiourea) NEPHGE buffer for solubilization of proteins: 7 *M* urea, 2 *M* thiourea, 4.0% CHAPS (w/v), 1.0% Triton X-100 (v/v), 65 m*M* DTT, and 2.0% preblended ampholytes pH 3 to 9.5 (Amersham, Piscataway, NJ) (v/v). Prepare 10 to 20 ml, sterile filter (0.45 µm), and store at −80°C until use. Shelf life is approximately 1 year.
2. NEPHGE overlay solution: C_4TT NEPHGE buffer mixed 1:1 with dH_2O. Store at −80°C until use. Shelf life is approximately 1 year.
3. NEPHGE tube gel solution: 8 *M* urea, 4.4% Duracryl acrylamide (30T, 2.6C) (Genomic Solutions, Ann Arbor, MI), 4.0% CHAPS (w/v), 1.0 % Triton X-100 (v/v), and 2.0% preblended ampholytes pH 3 to 9.5 (Amersham, Piscataway, NJ) (v/v). This solution should be prepared fresh each time tube gels are to be poured.
4. SDS equilibration buffer: 0.125 *M* Tris-base (pH 8.8), 3 *M* urea, 2.0% SDS (w/v), 10% glycerol (v/v) in dH_2O. Prepare 200 to 500 ml, sterile filter, and store at room temperature. Measure the necessary volume for several equilibrations and add DTT to final of 100 m*M* before application.
5. Ammonium persulfate (APS) stock solution: 10% APS in dH_2O. Store at 4°C protected from light. Shelf life is 2 to 3 weeks.
6. Bromophenol blue stock solution: 0.1% (w/v) in dH_2O stored at room temperature.
7. Anode solution*:* 6.0 m*M* H_3PO_4 in dH_2O made fresh (1 liter). Degas under vacuum for 15 minutes
8. Cathode solution: 20 m*M* NaOH in dH_2O made fresh (2 to 3 liters). Degas under vacuum for 15 minutes.
9. Agarose sealing solution*:* 1.0 % agarose in 50 m*M* Tris-base, 0.15% SDS (w/v), 384 m*M* glycine in dH_2O. Add 500 µl of bromophenol blue stock solution to 250 mLagarose sealing solution. Store at room temperature.

2.2. SDS-PAGE Reagents

Standard SDS-PAGE in the second dimension at a variety of final acrylamide percentages. We typically separate our protein mixtures using a final concentration of 12.5 % acrylamide.

3. Methods

3.1. NEPHGE Sample Preparation

For sample preparation, proteins can be precipitated from cell lysates or protein fractions by the addition of 1 volume saturated TCA and 8 volumes of ice cold acetone. The sample is incubated for 1 hour at −20°C and proteins recovered by centrifugation (16,000 × *g*, 4°C, 20 min). The protein pellet is washed in 80% ice

cold acetone in dH_2O, centrifuged again, and briefly air dried to remove residual acetone. Alternatively, rinsed pellets of cells or tissue can be used without precipitation. Proteins are suspended in C_4TT NEPHGE buffer to a concentration of 5 to 10 µg/µl and incubated overnight (approximately 16 hours) at 23°C with gentle agitation. Samples are subsequently clarified by ultracentrifugation (≥ 200,000 × *g*, 30 min, 23°C) to remove insoluble material that may inhibit focusing (*see* **Note 1**). Samples can be loaded immediately onto NEPHGE tube gels or stored at −80°C until use.

3.2. Casting NEPHGE Tubes and Slab Gels

1. Similar to the IEF protocol, draw a line on the clean glass tubes at the desired height (12 to 16 cm depending on the slab gel apparatus used in the second dimension). We typically use glass tubes with an internal diameter of 1.0 or 2.0 mm. A stack of tubes (approximately 20 to 30) is placed vertically into a clean glass 100 mLgraduated cylinder for casting.
2. To cast the NEPHGE tube gels, mix 7.21 g urea, 2.0 mL Duracryl acrylamide, and 0.3 gm CHAPS in 6.5 mL dH_2O until the urea is dissolved (caution: do not heat this mixture).
3. Add 750 µl preblended ampholytes pH 3 to 9.5 (Amersham, Piscataway, NJ) to the mixture and bring up to 15 mLwith dH_2O. Invert several times to mix without the introduction of bubbles and degas under vacuum for 5 minutes.
4. Add 70 µL of 10 % APS and 10 µl TEMED and mix again by gentle inversion of the tube.
5. Immediately pipet the entire amount into the graduated cylinder holding the glass tubes for casting **(Figure 1).**

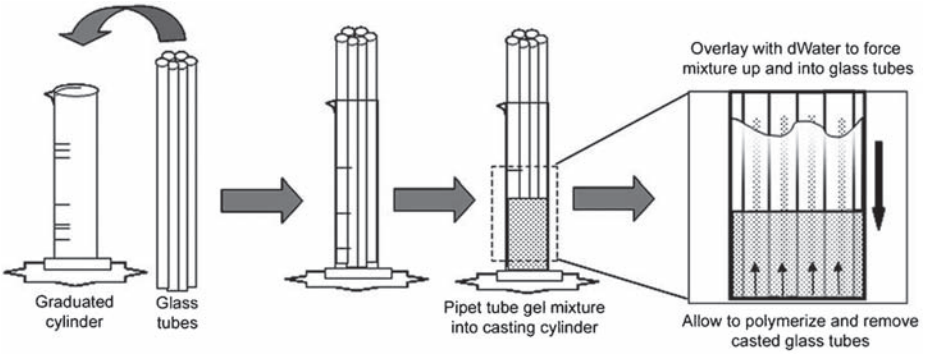

Fig. 1. Pouring NEPHGE tube gel**s.** Place the bundle of clean glass tubes into a clean graduated cylinder. Slowly pipet the NEPHGE acrylamide mixture into the casting cylinder, while avoiding bubbles. Gently overlay dH_2O using a squirt bottle, forming an emulsion layer, and force the NEPHGE acrylamide mixture into an up the glass tubes. Apply dH_2O until the level of the NEPHGE acrylamide mixture reaches the desired height inside the glass tubes.

6. Immediately use a squirt bottle to gently apply dH_2O, forming an emulsion layer of water atop the NEPHGE gel mixture. This forces the NEPHGE gel mixture up into the glass tubes by hydrostatic pressure. Apply water until the gel mixture reaches the marked level on your glass tubes.
7. Allow to polymerize for at least 2 hours at room temperature. Once polymerization is complete, pour off the water overlay and gently twist each glass tube gel and remove from the graduated cylinder casting stand. Look for air bubbles or malformations in the tube gels. Poured tube gels can be stored in a plastic bag for up to 2 weeks at 4°C, but best results are obtained when focused immediately.

3.3. Focusing NEPHGE Tube Gels

1. Load the protein sample solubilized in C_4TT NEPHGE buffer (up to 200 µg of protein) onto the tube gel using a 50 or 100 µLHamilton syringe. We typically dilute the sample so that we load approximately 50 to 100 µL of sample per tube gel.
2. Gently overlay the protein sample with 50 µl NEPHGE overlay solution using a Hamilton syringe to protect the sample from acid hydrolysis. A line of demarcation should be visible between the sample and the overlay as an emulsion layer forms.
3. Fill the remainder of the glass tube headspace with 6 m*M* H_3PO_4 (anode solution) using a long pasture pipet.
4. Fill the lower chamber with the cathode solution (20 m*M* NaOH).
5. Insert the NEPHGE glass tubes into the electrophoresis chamber and place into the lower chamber.
6. Add the anode solution until the tops of the glass tubes are submerged.
7. Connect the electrophoresis chamber to the power supply, but remember to *REVERSE* the polarity of the unit (*see* **Note 2**). We simply reverse the leads.
8. Electrophoretic focusing begins at 200 V for 1 hour and is then increased to 600 V for 4 hours (a total of 2600 Vhr) (*see* **Notes 3** and **4**). Times will vary dependent on the degree of separation desired and must therefore be empirically determined **(Fig. 2).**
9. With focusing complete, tube gels are extruded by force using a 3 mLsyringe filled with dH_2O with a piece of flexible tubing to attach it to the glass tube and stored at −80°C until separated in the second dimension by SDS-PAGE. Best results are achieved when focused NEPHGE tube gels are immediately separated by SDS-PAGE in the second dimension.

3.4. Applying NEPHGE tube gels onto the second dimension

1. To separate the proteins by SDS-PAGE, the tube gels must be equilibrated in SDS equilibration buffer with fresh 100 m*M* DTT.
2. Add 10 mLof SDS equilibration buffer with DTT and rock for 10 minutes at room temperature, and repeat.
3. Apply the tube gel to the top of a 1.5 mm SDS-PAGE gel. We typically lay the tube gel onto a 13.5 cm × 1.5 mm × 14 cm (L × W × H) 12.5% acrylamide gel using a Hoefer

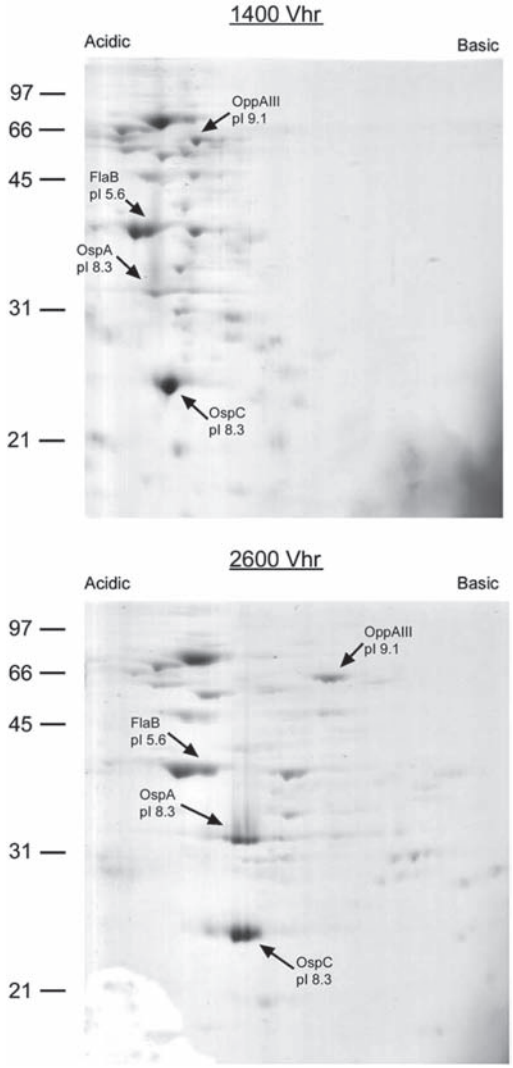

Fig. 2. Separation of Membrane Proteins from *Borrelia burgdorferi* by NEPHGE. Membrane-associate proteins from *B. burgdorferi* were separated in the first dimension by NEPHGE on 15 cm tube gels for a total of 1,400 or 2,600 Vhr. After focusing was halted, the tube gel was equilibrated with SDS, separated in the second dimension by 12.5% SDS-PAGE, and stained with Coomassie blue. Acidic and Basic ends of the gel are indicated. The positions of several proteins (OppAIII, FlaB, OspA, and OspC) are labeled and are accompanied by their theoretical pI. Relative molecular mass standards are indicated to the left of each gel. Note how the resolution of proteins differs with increasing Vhr.

SE600 gel apparatus. Be careful that no bubbles are introduced between the tube gel and the polyacrylamide gel.

4. Once the gel is in place, gently place the upper SDS-PAGE chamber on top of the tube gel/polyacrylamide gel. Seal in the tube gel with approximately 5 mLof warm agarose sealing solution so that the tube gel will not float out of position during filling of the chamber with buffer or during electrophoresis.
5. Perform SDS-PAGE to resolve proteins as described.

4. Notes

1. It is important to reduce the amount of nucleic acid, salt, polysaccharide, and lipid contamination in the sample material for optimal separation. These abundant molecules can inhibit separation by physical obstruction of the acrylamide matrix or by altering the conductivity of the sample. This can be accomplished in part by precipitation prior to solubilization and clarification of the sample by ultracentrifugation prior to loading.
2. NEPHGE requires that the anode buffer and cathode buffer be reversed compared to standard IEF. Remember to reverse the polarity of the electrophoresis apparatus.
3. Due to the nature of the procedure where the pH gradient does not reach equilibrium, solubilized proteins are typically migrating towards their pI. Close attention to the accumulated Vhr **(Fig. 2)** is required for reproducibility and must be empirically determined by the investigator.
4. Occasionally, proteins will precipitate as they move from the liquid phase into the semi-solid phase of the tube gel, resulting in sample loss. This precipitation event can be reduced by the inclusion of a small amount of Sephadex G-200 between the sample and tube gel ***(5).***

Microchip Capillary Electrophoresis

Application to Peptide Analysis

Barbara A. Fogarty, Nathan A. Lacher, and Susan M. Lunte

1. Introduction

Peptides are a large class of molecules that differ in size, charge, conformation, hydrophobicity, and the ability to form biospecific complexes. Peptides play an important role in many physiological processes, including the regulation of pain, blood pressure, and immune response, and can act as antibiotics, coenzymes/enzyme inhibitors, drugs, growth stimulators, hormones, neurotransmitters, and toxins ***(1).***

Since the identification of leu-enkephalin in the 1970s, the role of neuropeptides in the regulation of the central nervous system and signal transduction has been extensively investigated ***(1).*** Identification of specific peptides and their functions may permit the design of pharmacologically active synthetic analogs that could be used for the treatment of neurological diseases such as Parkinson's and Alzheimer's. Peptide analysis is also important for proteomics research. Digestion of a protein yields distinct peptide mixtures, which are separated and mapped in order to characterize the parent molecule. In some cases, multidimensional separations are needed to achieve resolution and identification of all peptide components.

1.1. Considerations for Peptide Analysis

The determination of peptide concentrations in complex biological samples, protein digests, and drug formulations demands the use of highly efficient, sensitive, and selective analytical methods. Electrophoretic separation techniques are routinely employed due to their fast analysis times, high separation efficiencies, and compatibility with sensitive detection techniques ***(2).*** Electrophoretic-based separation modes have been used for the determination of peptide mobility,

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

isoelectric point, relative mass and charge, dissociation/association constants of complexes, diffusion coefficients, and hydrophobicity ***(3).***

For enzyme and immunoassays where biological activity must be maintained, buffers of physiological pH and temperature can be used. For hydrophobic peptides, the addition of surfactants to the run buffer can aid peptide solubility. Coating the capillary wall is also used to minimize adsorption of analyte to the capillary surface ***(4)***. Buffer conditions must also be optimized if mass spectrometry is used for detection due to the possibility of ion suppression. Lastly, since most peptides are amphoteric, analyte charge can be altered by adjusting the pH. This can change mobility, as well as enhance solubility and reduce adsorption to the negative wall.

Many of the methods developed for peptide analysis on conventional capillary electrophoresis systems are now being transferred to microchip platforms due to the many additional advantages of miniaturized analytical systems ***(5).*** This chapter will discuss general considerations for peptide analysis using microchip CE, highlight different techniques that can be used, and look at some specific applications of this technology.

1.2. Microchip Devices

In microchip electrophoresis, separation is typically achieved through a combination of electrophoresis (μ_e) and electroosmotic flow (μ_{EOF}). Charged analytes migrate under the influence of an electric field and are separated due to

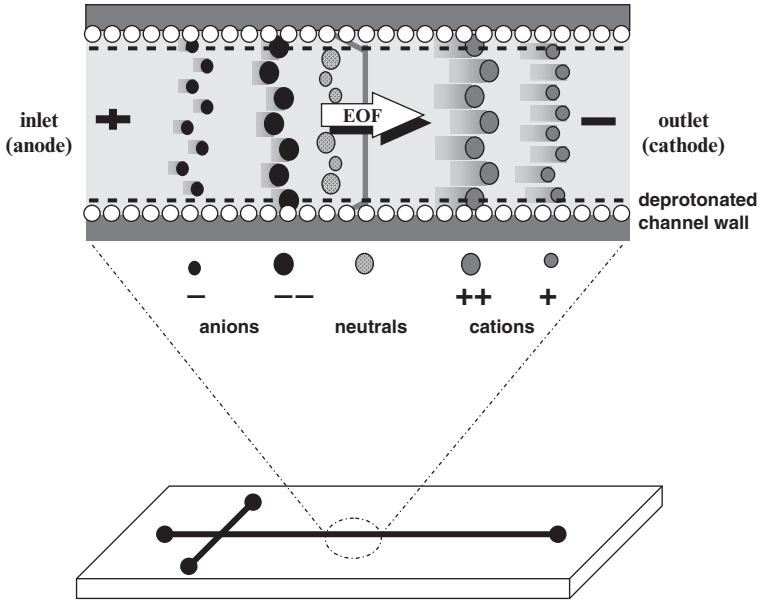

Fig. 1. Microchip capillary electrophoresis.

differences in their mass/charge ratios (**Fig. 1**). Generation of EOF (a bulk flow that causes all ions, regardless of charge, to migrate to the cathode) is achieved through the ionization of silanol groups on the wall of the separation channel. The net negative charge on the channel wall attracts positively charged solvated ions from the buffer solution, forming an electric double layer. Upon generation of the electric field, the migration of solvated cations to the cathode creates a bulk flow of solution within the channel toward the cathode where the detection region is located. As long as the magnitude of the EOF is greater than the electrophoretic mobility of the analytes ($\mu_{EOF}>\mu_e$), all species in solution. regardless of charge will eventually pass the detector.

Separations on microchips are faster and more efficient, and higher sample throughput can be realized than with conventional systems. The ability to move small volumes of fluids around the chips makes it possible to analyze samples of limited volumes as well as integrate sample handling and preparation steps onto a single platform. The planar nature of microchip devices also facilitates the use of 2-D separation mechanisms for the resolution of complex mixtures. This will be discussed in further detail later.

Microchip devices have been fabricated in a number of different substrates. Glass devices fabricated in soda lime, borosilicate, and quartz substrates have surface chemistries similar to that of the fused silica capillaries used in conventional systems. This allows the direct transfer of conventional methods to microchip systems. However, glass microchips have limitations, including the time required for fabrication, high cost, and fragile nature of the devices. In addition, integration of functional elements, such as separation and detection electrodes, is challenging due to the high temperatures needed for the glass bonding process.

Inexpensive polymer substrates, including poly(methylmethacrylate) (PMMA) and poly(dimethylsiloxane) (PDMS), have been employed for the production of low-cost microchips ***(6).*** These disposable devices eliminate issues of sample carryover and cross-contamination. However adsorption of peptides to hydrophobic polymers such as PDMS can be an issue ***(7).*** In addition, PDMS generates a reduced EOF relative to that of glass, which can influence the efficiency of separation (*see* **Note 1**).

Approaches to minimize peptide adsorption to channel walls include the use of dynamic and permanent modifications. Dynamic coatings have been used to minimize adsorption of hydrophobic peptides to channel surfaces. Polymers such as polyvinylpyrrolidine have been used to modify channels in a glass microchip, resulting in improved resolution of small test peptides ***(8).*** PDMS devices have also been modified with different monomers using UV grafting techniques ***(9).*** Reduced peak adsorption and improved peak efficiencies were observed for two model peptides, F-PKC and F-src. Poly(ethylene glycol) has also been grafted onto the surface of PMMA using atom-transfer radical polymerization ***(10).*** The modification resulted in a substantial reduction

in EOF and nonspecific adsorption of proteins on the surface of the PMMA. The separation of a tryptic digest of BSA was demonstrated with the device. Dynamic coating of a PMMA microchip with sodium dodecyl sulphate (SDS) allowed the separation of proteins and peptides up to 116 kDa in size ***(11).*** Cathodic EOF was used as the driving force for the separation. For a more detailed look at approaches to th e permanent surface modification of polymer-based electrophoretic devices, the reader is referred to a recent review of the area ***(12).***

The major advantages of using planar microchip devices for peptide analysis include the ability to integrate sample preparation, injection, separation, and detection steps onto a single platform. Approaches to each of these stages of peptide analysis with respect to microchip technology will be examined in further detail.

2. Methods

2.1. Sample Preparation

Preparation of peptide samples prior to analysis can involve dialysis, filtering, or extraction techniques to ensure that the sample is as clean as possible, preferably free from proteins and salts. Techniques such as solid-phase extraction can be used for preconcentration of peptides present at low concentrations in complex mixtures. While sample preparation is generally carried out offline, the integration of extraction, dialysis, and digestion steps for the development of a true miniaturized total analysis system has been implemented with some success. However, much of the work in this area has been proof-of-concept with limited application to real-world samples thus far ***(13).***

2.1.1. Sample Preconcentration and Desalting

Extraction and preconcentration of peptides for electrophoretic analysis is traditionally achieved using conventional chromatographic stationary phase materials. To use conventional stationary phase particles in microfluidic devices, a mechanism for effective particle containment is needed to prevent clogging of microchannels. This is typically achieved using tapered reaction chambers to promote keystone packing of particles or the use of weir-like structures. Packed C18 particles have been used to preconcentrate and to remove salt and urea from peptide mixtures ***(14).***

Limitations of particle-based systems include the generation of high back-pressures and the potential for clogging. One solution to these problems involves the use of polymer monolith materials. Advantages of these continuous bed systems for sample extraction and preconcentration include low back-pressures, tailored chemistries and easy control of pore size. For microfluidic applications, monoliths can be formed *in situ* and polymerized using heat or UV light. Methacrylate-based monolith systems have been employed for preconcentra-

tion of the hydrophobic tetrapeptide Phe-Gly-Phe-Gly by a factor of 1000 ***(15).*** Lauryl methacrylate monoliths have been polymerized in SU8 channels for desalting and subsequent separation of a cytochrome c digest peptide digest ***(16).*** Further optimization of column dimension was needed to improve the separation of the fragments. A PMMA substrate was modified with zeolite nanoparticles for the digestion and enrichment of protein samples ***(17).*** Trypsin immobilized in a sol-gel matrix was used to form a bioreactor for the digestion of cytochrome c and bovine serum albumin with a reaction time of under 5 s.

A 2-D approach to sample preparation and desalting has also been described ***(18).*** The chip device contains two channels with integrated conductivity detectors. A combination of isotachophoresis followed by capillary zone electrophoresis was used for the preconcentration of myoglobin and for the desalting of a protein mixture. The salt was removed during the ITP step, allowing subsequent separation of proteins in the second channel.

2.1.2. Microdialysis

Microdialysis is an *in vivo* sampling technique used for continuous monitoring applications. Probes are implanted in biological tissues and fluids to monitor biological events such as neurotransmitter release. A membrane with a predetermined molecular weight cutoff is used to exclude large molecules such as proteins while allowing smaller molecules such as amino acids and peptides to pass. This technique has recently been coupled to microchip electrophoresis ***(19).*** **Fig. 2** shows a microchip CE separation of two fluorescently labeled peptides following on-line recovery through a microdialysis probe ***(19).*** This system has been further improved by the incorporation of an online labeling protocol for the detection of a peptide mixture that included Leu-enkephalin **(19).**

2.1.3. Protein Digestion: Proteomic Applications

Proteolytic enzymes such as trypsin are used for the cleavage and digestion of protein molecules into their respective peptide fragments prior to identification/sequencing. Trypsin-coated beads have been employed for the on-chip digestion of proteins in microchip CE devices. High bead-to-peptide mass ratios and efficient mass transfer can permit rapid digestions of proteins including melitten, cytochrome c, bovine serum albumin, and β-casein. Digestion times ranged between 5 sec and 6 min at room temperature ***(20).*** This is in contrast to conventional protein digestion procedures that can often take up to 24 hours. Pressure or electroosmotic flow can be used to pump proteins through trypsin reactors ***(21).*** Localization of trypsin by enzyme adsorption to integrated membranes such as poly(vinylidene fluorine) has been used for the on-chip digestion of cytochrome c ***(22, 23).*** Trypsin has also been immobilized in monolithic supports and applied to the digestion of myoglobin ***(24).*** More recently, sol-gel

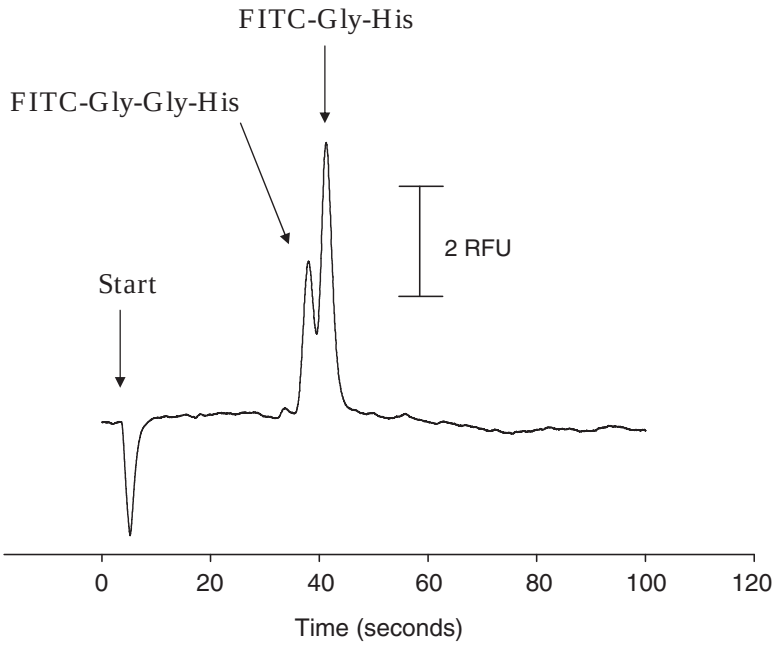

Fig. 2. Microchip CE separation of two-peptide mixture sampled on-line through 2-mm brain probe. (Parameters: 1.5 sec fill time, 2200 V). Analytes: FITC-Gly-His, 15 u*M*; FITC-Gly-Gly-His, 10 u*M*. Reprinted with permission from (19).

encapsulation has been investigated and used for the digestion of arginine ethyl ester (ArgOEt) and bradykinin ***(25, 26)*** (see ***Note 2***).

Fig. 3 shows a microchip device with integrated digestion, separation and postcolumn derivatization for the detection of labeled peptide fragments of insulin B-chain ***(27).*** More recently, an on-chip enzymatic reactor was demonstrated for rapid protein digestion ***(28).*** Protease was encapsulated in a silica sol-gel in a poly(ethylene terephthalate) PET microchannel. The digestion of cytoplasmic proteins from a human liver was achieved in the silica-gel based reactor within a few seconds.

Protein digestion followed by selective phosphopeptide enrichment has been demonstrated on a glass microchip device ***(29).*** The microchip consisted of two channels connected by a weir structure. The first channel contained agarose beads with immobilized trypsin while agarose beads with ferric ion were used in the second channel for immobilized metal ion affinity chromatography (IMAC). The device was also used for the enrichment of glycopeptides by replacing the IMAC beads with beads containing immobilized concanavalin A.

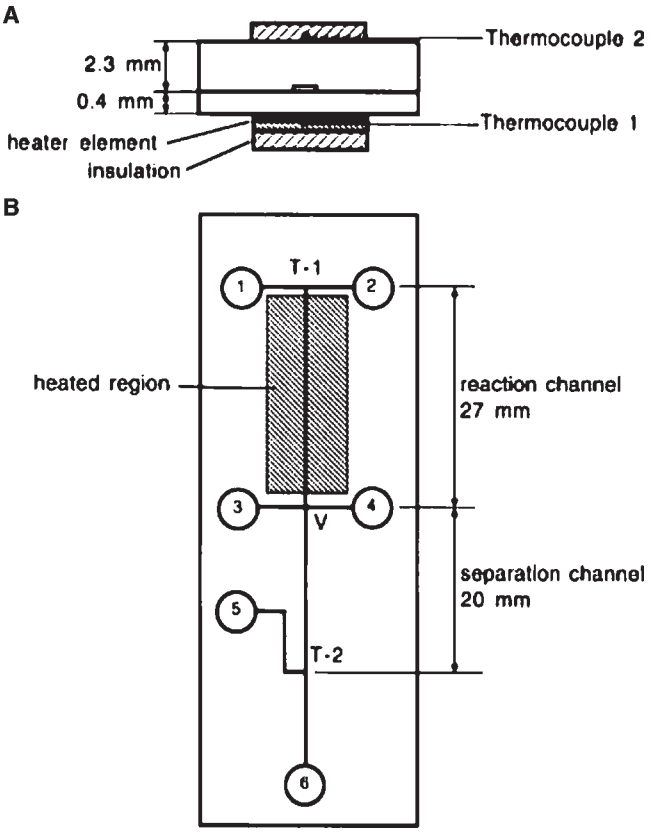

Fig. 3. **(A)** Cross-sectional view of a CE microchip, heating element, and the thermocouples. **(B)** Schematic of the microchip used for on-chip reactions, incorporating separation and postcolumn labeling. The fluid reservoirs are: (1) substrate, (2) enzyme or DTT, (3) buffer, (4) sample waste, (5) NDA, and (6) waste. Reprinted with permission from ***(27).***

2.2. Injection

Once sample cleanup has been performed there are a number of different options for loading into the separation channel. Generally, this necessitates voltage control over multiple reservoirs ***(30).*** Popular methods include pinched and gated injections.

Pinched injections demand simultaneous voltage control over all microchip reservoirs. A double T injector configuration reproducibly defines the volume of the sample plug. During separation, sample leakage into the channel is prevented by the application of a "pinching" or pushback voltage. Limitations of this approach include the need for multiple power supplies and the inability to change the volume injected using a double T design.

In gated injection schemes, the sample plug is not volume defined and can be altered. A voltage is applied to the sample reservoir with the sample waste reservoir held at ground. A second voltage is applied at the buffer reservoir with the buffer waste reservoir held at ground. Two separate flowing streams are established within the device. For injection, the sample reservoir is floated and a small plug of sample enters the separation channel. Both flows are then reestablished for separation. This approach uses a simple T injector configuration and requires two power supplies. While injection volumes can be varied, sample and buffer streams must be of similar ionic strength. Further information on injection methods is included in a recent review ***(31).***

2.3. Separation Methods

2.3.1. Capillary Zone Electrophoresis

Capillary zone electrophoresis (CZE) has been investigated for peptide separations on microchip systems due to the simplicity of the buffer system *(see* ***Note 3****)*. The separation of Gly-Leu and Gly-Gly on a glass microchip was demonstrated using a 20 m*M* borate buffer, pH 9.5 ***(32).*** A mixture of bradykinin, substance P, luteinizing hormone, bombasin, oxytocin, and enkephalins was separated on a PMMA device in 100 µM phosphate at pH 5.0 (33). A simple CZE buffer consisting of 15 m*M* boric acid, pH 9.2, was used for the separation of neuropeptides on PDMS microchip devices ***(34).*** Angiotensin peptides have been separated on both PDMS and glass microchip devices using 20 m*M* boric acid and 100 m*M* tris(hydroxymethyl)aminomethane, pH 9.0 ***(7)***. **Fig. 4** shows separations of these peptides performed on both glass and PDMS microchips with the polymer devices displaying significantly lower separation efficiencies. This is most likely due to peptide adsorption to the channel surface *(see* ***Note 4****)*. Methods to improve detection limits for microchip CZE of peptides include the use of polarity switching to initiate sample stacking ***(35).***

2.3.2. Micellar Electrokinetic Chromatography (MEKC)

In micellar electrokinetic chromatography (MEKC), separation is based on differences in the extent to which analytes partition between surfactant micelles and the surrounding aqueous buffer solution. When the concentration of a charged surfactant added to the buffer exceeds a value known as the critical micelle concentration (CMC), an aggregate, termed a micelle, is formed ***(36).*** The hydrophobic tails of the surfactant orient toward the center of the aggregate, and the polar headgroups orient toward the aqueous solution ***(37).*** A hydrophobic core is formed into which neutral hydrophobic analytes can partition ***(38).*** This method, initially developed for the separation of neutral molecules, is especially useful for peptides with a blocked N- or C-terminus. MEKC can also be used to separate charged peptides with similar electrophoretic mobilities but different

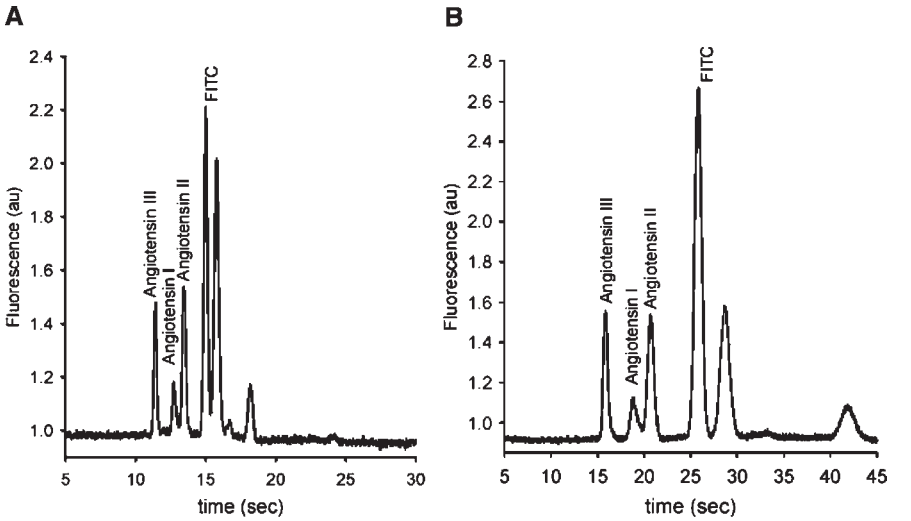

Fig. 4. Separation and laser induced fluorescence detection of FITC-labeled angiotensin peptides (angiotensin I, angiotensin II, and angiotensin III) at a concentration of 500 n*M* using an injection voltage of 2000 V. The buffer consisted of boric acid, Tris (20 m*M*, 100 m*M*, pH 9.0). **(A)** Separation obtained using a Pyrex microchip. The separation voltage used is 3200 V with an anti-leak voltage of 1600 V. **(B)** Separation obtained using a PDMS microchip. The separation voltage used is 4000 V with an antileak voltage of 2000 V. Reprinted with permission from ***(113).***

hydrophobicites. A microchip MEKC separation of lysozyme, trypsin inhibitor, and carbonic anyhydrase was accomplished on a PMMA microchip with 1% SDS in the TRIS-HCl run buffer ***(33).*** The separation of fluorescently labeled bovine serum albumin from other model proteins (cytochrome c, lysozyme, ribonculease A, myoglobin, and lactalbumin) in approximately 1.5 seconds on PDMS-based devices was accomplished by microchip-based MEKC ***(39).*** The separation efficiencies achieved were higher than those reported previously on native and modified PDMS microchip devices. MEKC has also been used in conjunction with 2-D separation schemes, which will be discussed later.

2.3.3. Isotachophoresis (ITP)

Isotachophoresis (ITP) is a separation technique based on electrophoresis occurring at a uniform speed where analyte migration is independent of mobility. It has been termed a "moving boundary" electrophoretic technique ***(40).*** ITP employs a leading and a terminating electrolyte with the sample zone sandwiched between them. For successful implementation of ITP, careful control of sample conductivity is needed. This can be difficult to obtain for biological

samples containing high salt concentrations. In contrast to CZE, ITP will not separate anions and cations in the same run because EOF is generally suppressed.

For successful implementation of ITP, the leading electrolyte must have a greater mobility than any of the analytes in the sample, while the terminating electrolyte must have a lower mobility. When the electric field is generated, the ions of interest will migrate toward the electrode of opposite charge in zones determined by their electrophoretic mobility. Zone width adjusts so that all zones have same conductivity. After the initial zone formation, equilibrium is reached inside the channel, and the analyte ions then migrate past the detector at the same velocity. Narrowing of the analyte band can be accomplished by adding a high concentration of both the leading and terminating electrolyte.

Microchip-ITP has been used as a preconcentration technique to improve detection limits for the determination of fluorescently labeled peptide substrates following enzyme assay ***(41).*** Other applications have included the preconcentration of cytochrome c following on-line protein digestion ***(22)*** and characterization of peptide phosphorylation by protein kinase ***(42).***

2.3.4. Isoelectric Focusing

Isoelectric focusing (IEF) separates peptides and proteins based on differences in their isoelectric point (pI). IEF can be used to separate proteins differing in pI by 0.0005 units or less ***(40, 43–46).*** An advantage of IEF is that the whole channel can be filled with sample, improving detection sensitivity. The sample is dissolved in a mixture of carrier ampholytes prepared in different pH ranges, and the channel is filled ***(47).*** Loading is followed by focusing and mobilization steps (**Fig. 5**).

Once the sample has been loaded, a voltage is applied and the carrier ampholytes separate into individual bands, establishing a pH gradient inside of the microchip. There are three different types of behavior that the peptide can exhibit once the voltage is applied. If the pH of the band is lower than the pI, the peptide will be positively charged and will migrate toward the cathode. If the pH is higher than the pI, the peptide will be negatively charged and will migrate toward the anode and, if the pI is equal to the pH, the peptide is neutral and will not migrate. All peptides will migrate until the pH is equal to the pI. At this point the current will approach zero, the resistance in the channel will be high, and focusing will cease. Eventually, all of the peptides will be focused into bands where their pI is equal to the pH and they will stop migrating. One drawback of IEF is that, because there is a pH gradient formed along the channel, the extent of surface ionization varies. This can produce an uneven generation of EOF and cause band broadening. Therefore, the channel is usually modified to eliminate the EOF and to ensure that focusing is achieved prior to detection. This is accomplished by coating the microchip walls with a neutral coating, which also limits peptide adsorption ***(48).***

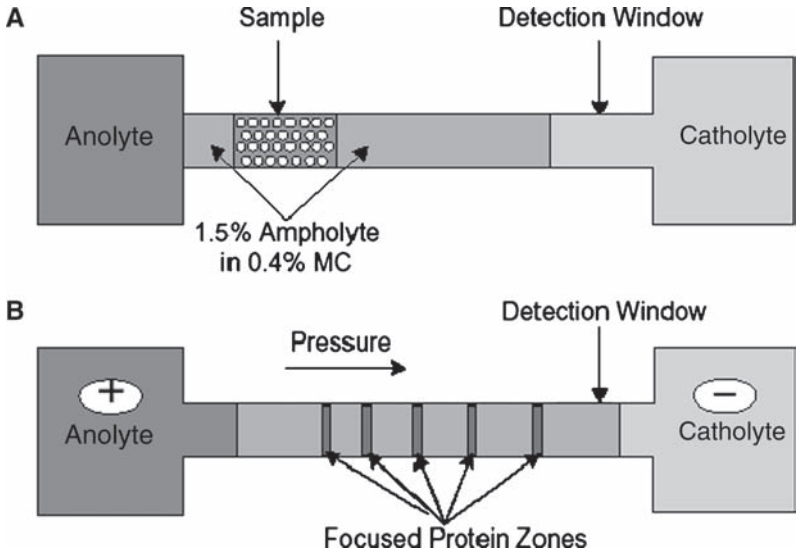

Fig. 5. Principle of capillary isoelectric focusing by simultaneous pressure/voltage mobilization. **(A)** Catholyte is backflushed past the detection point and a sample plug is introduced into the coated capillary (no high voltage). **(B)** Focusing of sample is complete and the sample components are driven toward the detector by a low-pressure rinse. High voltage is applied during this step. Reprinted with permission from ***(47).***

For single point detection systems, analytes must be mobilized past the detector region following the focusing step. The two most common approaches to analyte mobilization are hydraulic or chemical ***(37).*** Hydraulic mobilization of the focused zones occurs by applying either pressure or a vacuum to one end of a channel. Chemical mobilization is accomplished through the addition of a salt, such as NaCl, to one of the buffer reservoirs, followed by application of a high voltage. The actual mobilization in this case occurs due to the presence of a competing ion such as Cl^- that competes with OH^-. This lowers the pH, and the peptides become charged and migrate toward the cathode. The Na^+ competes with H^+, causing an increase in pH and making more negative analytes migrate toward the anode. This pH shift occurs across the entire length of the microchip channel ***(37).*** The end result of this pH shift is the mobilization of the previously focused analytes toward the cathode.

An alternative approach termed "one-step IEF" achieves focusing and mobilization simultaneously. As the pH gradient is not stationary, the EOF mobilizes the sample zones during focusing. One-step IEF can be accomplished using either coated or uncoated devices ***(49).*** EOF-driven mobilization is useful for microchip systems due to the speed of analysis and minimal instrumentation requirements. This approach was used for the separation of Cy5-labeled peptides; however,

higher separation efficiencies and reproducibilities were achieved using chemical and hydraulic mobilization strategies ***(49).***

The requirement for sample mobilization past a single detection point can be obviated through the use of whole column imaging. This technique has been applied to the separation of test peptides using a UV absorbance detector ***(50).*** Due to reduced detection sensitivity, high concentrations of peptide were required, and glycerol was added to maintain peptide solubility. A more sensitive approach used fluorescence detection for microchip IEF of rhodamine green-labeled peptides on a PMMA device ***(51).*** Real-time imaging of the channel was performed using a scanning detection system that facilitated the determination of peptide migration times along with the estimation of EOF and pressure-driven flows. A scanning detection system based on acousto-optical deflection has also been developed and used for imaging of proteins during IEF ***(52).*** Advantages of this technology include fast response times, the absence of mechanical parts, and minimal background noise. It is also possible to perform on-chip mobilization with an on-chip diaphragm following isoelectrofocusing in the microchip channel ***(53).***

2.3.5. Electrochromatography

The development of capillary electrochromatography (CEC), a hybrid of CE and liquid chromatography (LC), has allowed highly efficient separations of peptide mixtures ***(54).*** In CEC, the channel is packed with a stationary phase for chromatographic analyte retention similar to LC, but electroosmotic flow is also generated. The main advantage of this technique over LC is improved peak efficiencies due to the flat plug flow profile generated by the EOF ***(48).***

The use of conventional bead-based retention systems in microfluidic devices requires methods (weirs, channels) to localize the beads and prevent device clogging. A 200-μm channel packed with octadecylsilyl (ODS) stationary phase particles was used to separate a fluorescently labeled angiotensin peptide from excess labeling agent ***(55).***

In chip-based electrochromatography, the stationary phase, the channel, inlets, and outlets can all be produced in one device using lithographic patterning techniques that are already employed for the fabrication of microfluidic devices. Collocated monolithic support structures (COMOSS) that are molded directly into the channel have been created in both quartz and PDMS ***(56, 57).*** Advantages of this approach include a uniform distribution of support structures defined during fabrication and homogenous channel dimensions. Issues involved with packing and retention of stationary phase particles are also eliminated as the reversed-phase stationary phase is bonded directly to the structures, and there is no need for the production of frits. **Fig. 6** shows a COMOSS fabricated in PDMS. Applications of COMOSS modified with C18 phases include the

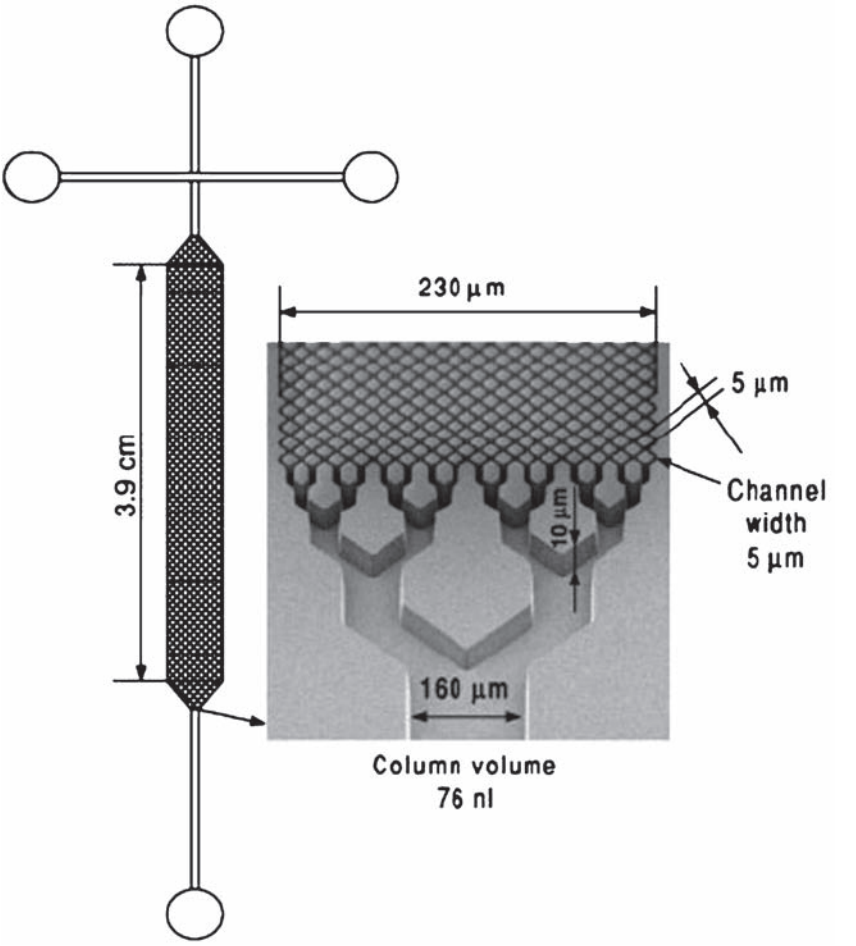

Fig. 6. Scheme of a COMOSS separation column. Reprinted with permission from ***(57).***

separation of tryptic digests of ovalbumin ***(56)*** and fluoroisothiocyanate-labeled bovine serum albumin ***(58).***

Monolithic polymer stationary phase materials are proving useful for microchip CEC applications (**Fig. 7**). Advantages of these phases include *in situ* polymerization, high flow rate tolerance, and functionalities that can be tailored to suit a specific application (59). In situ photopolymerization can be achieved by selective exposure to UV light. The location of the polymer can be accurately defined using a photomask. Acrylate-based porous polymers have been cast in glass channels for the separation of fluorescently labeled peptides, including angiotensins ***(60).*** The glass microchips could be reused following thermal incineration of the monolith at 550°C for 2 h and overnight incubation in 0.2 N NaOH.

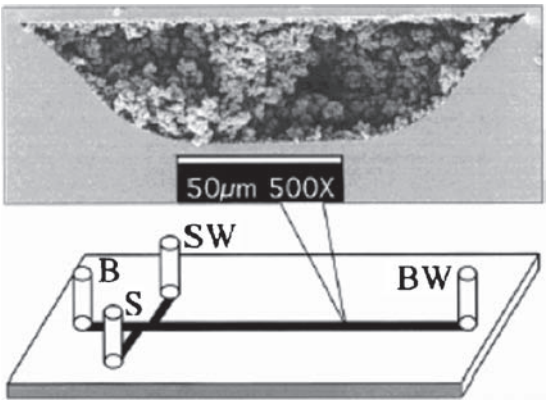

Fig. 7. Schematic of the microchip used for electrochromatography. B, S, BW, and SW denote reservoirs containing buffer, sample, buffer waste, and sample waste, respectively. The inset shows a scanning electron micrograph (SEM) of a channel cross section filled with photoinitiated acrylate polmer monolith. The mean pore diameter is 1 mm. Reprinted with permission from ***(60).***

Sol-gels modified with polyelectrolyte multilayers are also being investigated for potential application as cation-exchange materials for microchip CEC separations of peptides including enkephalins ***(61).***

2.3.6. Electrophoretic Bioaffinity Assays

Electrophoretic bioaffinity assays combine the specificity of an immunological or enzymatic response with the separation power of electrophoresis. Separation and quantification of enzymatic conversion or antibody/antigen binding can be achieved using microchip CE. Potential applications of affinity separation technologies include biochemical, clinical, and drug development operations ***(62).***

2.3.6.1. Immunoassays

Immunoassay techniques are employed for the determination of binding constants for antibodies and antigens in competitive and noncompetitive studies. The separation of human IgM and antihuman immunoglobulin *M* has been achieved using a PMMA microchip device with conductivity detection ***(63).*** Tween surfactant was added to the run buffer to reduce the adsorption of the proteins to the channel wall. A PMMA device was also used for the separation of fluorescently labeled human anti-goat antibody and unlabeled goat immunoglobulin G (IgG). In this case, no significant adsorption of IgG protein was observed ***(64).***

MEKC has been employed for an immunoassay monitoring serum levels of theophylline ***(65).*** A competitive immunoassay to monitor theophylline in serum

samples and a direct assay for the determination of monoclonal mouse immunoglobulin G in mouse ascites fluid were demonstrated on-chip using a tricine buffer containing Tween 20 and NaCl ***(66).*** A subsequent microchip system incorporating mixing, reaction, separation, and detection steps was developed for the same application ***(67).***

A microchip CE device that performed electrokinetic mixing of antibody to bovine serum albumin (BSA) and a diluting buffer was demonstrated for the on-chip preparation of calibration standards. These standards were then reacted with flourescein-labeled BSA, allowing the on-line generation of a standard curve. The device was used to assay the BSA antibody prepared from diluted mouse ascites fluid ***(68).***

A competitive chip-based immunoassay has been developed for the determination of insulin secretion from single islet cells ***(69).*** Online mixing of reagents allowed continuous sampling, and the simple device design needed only one voltage power supply for operation. A competitive immunoassay using rabbit polyclonal anti-cortisol antiserum and a fluorescently labeled cortisol derivative was demonstrated on a glass microchip device ***(70).*** The working range of the device was determined to be within clinical range (1–60 µg/dL cortisol).

A heterogeneous competitive immunoassay of human immunoglobulin G (IgG) was demonstrated on a hybrid PDMS and glass device ***(71).*** Cy5-labeled human IgG was used as a tracer and Cy3-mouse IgG was used as internal standard. The microchip system was used for the determination of IgG levels in human serum with fluorescence detection. The determination of binding efficiencies between diketopiperazine receptors and Arg-containing peptides was demonstrated on a commercial Shimadzu microchip system ***(72).*** The separation times achieved with the microchip system were 50 times shorter than what could be achieved on a conventional system.

2.3.6.2. Enzyme Assays

The determination of endogenous extracellular signal-regulated protein kinase was achieved using microchip CE to separate the substrate and product of the enzyme assay from an internal standard within 20 s. The device was used to measure the activity of endogenous levels of the enzyme in cell lysates ***(73).*** **Fig. 8** shows a separation of unphosphorylated and phosphorylated fluorescein-labeled "Kemptide" following on-chip enymatic conversion in a reagent well by protein kinase ***(74).*** The Km for "Kemptide" was determined using Lineweaver-Burk plots.

A capillary array was used to demonstrate a multiplexed approach to the analysis of kinases ***(75).*** The assay was performed by the addition of multiple enzymes to a reaction tube. Simultaneous resolution of four product and three substrate peaks was demonstrated within 30 s. The multiplexed approach was

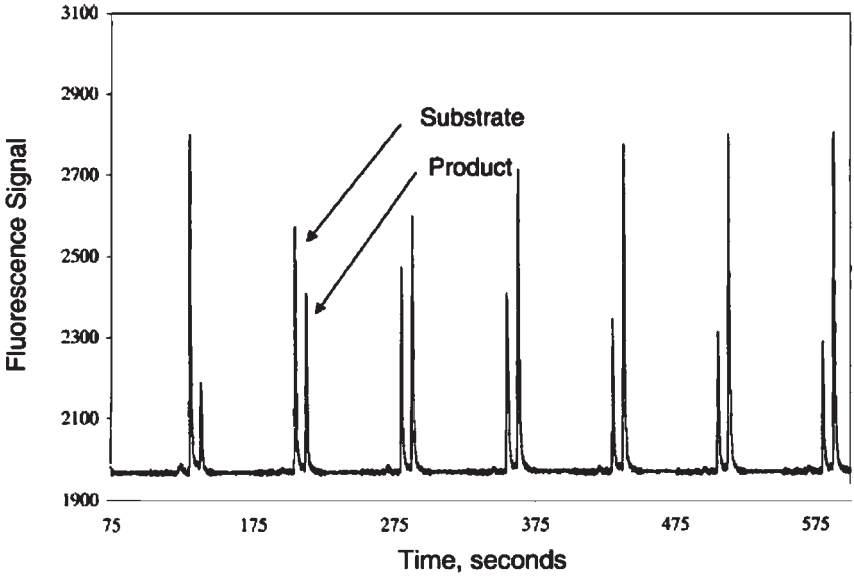

Fig. 8. Time course of the Protein Kinase A (PKA) reaction on a 12A chip. Electrophoretic separation of unphosphorylated and phosphorylated fluorescein labeled Kemptide upon enzymatic conversion by PKA in a reagent well of the 12A microchip. Conditions: 13.3 m*M* Fl-Kemptide, 24.5 m*M* PKA in 100 m*M* Hepes, pH 7.5, 1 *M* NDSB-195, 5 m*M* $MgCl_2$, 100 m*M* ATP, 50 m*M* cAMP, 0.1% Triton X-100, 10 m*M* DTT. Reprinted with permission from ***(74).***

also tested using a phospholipase and another kinase, demonstrating the ability to screen different types of enzymes and potential inhibitors in one analysis.

Another advantage of microchip systems is the ability to fabricate multiple channels for high throughput analysis. Microchip array electrophoresis has also been used to monitor the kinetics of a phosphate substrate and alkaline phosphatase conjugate as a function of reaction time ***(76).*** The enzymatic products were detected using laser-induced fluorescence with a miniature semiconductor laser. An electrochemical enzyme immunoassay was developed incorporating post-column reactions of alkaline phosphatase-labeled antibody ***(77).*** Amperometric detection was then used to identify the free antibody and the antibody-antigen complex.

Microchip CE has been used for the separation of four different inhibitors of acetylcholinesterase following on-chip mixing of enzyme, substrate, inhibitor and derivatizing reagents ***(78).*** Acetylthiocholine is hydrolyzed to thiocholine by acetylcholinesterase. The reaction of thiocholine and coumarinylphenylmaleimide forms a thioether that can be detected using fluorescence. Modulation of enzyme activity was identified by a decrease in fluorescence intensity.

2.3.7. Multidimensional separations

Chromatographic and electrophoretic separation systems have a maximum peak capacity that is dependent on column length and separation efficiency. With LC the peak capacity typically ranges from 20 to 100, while for CE values of 50–100 can be obtained ***(79).*** For the analysis of complex biological samples, a one-dimensional system will have a limited peak capacity; therefore, the use of two-dimensional separations can extend the applicability of the technique. For 2-D separations, the output of the first separation technique serves as the input to the second. Therefore to successfully analyze each peak, the separation in the second dimension must be faster than in the first.

A conventional capillary HPLC system has been interfaced to microchip electrophoresis for the separation of fluorescently labeled peptides from tryptic digests of bovine serum albumin ***(80).*** Effluent from the HPLC was injected into the CE channel every 20 s. On- chip coupling of 2-D separation systems is facilitated by the planar nature of the microchip device. A combination of MEKC (10 m*M* sodium dodecyl sulfate) and CZE was demonstrated on a microchip platform for the separation of tryptic peptides (79). Output from the first dimension was introduced to the second using a gated injection scheme. A similar approach was adopted for the coupling of open channel electrochromatography and CE on a glass microchip ***(81).*** **Fig. 9a** shows the device used with the spiral channel employed for the CEC, which was coated with a C18 phase connected

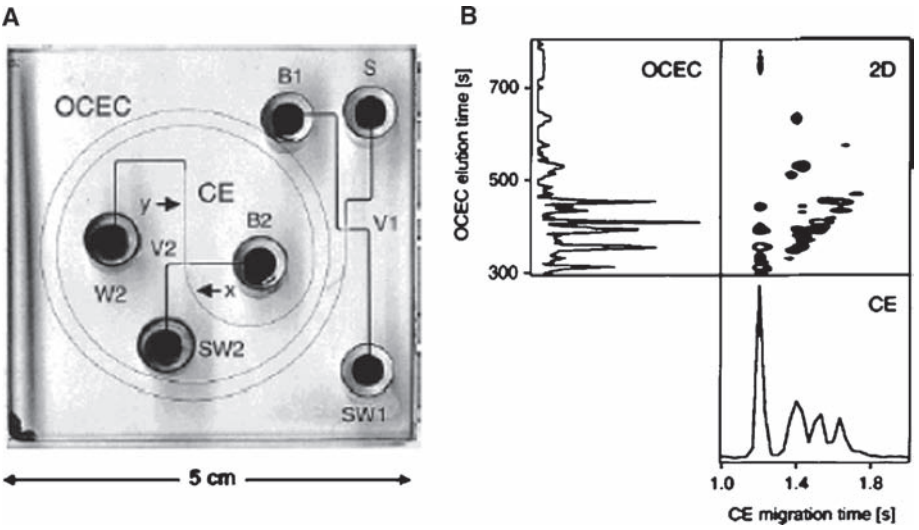

Fig. 9. CEC-CE chip. **(A)** The CEC serpentine channel extends from V1 to V2 (25 cm), the CE channel from V2 to the detection point y (0.8 cm), **(B)** 2-D contour plot of a β-casein tryptic digest. Reprinted with permission from ***(81).***

to the straight channel employed for CZE in the second dimension. **Fig. 9b** shows the application of the device to a 2-D separation of fluorescently labeled tryptic peptides of β-caesin.

Acrylic devices have been employed for the on-chip coupling of IEF and CZE ***(82).*** The acrylic microchip supported a reduced EOF relative to that of glass, and this property was exploited as a slow mobilization method. When the output of the first dimension (IEF channel) is introduced to the second (CZE channel), the voltage is switched and applied to the CE channel only. As a result, the analysis time for the entire system is dominated by that of the second dimension (<1 min). The device was applied to the analysis of fluorescently labeled dextran and ovalbumin.

On-chip tryptic digestion followed by 2-D electrochromatography has been demonstrated for histidine-containing peptides on a PDMS device ***(83).*** Digestion of bovine serum albumin was followed by separation of the peptides by metal affinity chromatography and reversed-phase electrochromatography.

2.4. Detection modes

Once a separation has been achieved, the most popular modes for peptide detection include fluorescence, electrochemistry (EC), or mass spectrometry (MS). Due to enhanced sensitivity, fluorescence and MS are the more popular modes of detection for peptide analysis with microchip CE.

2.4.1. Fluorescence detection

Fluorescence detection is the most commonly reported detection mode for microchip CE due the high sensitivity that can be obtained and the ability to focus collimated light onto micron-sized separation channels with relative ease. Excitation sources include lamps and LEDs; however, despite their high cost, lasers are also popular due to their ability to provide high intensity radiation.

Some peptides and proteins contain fluorescent amino acids such as tyrosine and tryptophan and exhibit native fluorescence ***(84).*** Recent advances in laser technologies may facilitate the on-chip detection of peptides by native fluorescence in the near future. However, in most cases, peptides and proteins must be labeled with an extrinsic fluorophore prior to analysis in order to be detected. Fluorescein-5-isothiocyanate (FITC) is the most popular reagent used for labeling of peptides; it is compatible with the 488 nm line of the argon-ion laser. Other fluorophores that have been employed include fluorescein, o-phthaldialdehyde (OPA), naphthalene-2,3-dicarboxaldehyde (NDA), BODIPY® TR, rhodamine red, dansyl chloride, 5- (and 6-) carboxyfluorescein, and NanoOrange. Cy5 label has been used to label proteins through the primary amines. Cy5 is excited at 633 nm, with collection of resulting emission at 680 nm.

The reaction rate, fluorescent product stability, quantum yield, excitation wavelength, and emission wavelength should all be considered when selecting

a reagent for a specific application. On-chip derivatization can take place prior to analysis (precolumn) or after the separation (postcolumn). The on-line post-column labeling of peptide fragments following tryptic digestion of oxidized insulin B-chain has been demonstrated using NDA/CN ***(27).***

2.4.2. Electrochemical detection

Electrochemistry is currently the detection mode most amenable to the production of a truly portable device. As the response at the electrode is not pathlength dependent, electrochemical detectors can be miniaturized without a loss in sensitivity. Electrodes can be microfabricated using the same techniques employed for chip manufacture and integrated onto the microchip platform. While EC detection encompasses conductimetry, potentiometry, and amperometry, the latter is the most commonly reported mode of EC detection for microchip-based peptide separations ***(31, 85–91).***

Electroactive amino acids include tyrosine (Tyr), tryptophan (Trp), and cysteine (Cys). If the peptide does not contain one of these electroactive amino acids, it must then be derivatized or complexed with an electroactive substance in order to enable detection. Derivatization agents that label the primary amine of the peptide have been used to enable electrochemical detection of amine-containing compounds; these include o-phthaldialdehyde/β-mercaptoethanol (OPA/βME) and naphthalene-2,3dicarbox-aldehyde/cyanide (NDA/CN). Both are oxidized at + 750 mV vs. Ag/AgCl at a carbon electrode ***(90, 92).*** Precolumn derivatization of small peptides with NDA/CN for electrochemical detection was demonstrated on a glass microchip device using a reaction chamber ***(32).*** An end-column detection alignment was used in conjunction with an external screen-printed carbon electrode *(see* ***Note 5****)*.

Most schemes require that the analyte possess a primary amine functionality for derivatization; however, it is possible to detect peptides with blocked N-termini, peptides lacking lysine, and cyclic peptides by the formation of a peptide-copper (II) complex ***(93, 94).*** As these complexes can undergo reversible redox reactions, dual-electrode detection can be used. This approach typically involves oxidation at the first electrode and reduction at the second. **Fig. 10** shows a dual-electrode electropherogram of the Des-Tyr Leu-enkephalin copper complex obtained using a microchip CE-EC device **(88).** A mixture of 50 m*M* boric acid, 3 m*M* tartaric acid, and 1 m*M* $CuSO_4$ buffered at pH 9.8 was used for separation ***(see note 6).***

While amperometry has proven to be the most popular mode of electrochemical detection for peptides, several examples of the use of conductivity detection have also been described. Conductivity detection is a universal detection technique that can be used in conjunction with microchip CE. The only requirement is that the conductivity of the analyte is different from that of the carrier electrolyte. An integrated conductivity detector for microchip CE has been described ***(33).*** The detector was constructed from platinum wires aligned using guide channels

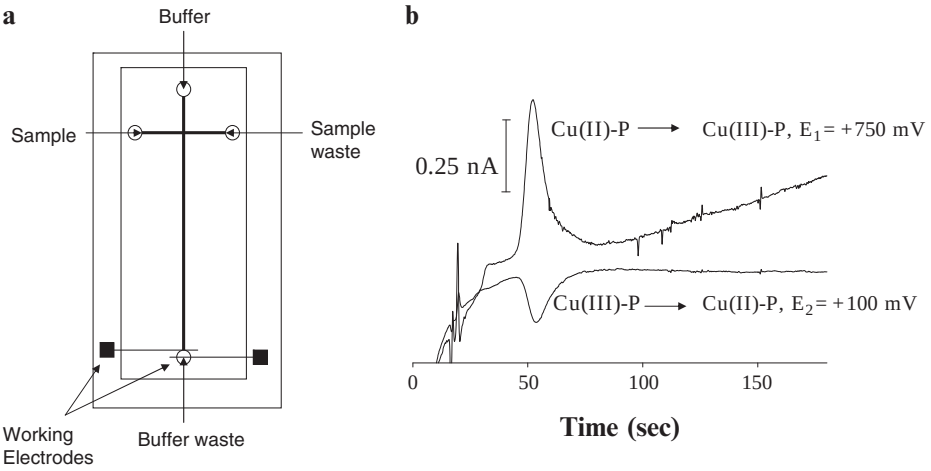

Fig. 10. **(A)** Microchip CE with end-column dual electrode detection. **(B)** Separation and dual-electrode detection in a series configuration with carbon paste electrodes. Detection of precomplexed copper complexes of: TyrGlyGly (340 µ*M*) and des-Tyr leu-enkephalin (450 µ*M*). Separation conditions: 50 m*M* boric acid, 3 m*M* tartaric acid, 1 m*M* copper sulfate, pH 9.8; applied voltage = 1170 V (350 V/cm). Injection: 1 second (S to SW) at 1170 V. E1 = +900 mV vs. Ag/AgCl; E2 = +300 mV vs. Ag/AgCl. Reprinted with permission from ***(88).***

and integrated into a PMMA microchip device by the thermal annealing of a PMMA cover plate. A CZE separation with indirect detection of a mixture of nine peptides, including bradykinin, substance P, and leu-enkephalin, was demonstrated. The same device and configuration were applied to the separation of a protein mixture by MEKC.

While the simultaneous detection of multiple targets is a feature of any separation-based system, a key advantage of microchip platforms is the potential to multiplex the analysis through the use of parallel processing. A 16-channel chip system that combines an integrated conductivity sensor array has been fabricated using a polycarbonate substrate ***(95).*** Each channel was addressed individually by a pair of detection electrodes incorporated during the fabrication of the device. High-speed parallel separations of amino acids, peptides, proteins and oligonucleotides were achieved using both CZE and CEC. The microchip reservoirs were designed to the same pitch as a multipipettor, thus allowing rapid loading of samples and regents to the chip.

A limitation of contact conductivity detection is the lower field strengths that must be applied (generally in the order of 50 V/cm) to minimize gas generation and bubble formation at the electrodes. This can influence separation efficiency but can be overcome through the use of a contactless approach. As there is no direct contact with the solution, electrode fouling is no longer

an issue. This approach was used in conjunction with glass microchips for the detection of two small test peptides. Capacitive coupling with the separation electrolyte was achieved by coating electrodes with a thin layer of silicon carbide, that acted as the insulating layer ***(96).*** A contactless configuration was also employed for the detection of human immunoglobulin *M* in glass and PMMA microchip devices ***(63).*** Tween surfactant, added to the buffer to minimize adsorption to the walls of the device, did not appear to interfere with the detection.

2.4.3. Mass Spectrometric Detection

Due to the ability of mass spectrometry to provide molecular weight and structural information without the need for derivatization of analytes, it has become a very desirable detection mode for peptides. Mass spectrometry is also useful for high throughput analysis. The ability to make disposable separation devices obviates many of the issues of cross contamination, a concern for high throughput applications. Often, microfluidic chips are used for sample introduction into the MS as the low flow rates used are compatible with sample delivery. The ability to integrate sample cleanup prior to analysis is also an advantage.

Electrospray ionization (ESI) is the most popular ionization technique used in conjunction with microfabricated devices, although matrix–assisted laser desorption/ionization is also compatible ***(97–99).*** Ionization can occur on– or off–chip, with some emitters fabricated directly onto the chip device ***(97, 100).*** For successful ionization, analytes must be charged and in solution. Ions are transferred to the gas phase by generation of an electric field between two electrodes, forming a spray of sample. ESI is compatible with a number of mass analyzers; however, time-of-flight and quadrupole-time-of-flight mass analyzers are perhaps best suited to handling high throughput analyses and have found greater application.

Considerations for coupling microchip to MS include minimization of dead-volume, establishing a steady flow rate for sample introduction, minimizing sample adsorption to the microfluidic device, and solvent compatibility of the device. In addition careful selection of the pH of the analyte solution is required, as this will determine analyte charge (this relates to the detection mode setting for positive or negative ion monitoring), and the magnitude and direction of EOF generated on the microchip device (this will determine whether the peptide mobility is sufficient to reach the emitter) ***(101).***

A microfabricated chip was interfaced to ESI-MS and applied to the analysis of a tryptic digest of β-caesin ***(102).*** Coating the microchannel and the transfer capillary with a polybrene solution improved both delivery and response. The separation and identification of peptides were achieved using a microfabricated CE device with nanoelectrospray mass spectrometry ***(103).*** Initial protein extraction was followed by SDS-PAGE and tryptic digestion. The microfluidic device was then used to perform sample cleanup prior to mass spectrometric analysis.

A microfluidic device has also been coupled to a quadrupole TOF-MS for trace analysis of protein digests isolated on a gel. Sample stacking was used to improve detection limits for hydrophilic peptides while solid-phase extraction techniques were used to preconcentrate hydrophobic peptides ***(35).***

Sample preparation procedures such as filtration, solid phase extraction (SPE), preconcentration, and protein digestion have been incorporated onto the chip platform prior to the introduction of the sample into the mass spectrometer representing some of the highest degrees of integration ***(104–107***). Analysis of both proteins and peptides has been achieved using this approach ***(108).*** Further optimization of chip-to-MS interfaces combining ionization and de-salting steps is needed before this technology will be used on a routine basis.

Many groups are now attempting to fabricate the tips for electrospray as part of the fluidic device. This approach allows easier coupling of high density devices directly to MS detection systems. A micro-nib interface for NanoESI-MS has been developed for microfluidic applications ***(109).*** The fabrication of a planar nib structure was achieved using SU-8 and applied to an ion trap mass spectrometer for the analysis of a standard peptide solution of Gramicidin S down to 1 μM. The same group has also implemented a polysilicon nanoelectrospray-mass spectrometry source ***(110).*** The source is based on a planar low-stress triangular polysilicon cantilever that projects horizontally from a silicon wafer to form a nib-like structure. Detection of a standard peptide sample of Glu-Fibrinopeptide B was achieved.

An integrated system for the preparation of a protein sample followed by online analysis by ESI-MS has also been reported ***(111).*** The system is fabricated in SU8 and contains a digestion module and monolithic phase material for chromatographic separation. Coupling of the microchannel outlet to ESI-MS through a nib-shaped outlet interface allowed the detection of a standard peptide mixture.

Another highly integrated approach to peptide analysis incorporating 2-D solid phase extraction capillary electrophoresis for ESI-TOF-MS has been described ***(112).*** The PDMS microchannel device comprised two channels; one for sample introduction and desalting and the other for CE separation. The desalting was achieved using 5 μm polystyrene beads. The channels were modified with a positively charged polymer PolyE-323 to reduce the adsorption of the peptide mixtures. A sample solution of six neuropeptides was desalted, separated, and sprayed into a TOF-MS for detection.

3. Summary

Microchip electrophoresis has made great strides since the initial concept was described by Manz and coworkers in 1990 ***(5).*** Thus far, CZE has been commonly employed as separation method on-chip, but other CE modes such as MEKC, CEC, ITP, IEF, and 2-D separations are being applied to peptide analysis. Many of

the detection methods used with conventional systems, such as LIF, EC, and MS, have been successfully adapted for use with microchip systems. Recent advances in microfabrication and packaging techniques have facilitated the production of highly integrated devices capable of parallel processing for high throughput analysis and the incorporation of nib-like structures for easier and reproducible interface to mass spectrometers. The continued development of truly integrated miniaturized analysis systems that can perform sample isolation, digestion, separation, and detection will significantly improve the field of peptide analysis. The resulting devices could then be used for screening, cell culture, and proteomic studies.

4. Notes

1. Selection of the microchip substrate will ultimately depend on compatibility with sample and buffer solutions and fabrication facilities available. Glass microchips are fabricated using chemical etch procedures whereas polymer devices are typically fabricated by hot embossing or casting techniques. Due to the hydrophobic nature of the polymer PDMS, reversible sealing of the separate layers can be achieved through contact bonding. If a permanent seal is required, PDMS may be plasma oxidized, which also improves the magnitude of EOF over that of native devices.
2. For on-chip protein digestion, immobilization of trypsin in sol-gel materials can increase stability compared to that in free solution.
3. For simple CZE separations, microchip channels should be conditioned at the beginning of the day by sequentially flushing for 10 min with degassed and filtered solutions of 0.1 *M* NaOH, H_2O, and buffer. At the end of the day, channels should be rinsed with water to prevent buffer crystal precipitation.
4. The use of acidic or basic buffer pHs can aid charge repulsion from channel surfaces minimizing peptide adsorption. Neutral hydrophilic coatings can help to reduce issues of peptide adsorption to channel walls. For CEC applications, using an acidic elution buffer can reduce peptide adsorption and tailing effects, commonly seen with silica-based phases.
5. A major consideration for EC detection with any CE application is the isolation of the separation field from the detector to protect the potentiostat. For amperometric detection, electrodes can be aligned at the end of the channel to protect the poten-tiostat from the high field strengths needed for the electrophoretic separation. However, limitations of this approach include analyte diffusion, leading to reduced peak efficiencies. Alternative approaches to the effective isolation of the detector from the separation voltage include off-channel detection using decouplers designed to shunt away separation voltage prior to detection or in-channel detection requiring the development of electronically isolated (floating) potentiostats.

6. Copper(II)-peptide complexes oxidize at a carbon electrode (+750 mV) vs. an Ag/AgCl reference. For dual detection the Cu(II) complex is oxidized at the first electrode and the resulting Cu(III) complex is reduced to a Cu(II) complex at the second electrode. The reduction of the complex at the second electrode takes place at a mild reduction potential (+100 to +200 mV), which results in a better S/N ratio, lower LOD, and better selectivity.

Protein Separations in Microfluidic Chips

Andrea W. Chow and Bahram Fathollahi

1. Introduction

Identifying protein structure, function, and expression level under varying environmental conditions in cells is an important activity in most life science research and pharmaceutical discovery. Determining the molecular weight and purity of protein samples is routinely done in laboratories using sodium dodecyl sulfate-polyacryamide gel electrophoresis (SDS-PAGE) in the last few decades ***(1, 2).*** This process is highly manual and takes many hours to prepare the gel, run the samples, stain and destain the protein fractions, capture the gel image, and analyze the image to determine the protein sizes against a ladder. With commercially available precast gel, the first step of the process is becoming simpler and less messy, but overall it is still a relatively slow and tedious procedure. In large-scale protein processing operations and proteomics research laboratories, protein analysis often is a bottleneck in the workflow. Over the last 10 years capillary gel electrophoresis-SDS (SDS-CGE) is being increasingly used for analysis of therapeutic proteins. Compared to SDS-PAGE, SDS-CGE offers advantages of on-column detection, improved quantitation and resolution, and automation. However, SDS-CGE is limited by low sensitivity, throughput, and reliability. In the past several years, microfluidic-based assay for sizing, quantitiation, and purity assessment of proteins are also finding rapid adoption. The benefits in integration, fast separation, automation, and ease of use offered by microfluidics address the limitations of SDS-PAGE and SDS-CGE, and have proven to be a faster and easier alternative to the traditional SDS-PAGE or SDS-CGE.

In microchip devices, gel electrophoresis can be performed in a much shorter time scale, typically by more than an order of magnitude improvement, than in capillaries and slab gels with equivalent performance metrics such as the number of theoretical plates and resolution. The main reason for the faster separation is the ability to inject a much narrower band of sample in a microfluidic

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

device, typically on the order of 10–100 µm. In electrophoretic separation, the number of theoretical plates *(N)* increases as the square of column length *(L)* for small sample plug:

$$N = 12\,(L/w)^2/(1+L/L_0);$$

$$L_0 = \mu E w^2/24D$$

where µ is the electrophoretic mobility of the analyte, E is the electric field, D is the diffusion coefficient of the analyte, and w is the root mean square of the width of the sample band and the width of the detector. In microfluidic experiments, the detector is typically focused down to 10–50 µm where it becomes comparable in length scale to the sample width. The time needed to achieve certain degree of resolution between peaks (for $L=L_0$) scales strongly with w:

$$t_0 = w^2/24D$$

A reduction of "w" by 10-fold results in a reduction of separation time by 100-fold. As a result of the faster separation time, the requirement for column length L has also been reduced from tens of centimeters in capillaries and slab gels to merely a few centimeters in a microchip.

When a protein sample is denatured in the presence of a high concentration of SDS above its critical micellar concentration (CMC), the protein molecules are coated by SDS micelles, in general in the ratio of about 1.4 g of SDS per g of protein ***(3).*** This binding ratio, somewhat surprisingly, is relatively independent of the protein sequence for proteins above 15 kDa. As a result of this interaction, the native charge of the protein is mostly masked by the charge of SDS, and the overall charge of the protein-SDS complex is primarily determined by the number of SDS micelles associating to the protein molecule. In the presence of an electric field without a polymer sizing matrix such as a polyacryamide gel, all protein-SDS complex species migrate electrophoretically at roughly the same speed regardless of protein size, because the charge of the complex increases proportionately with the protein molecular weight. In the presence of a sizing matrix, on the other hand, the differential hydrodynamic interaction of the complex with the matrix causes the larger complexes to migrate slower than the smaller ones, resulting in an effective sizing mechanism by electrophoresis.

The implementation of sizing protein-SDS complexes in capillary electrophoresis (CE) has not been widely adopted, unlike in sizing of DNA using CE. The difficulty comes from the lack of a convenient and sensitive means to detect the separated protein species. For DNA, a selection of fluorescent intercalation dyes binding to the double stranded DNA structure is available to detect the separated DNA fragments in CE with high sensitivity. For proteins, however, fluorescent dyes are available to stain the SDS micelles bound to the protein molecules, but they also stain the free SDS micelles in the gel, resulting in a low

signal-to-noise protein measurement due to the high fluorescent background caused by the signal from the free micelles.

This high fluorescent background problem has been cleverly solved in a microfluidic chip using an integrated on-chip "destaining" step ***(4).*** After the protein fractions are sufficiently resolved in the separation column, an intersecting channel structure is introduced as shown in **Fig. 1.** The side channels are filled with the same polymer sizing matrix as in the main separation channel, but the buffer solution contains no SDS. By applying an electric current from the side channels into the main channel, two focusing streams containing no SDS are induced, creating a concentration gradient in SDS transverse to the flow direction downstream of the intersection. By Brownian diffusion, free SDS micelles in the center of the channel diffuse laterally outward into the zones of low SDS concentration, causing a breakup of the micellar structure when the local concentration of SDS drops below CMC. As free micelles break up, fluorescent dyes are released. Using dyes that do not fluoresce when they are dissociated from the micelles, the high background drops to a low level. This destaining process inside the microchannel network is photographically captured in the right-hand side in **Fig. 1.** Bound SDS micelles, on the other hand, cannot migrate outward as readily due to the large protein size and they tend to remain stable due to the association with the proteins. Consequently, dyes captured in the protein-SDS complexes remain highly fluorescent after destaining.

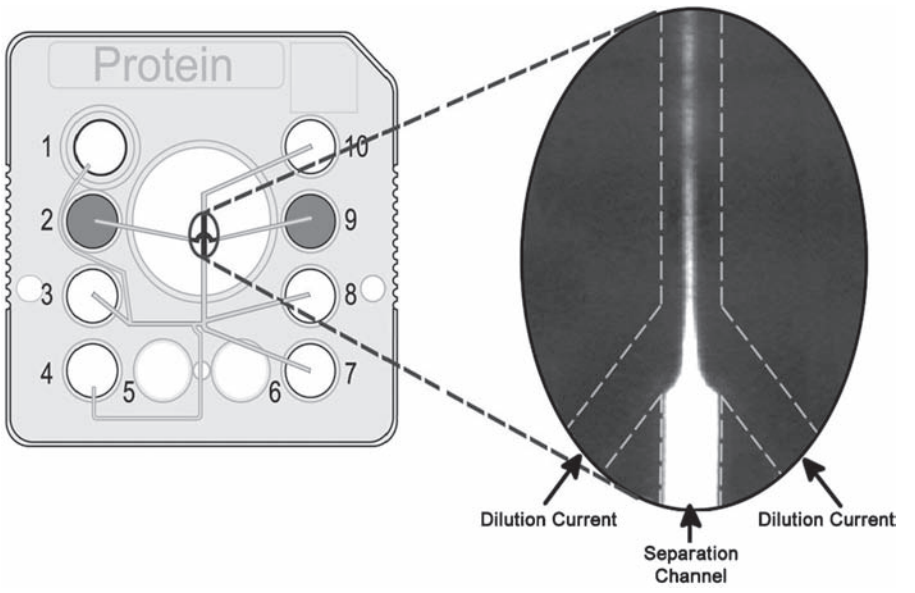

Fig. 1. Illustration of the destain intersection in a microfluidic chip for protein separation.

Fig. 2 illustrates the phenomenon in a plot of measured fluorescent intensity as a function of protein migration time when a detector is placed downstream of the destaining channel intersection. When the destain ratio, a ratio of flow from the destain channels to that from the separation channel, is high enough to break down the free micelles, the background signal drops significantly and the protein peak intensity goes up simultaneously, most likely due to the availability of more dyes for the bound micelles after they are released from the free micelles.

The time required for destaining of the free micelles is dictated by Brownian diffusion as described by the Einstein relationship:

$$t = x^2 / 2D$$

For free SDS micelles in the center streamline pinched laterally by two destaining solution streams as shown in Fig. 1, the diffusion distance into the SDS-free zone is about 15 µm, and the characteristic diffusion time is on the order of 200 ms. As a result, the location of the detector can be designed to be appropriately placed downstream of the destaining intersection to optimize the benefits of the on-chip operation. This destaining step in protein sizing is one good example of

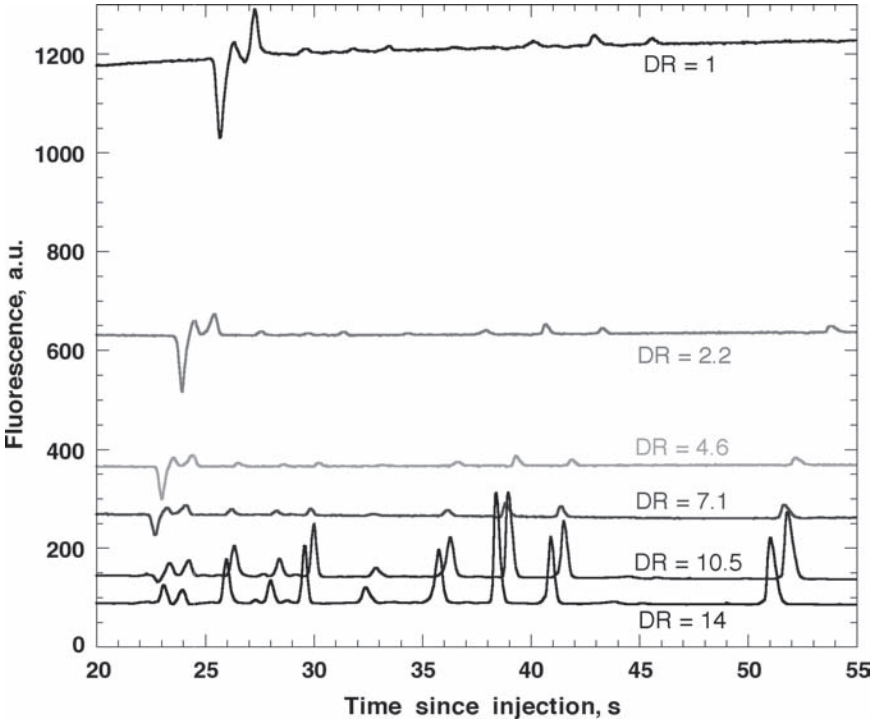

Fig. 2. A plot of fluorescence versus protein transit time at a range of destain ratios.

an integrated function easily performed on chip by exploiting the scaling laws of microfluidics that cannot be readily achieved in a conventional format.

2. Materials

Two types of microfluidic chips are available for protein sizing and relative quantitation. A planar chip format, where the samples are pipetted into designated well manually, is suitable for analyzing a low number of protein samples (up to 10). The planar chip format is used on the Agilent 2100 Bioanalyzer (http://www.agilent.com/) and Bio-Rad Experion Automated Electrophoresis System (http://www.biorad.com/). **Fig. 3** shows examples of these planar chips. The second type of chip format, a sipper chip, is designed for higher throughput analysis, tens to hundreds of samples at a time. The Caliper LabChip® 90 instrument (http://www.caliperls.com/) uses the sipper chip format. The sipper is a capillary attached to the microfluidic chip to enable automated introduction of protein samples from a

Fig. 3. Examples of planar LabChip® devices for separations. (**A**) Chips for the Agilent 2100 Bioanalyzer. (**B**) Chips for the Bio-Rad Experion.

standard 96 microtiter plate format onto the microchannel network of the chip. Fig. 4 is a photograph of a sipper chip.

Fig. 5 illustrates the microchannel design layout of the planar chip for protein separation. The samples are manually pipetted into the reservoirs of the chip

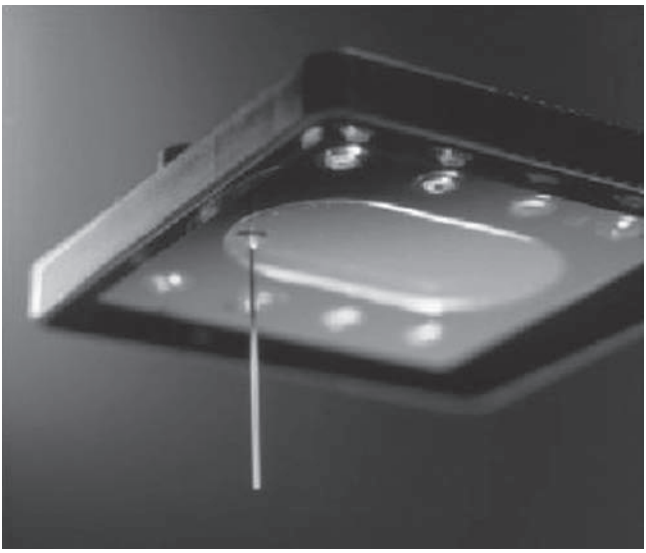

Fig. 4. A photograph of a sipper chip.

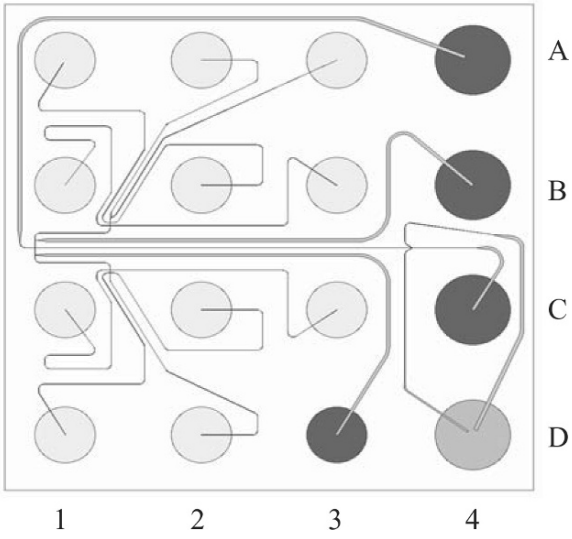

Fig. 5. The microchannel design layout of the planar protein chip.

after the microchannels are filled with the polymer sieving matrix. The matrix is a solution containing a high molecular weight polymer, poly(dimethyl methacrylate) or PDMA, in a Tris-Tricine containing buffer (the gel-matrix) mixed with a noncovalent fluorescent dye and SDS (the dye concentrate). Other reagents provided with the chips include a sample buffer, and a protein ladder with known molecular weight and concentration as a calibration standard for sizing and quantitation. The as-received reagents and buffers should be initially stored at −20°C. These reagents are supplied with 25 single-use, disposable chips in a kit, and should be stored at 4°C after opening and between use in order to avoid freeze-thaw cycles. The dye concentrate as well as the gel-dye mix should be kept in the dark due to light sensitivity of the dye. The details of the chip preparation method and the processes occurring inside the microchip are described in **Subheading 3.2.**

The microchannel design layout for the protein sipper chip is illustrated in **Fig. 6.** After the polymer solution with and without SDS-dye is properly introduced into the electrophoresis and destaining channels of the chip, the sipper dips into each of the microtiter well sequentially and samples a small quantity, about 100 nL, of protein sample, onto the chip by applying a small vacuum in the waste well. Subsequent injection and separation of samples are performed electrokinetically on chip. A single sipper chip can usually be used to analyze hundreds of samples. The details of the chip operations are provided in **Subheading 3.3**. Reagents provided with each LabChip® kit include a sample buffer, a denaturing buffer, a marker dye, a protein ladder, a destaining solution

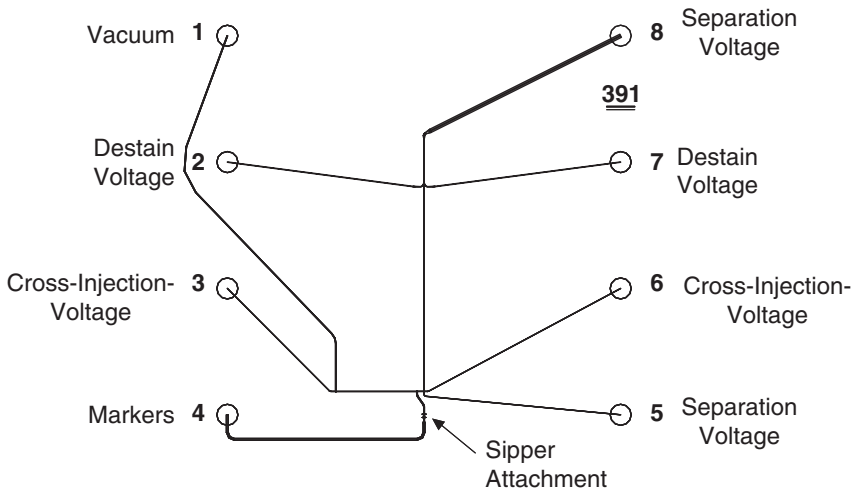

Fig. 6. The microchannel design layout of the protein sipper chip.

(PDMA polymer solution), and a dye concentrate (SDS mixed with an intercalating fluorescent dye). The dye concentrate and marker dye should be kept in the dark to avoid degradation. All reagents and buffers should be stored at 4°C after opening and between use. The as-received sipper chips should also be stored at 4°C and at room temperature after the first gel priming. Once the chip is primed, it can remain on the instrument for use throughout the day. Multiple batches of samples can be analyzed with the same chip without further reagent addition to the chip. After one 8-hr day use, the chip must be reprimed with fresh gel-dye mix prior to use the next day. Typically, each chip can be used for up to 300 samples if handled with good laboratory practices and care (*see* **Note 1**).

3. Methods

3.1. Denaturing Protein Samples

The protein samples and protein ladder are denatured in high concentration of SDS or LDS (lithium dodecyl sulphate), at >0.5%, either under reducing or non-reducing conditions. For reducing condition, β-mercaptoethanol or dithiothreitol is typically added to the denaturing solution. The following steps are recommended for denaturing protein samples:

1. The protein samples mixed with the denaturing solution according to the recommended protocol, are heat-denatured at 90–100°C for 3–5 min.
2. The samples are then further diluted with deionized water and/or sample buffer, usually by ~10–15 fold before use.

The protein samples should be analyzed in the same day after denaturization.

3.2. Planar Microfluidic Chips

The procedures to perform protein separations on planar chips consist of chip preparation, sample loading, and placing the chip onto the instrument. Chip preparation requires the complete filling of the separation channels of a dry chip with the polymer matrix mixed with SDS and dye (gel-dye mix) as follows:

1. First, 12 µL of the gel-dye mix is pipetted into the A4 well in the lower right corner of the well pattern of the chip (see **Fig. 5** for chip layout).
2. A priming station consisting of a syringe is used to fill the channels with the polymer solution by applying pressure of 3 atm at well A4 for 60 s.
3. Once the channels are filled, 12 µL of gel-dye mix is pipetted into wells B4, C4 and D3.
4. Next, 12 µL of the destaining solution (gel without SDS-dye) is pipetted into well D4.
5. Six µL each of sample diluted into the sample buffer containing lower and upper protein markers is pipetted in all 10 sample wells.
6. Six µL of the diluted ladder is pipetted into the ladder well D2.

The chip is now ready for loading onto the instrument.

Inside the instrument, the chip rests on a heater block and there is an electrode block located on the lid that matches the well pattern on the chip. After the lid is closed, each electrode pin makes contact with the liquid in each of the 16 wells, and voltage and current can be applied to the channels through the reagent wells. The optics is located below the chip to excite and record the fluorescence of the intercalating dye. The sizing experiment commences by activating the start button on screen.

The following procedures have been programmed into the software script controlling the voltage and current, so they are transparent to the users. The script starts with a warm and focus step, which allows the chip to come to temperature equilibration with the heater block at 30°C and the auto focus function to locate and focus the light source onto the separation channel. During this time, the instrument also checks for electrical connections in all the wells before starting the separation analysis. The protein ladder is first loaded by applying an electric field between the source "ladder" well (D2) towards well B4. After the upper protein marker reaches the injection intersection, the voltage is switched well A4 to wells C4 and D4 for separation. A small aliquot of ladder protein with a band on the order of 50 µm is injected into the separation channel, and the protein species are separated by size through the SDS-dye containing polymer matrix followed by destaining and detection as described in Section 1. Overlap loading and separation of subsequent samples is performed to minimize the total analysis time. All the steps after the start of the experiment take about 30 min to complete. The results are digital recordings of fluorescence intensity as a function of transit time for the ladder and samples as shown in **Fig. 7.** The electropherograms can also be displayed as a virtual gel image by software, and a result table. The protein size is computed from the transit time as compared to a calibration curve determined by the transit time of the ladder after the upper and lower markers in the samples and ladder are aligned by the software. Relative protein concentration is computed from the area under each peak as compared to the known concentrations of protein in the ladder.

3.3. Sipper Microfluidic Chips

Unlike the planar chip, which is shipped dry, a sipper chip comes in a wet container in which the microchannels, the sipper, and the wells of the chip are filled with storage buffer. Before starting an experiment, the chip should be prepared using the following steps:

1. After the chip is removed from the container, all the wells are rinsed with filtered deionized water.
2. Contents in wells 5, 6, and 8 are replaced with 75 µL of polymer matrix containing SDS and dye, contents in wells 2 and 7 are replaced with 75 µL of polymer matrix

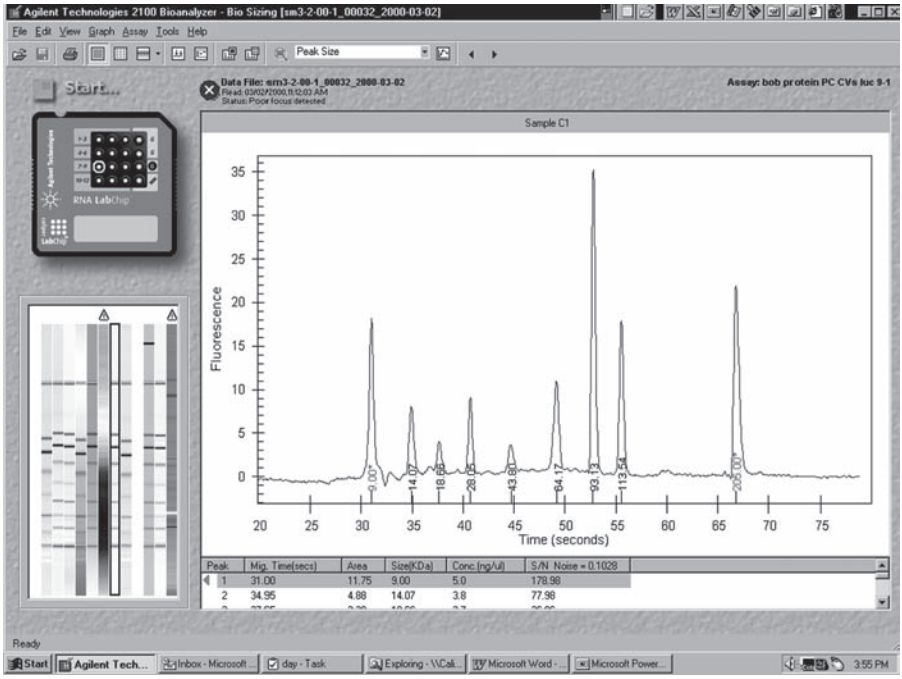

Fig. 7. Data output of the 2100 Bioanalyzer protein run.

without SDS, and addition of 120 µL of wash buffer to well 3 (see **Fig. 6** for chip layout).

3. The chip is next placed in a priming station where the electrophoresis channels are filled with the polymer-dye matrix solution by applying a pressure of 3 atm to wells 2, 5, 6, 7, and 8 for 6 min.
4. The fluid in well 3 is then replaced with 75 µL of the polymer matrix.
5. The fluid in well 4 is replaced with 120 µL of marker dye solution.

The chip is now ready to be loaded in the instrument for high throughput analysis.

When the sipper chip is placed onto instrument at the bottom of the optics module, the sipper capillary hangs out from the enclosed module where it can interface with the microtiter plate placed on the plate holder. The plate holder sits on a XYZ robotic arm and can accommodate the microtiter plate containing denatured protein samples and two well strips, one for the ladder and one for sample buffer. The buffer well is used to rinse the capillary between samples to eliminate cross-contamination. Inside the instrument, the sipper chip rests on a heater block which maintains the chip at a constant temperature of 30°C throughout the experiment. The initial chip warm up and focus step consists

of sipping sample buffer by applying a vacuum in the waste well followed by multiple injection and separation. The excitation laser is focused onto the separation channel using an autofocus mechanism.

At the start of an experiment, the sipper samples the ladder well to introduce onto the main channel about 100 nL of protein ladder by applying a small vacuum in the waste well. Once on chip, the protein sample from the sipper is mixed with the marker and flow toward the waste well 1. The mixture of protein and marker is next loaded onto the separation channel network electrokinetically by applying a voltage gradient between wells 3 and 6. Subsequently, the voltage is switched to wells 5 and 8 to inject a small aliquot of the mixture into the separation channel, which separates the protein species by size through the polymer matrix. Voltage is also applied to wells 2 and 7 for destaining as described in **Subheading 1.** The excitation laser and detector are located downstream of the destain intersection to record the fluorescence intensity of the protein fractions. During electrophoretic separation of the first sample, a second sample is simultaneously sipped from the plate to be ready for sample injection. The sipping operation of one sample does not affect the separation resolution of another due to the high matrix viscosity and shallower channel depth in the separation channel, which prevent significant pressure driven flow to occur in the separation channel. Such overlap sipping and separation processes are repeated sequentially until all the samples on the plate are analyzed. The protein ladder is sipped repeatedly after every 12 samples. A 96-well plate full of samples takes appropriately 1 hour and 20 min to analyze. The system can be used to analyze full or partially filled plates. It is also possible to do continuous or intermittent analysis throughout the day with a single chip that has been primed once.

The sizing of protein species in each sample is computed after the lower marker is aligned by software with that in the ladder sipped prior to the sample, and the transit times are compared with a calibration curve of ladder transit time versus known protein ladder size. The protein concentration for each peak is computed using the relative area under the peak as discussed before after the peak areas are normalized by the area of the marker dye peak. Alternatively, the protein concentration can be more accurately determined using an internal standard added to each sample. The separated proteins can be viewed as electrophoregrams and a virtual gel. The computed sizes, relative concentrations, and % purity for each protein within each well are presented in a table once two bracketing ladders per row have been analyzed (*see* **Fig. 8**). The software has an "expected protein" feature to mark protein peaks detected at a predetermined size range. Automated calculation of protein purity can also be enabled. The results from the tables can be exported for further postprocessing analysis.

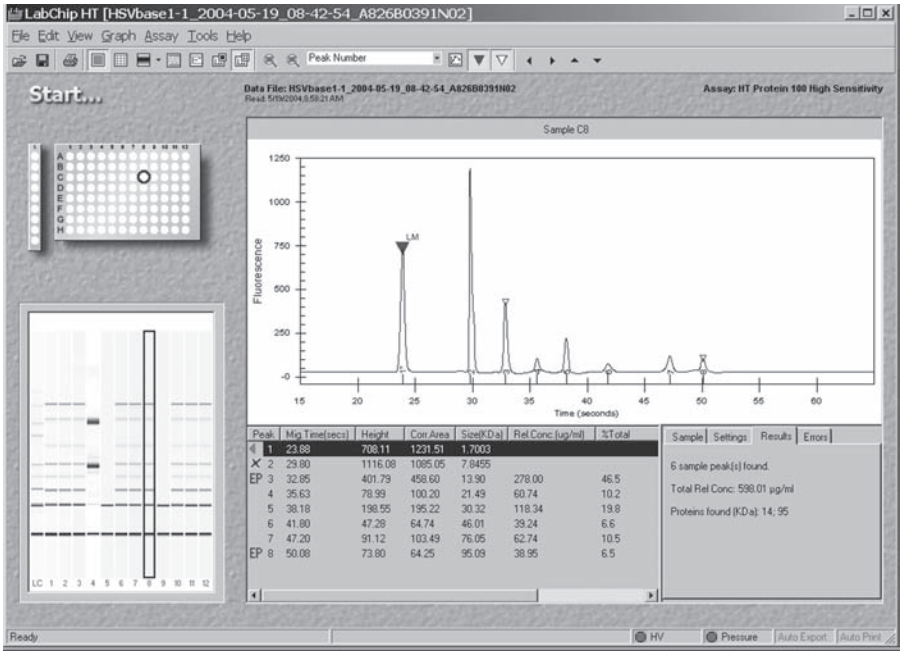

Fig. 8. Data output of a LabChip® 90 protein run.

4. Notes

1. In microfluidics chips, keeping bubbles and debris away from the channels is important for good device performance and lifetime. As in capillary electrophoresis, bubbles and debris in microchannels are usually detrimental to the separation performance and longevity of a microfluidic device. Before introducing any fluid onto the chip, it is highly recommended that it should be filtered with a micron- or submicron-pore filter first. During manual pipetting of solutions into chip wells, it is important to touch the tip of the pipette to the bottom of the small opening of the glass plate inside the well, not on top of the glass plate or to the side wall of the well, to avoid introducing or trapping bubbles in the well. Samples placed in tubes and microplates should be centrifuged in order to settle particulates to the bottom. Subsequent manual pipetting or automated sipping should be taken from the top half of the tube or microplate wells to minimize introducing particulates into the channels of the chip.

   The planar chips should always be run with all the sample wells filled with the recommended volume of fluid. If there are fewer than 12 samples to be used in one device, the remaining wells should be filled with an

equivalent amount of buffer to balance the hydrodynamics. The chip will not run properly if any wells are left empty. It is extremely important that the buffer and sample in the wells are thoroughly mixed using the vortex mixer at the conditions specified before loading the chip onto the instrument, otherwise protein concentration determination will not be reproducible. The speed of the vortex mixer should be set to the indicated setting at 2400 RPM. To avoid cross contamination, the electrodes in the instrument should be cleaned periodically as recommended in the user manuals.

As mentioned in **Subheading 2,** the intercalating dye is light sensitive. Therefore, it is important to keep solutions containing the dye in the dark when not in use. Otherwise, when the dye degrades significantly, signal intensity and thus detection sensitivity could be affected.

Because new sipper chips and many reagents are refrigerated before use, adequate time should be allowed for the chip and reagents to reach room temperature before starting the chip preparation steps outlined in **Subheading 3.2.** If cold reagents are introduced into the chip, warming up of an aqueous solution to room temperature in an enclosed microchannel could cause outgassing especially under slight vacuum condition.

2. Thus far, the detection sensitivity of proteins in commercial microfluidic chips is about the same as Coomassie Blue to mid-range of Colloidal Coomassie. It is advisable not to decrease protein sample dilution from the recommended ratio to try to increase sensitivity. Because protein buffers vary a lot in composition and conductivity due to different protein processing conditions, decreasing denatured protein sample dilution from the recommended value would result in more ionic species associated with the protein sample being injected into the separation column. It has been found that certain components of protein buffers, such as some detergents, in relatively high concentration in the injected sample band can affect the baseline flatness of the electropherogram or the migration rate of the lower marker, potentially causing degradation in accuracy of sizing and relative concentration determination.
3. Microfluidic devices are now being more widely used for sizing and quantitation of proteins by research laboratories that previously had used SDS-PAGE and to a lesser degree SDS-CGE. With greater use of microfluidic platforms, one obvious question is how well the measured molecular weight and relative concentration compares between the different methods. The experimental data up to now show these approaches provide similar answers for most proteins. For several proteins, minor migration variation relative to other proteins that result in differences in the determined size has been reported. The differences appear to be due to thevariations in the staining efficiencies by the fluorescent dye. It has been accepted by the SDS-PAGE user community that migration rates and dye staining of

protein-SDS complex are somewhat dependent on the protein sequence and the specific reagents used. However, complete understanding of how these parameters depend on sequence and reagents does not yet exist.

Unlike double-stranded DNA, which can be described successfully by a worm-like chain model with a measured persistence length ***(5),*** there has been no satisfactory conformational description of a protein-SDS complex structure that has received wide acceptance. It was first thought that a protein-SDS complex adopts a short rod-like segments connected by flexible regions ***(6).*** The "necklace" model, describing the protein-SDS complex as consisting of a series of spherical micelles surrounded by protein segment and connected by protein strands ***(7, 8),*** is receiving increasing attention. With a lack of good understanding of protein-SDS conformation, however, it is difficult to ascertain the fundamental electrophoretic migration behavior. So far, phenomenological observation shows a linear relationship of electrophoretic mobility plotted against logarithmic molecular weight for protein sizing data generated by SDS-PAGE ***(1).*** Data obtained from the LabChip® 90 sipper devices also show such a relationship in the molecular weight range of 10 kD to 250 kD in a variety of PDMA polymer solutions as illustrated in **Fig. 9.** In contrast, an equivalent plot for dsDNA migration is not linear (**Fig. 10**), and the changes in slope represent changes in the DNA conformation during migration through the polymer matrix ***(9).*** Thus, it is

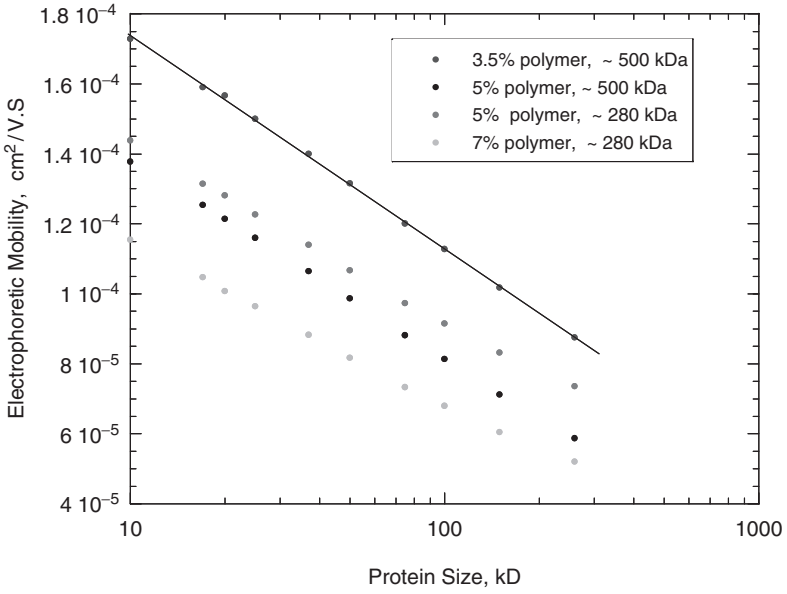

Fig. 9. A plot of electrophoretic mobility versus log protein size.

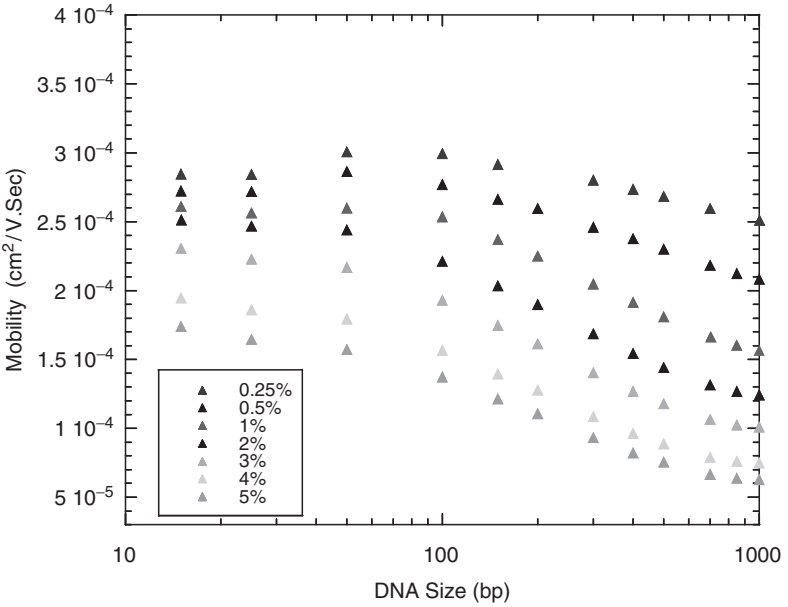

Fig. 10. A plot of electrophoretic mobility versus log DNA size.

reasonable to propose that protein-SDS complexes migrate very similarly in the conventional and microfluidic equivalent of SDS-PAGE for protein sizing. The small discrepancies observed in a gel image generated by a SDS-PAGE run versus the virtual gel image of a microfluidic sizing run are potentially due to the differences in the polymer matrix and dye used. Since the gel images of two SDS-PAGE runs generated by reagents made by two different manufacturers do not necessarily match, one should not expect a perfect match of separation resolution and relative staining intensities between a conventional gel image and one generated by a microfluidic chip on the same protein sample.

4. Analysis of whole cell lysates is essential for protein expression profiling studies. **Figure 11** shows a comparison of a lysate sample analyzed by a sipper chip and by SDS-PAGE. The over-expressed protein around 48 kD is detected well by bothmethods, although the data reproducibility appears better in the chip-based method. In analyzing lysates, it is important that the sample concentration to be within the upper limit of the recommended range, about 2000 ng/μL, in order to avoid the potential problem of sipper clogging by potential unsolubilized protein aggregates.

Development and production of antibody therapeutics require a significant amount of characterization and monitoring of stability and aggregation of these

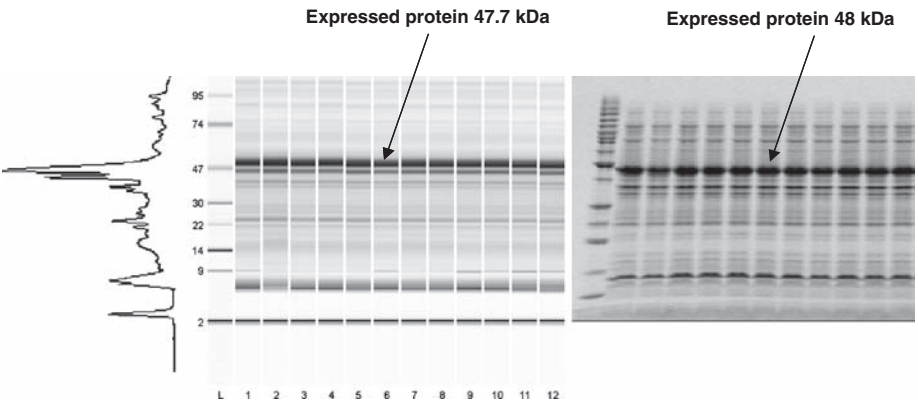

Fig. 11. A comparison of a LabChip® 90 virtual gel view and SDS-PAGE for a lysate sample (Data provided as the courtesy of Structural GenomiX of San Diego).

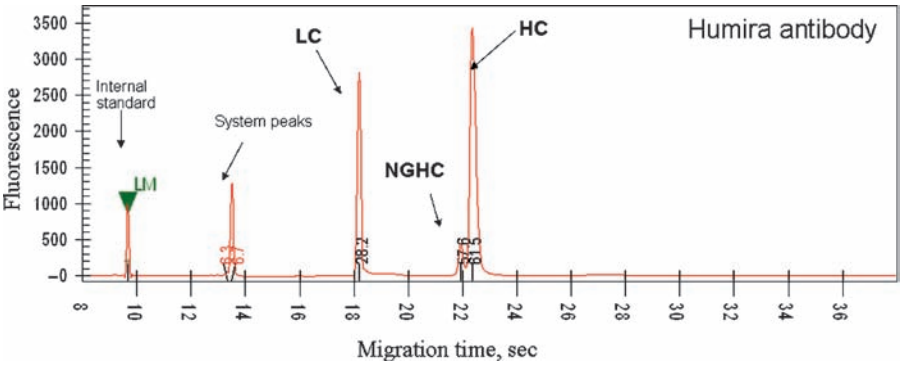

Fig. 12. Separation of reduced Humira (Abbott Laboratories) monoclonal antibody on Caliper LabChip 90. Abbreviations: light chain (LC), heavy chain (HC), and non-glycosylated heave chain (NGHC).

biological molecules. Microfluidic systems have been increasingly used for this application. **Figure 12** shows an electropherogram of separation of monoclonal antibody measured in the sipper chip system. The separation of light chain, heavy chain, and non-glycosylated heavy chain is comparable with data generated by SDS-CGE, but at a 60-fold reduction in separation time on a microchip ***(10).***

Another protein separation application demonstrated in chips is cereal protein characterization. **Fig. 13** shows an electrophoregram of wheat glutenin fractions. The composition of glutenin-subunit is an important predictor for the genetic potential of breeding lines, because these proteins are associated with differences in bread-making quality. Rapid separation and quantification of

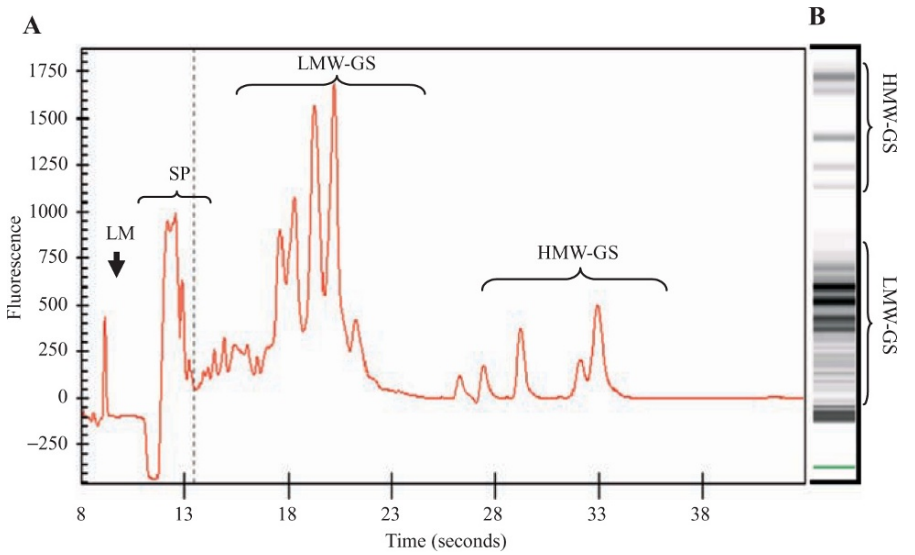

Fig. 13. (**A**) An electrophoregarm of wheat glutenin fraction under reduced conditions and (**B**) its corresponding virtual gel. Abbreviations: low molecular weight glutenin subunits (LMW-GS), high molecular weight glutenin subunits (HMW-GS), low marker (LM), and system peak (SP).

glutenin subunits have been achieved using microfluidic chip-based electrophoresis ***(11).*** However, the planar chips (Agilent 2100 Bioanalyzer platform) are limited to analysis of 10 samples at a time and thus not practical for large scale analysis. Glutenin subunits have also been analyzed on a high throughput integrated microfluidic-based platform (LabChip 90) ***(12).*** The electropherogram in **Figure 13** illustrates the separation of the HMW-GS and LMW-GS into two distinguished fractions with high resolution and fast analysis time.

It is well known in SDS-PAGE analysis that glycosylated proteins migrate slower than their expected molecular weights. Qualitatively similar phenomenon has been observed in microfluidic chip separation of glycosylated proteins. Therefore, similar precautions in data interpretation should be taken in chip-based analysis as in SDS-PAGE.

5. With some proper care and good laboratory practices, these microfluidics systems have been proven to be robust and labor-saving compared to the traditional SDS-PAGE. Perhaps more important, the output data is of high quality and available in a digital form which can be easily archived and shared with other laboratories across the company and around the world. Protein detection sensitivity down to silver-stain equivalence on microfluidic chips is not yet commercial, but approaches explored so far look promising ***(13)***. Moreover,

many research studies have also been reported on interfacing microfluidic chips with electrospray and MADLI mass spectrometry ***(14)*** and a polyimide LC/MS chip has recently been commercialized by Agilent. Microfluidics-based protein separation technologies have the potential to revolutionize the productivity of proteomics research in this era of increasingly more global community with lightning-speed demand for information sharing.

Difference Gel Electrophoresis (DIGE)

David B. Friedman and Kathryn S. Lilley

1. Introduction

The proteome is a dynamic entity, constantly changing both in levels of protein expression as well as in posttranslational modification and localization, all of which are hidden in the static DNA code. The repertoire of techniques and associated instrumentation which is now being applied to proteomics experiments is expanding exponentially, and although a complete visualization of the proteome is still beyond reach of any single technique, several technology platforms exist that can provide complementary datasets. Proteomics in the clinical setting is also developing, providing a major impact on the way in which diseases will be diagnosed, treated and monitored ***(1).***

In particular, approaches involving two-dimensional (2-D) gel electrophoresis (2-DE) separations and subsequent protein identification using mass spectrometry (MS) have been useful for imaging thousands of intact proteins (including modified/proteolyzed forms) in a single run, but quantification has been challenging, particularly over a large sample set. Difference gel electrophoresis (DIGE) has proven to be a powerful quantitative technology for differential-expression proteomics on a global level, where the individual abundance changes for thousands of intact proteins can be simultaneously monitored in replicate samples over multiple variables with statistical confidence (*see* **Note 1**). This includes quantitative information on protein isoforms that arise due to a charged post translational modification that results in a change in the isoelectric point of the protein (such as acetylation or phosphorylation), and splice variants or protein processing events, all of which can be resolved for individual quantification and subsequent analysis by mass spectrometry.

DIGE is based on conventional 2-D gel technology that is capable of resolving several thousand intact proteins first by charge using isoelectric focusing (IEF)

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

and then by apparent molecular mass using SDS-PAGE (2, 3) (*see* **Note 2**). Importantly, DIGE overcomes many of the limitations commonly associated with 2-D gels such as analytical (gel-to-gel) variation and limited dynamic range that can severly hamper a quantitative differential-expression study. This is accomplished using up to three spectrally resolvable fluorescent dyes (Cy2, Cy3 and Cy5, refered to as CyDyes) that enable low- to sub-nanogram sensitivities with $>10^4$ linear dynamic range, and then by multiplexing the prelabeled samples into the same analytical run (2-D gel). Multiplexing in this way allows for direct quantative measurements between the samples coresolved in the same gel, and is therefore beyond the limitations imposed by between-gel comparisons with conventional 2-D gels.

The highest statistical power of this multiplexing approach stems from the utilization of a pooled-sample internal standard comprised of an equal aliquot of every sample in the experiment (*see* **Subheadings 1.2.1., and 3.3.3.,**). With this method, two dyes (Cy3 and Cy5) are used to individually label two independent samples from a much larger experiment, and the Cy2 dye is used to label an internal standard which is comprised of an equal aliquot of proteins from every sample in the experiment. This pooled-sample internal standard is labeled only once in bulk to avoid additional technical variation, and enough is prepared and labeled to allow for an equal aliquot to be coresolved on each gel. The three differentially labeled samples are then coresolved on the same 2-D gel, after which direct measurements can be made for each resolved protein using the spectrally exclusive dye channels without interference from technical variation of the separation (gel-to-gel variation).

Rather than making direct quantitative measurements between the two samples in the gel, the measurements are instead made relative to the Cy2 signal from the internal standard for each resolved protein. This is done for each protein form under investigation separately, and so each feature is quantified relative to its own unique internal standard. The Cy2 signal should be the same for a given protein across different gels because it came from the same bulk mixture/labeling; therefore, any difference represents gel-to-gel variation, which can be effectively neutralized by normalizing all Cy2 values for a given protein across all gels. Using the Cy2 signal to normalize ratios between gels then allows for the Cy3:Cy2 and Cy5:Cy2 ratios for each protein within each gel to be normalized to the cognate ratios from the other gels, encompassing all samples. Each gel may contain different (and/or replicate) samples in the Cy3 and Cy5 channels, but all can be quantified relative to each other because each is measured to the cognate Cy2 signal from the internal standard present on each gel. With the use of sufficient replicates, a plethora of advanced statisitcal tests can be applied to highlight proteins of interest whose change in expression are related to the biology under investigation. *Since the technical noise is low, these vital replicates should be independent (biological) replicates*.

In a final step, specific proteins of interest are then identified using standard mass spectrometry approaches on gel-resolved proteins that have been excised

and proteolyzed into a discrete set of peptides. Briefly, excised proteins are subjected to in-gel digestion with trypsin protease (typically), and mass spectrometry (MS) is used to acquire accurate mass determinations on the resulting peptides and peptide fragments generated using tandem mass spectrometric approaches. The mass spectral data are then used to identify statistically significant candidate protein matches through sophisticated computer search algorithms that compare the observed MS data with theoretical peptide masses (using data generated by peptide mass fingerprinting) or collision-induced fragmentation patterns (obtained from tandem mass spectrometry) generated *in silico* from protein sequences present in databases.

1.1. Optimizing Sensitivity and Resolution

There are currently two forms of CyDye labelling chemistries available: minimal labeling involving the use of N-hydroxy succinimidyl ester reagents for low-stoichiometry labeling of proteins largely via lysine residues, and saturation labeling which utilize maleimide reagents for the stoichiometric labeling of cysteine sulfhydyls.

The most established DIGE chemistry is the "minimal labeling" method, which has been commercially available since July 2002. Here the CyDye DIGE Fluors are supplied as *N*-hydroxy succinimidyl (NHS) esters, which react with the ε-amine groups of lysine side-chains. The three fluors are mass matched (c. 500 Da), and carry an intrinsic +1 charge to compensate for the loss of each proton-accepting site that becomes labeled (thereby maintaining the pI of the labeled protein). Each dye molecule also adds a hydrophobic component to proteins, which along with MW, influences how proteins migrate in SDS-PAGE.

Minimal labeling reactions are optimized such that only 2–5% of the total number of lysine residues are labeled, such that on average a given labeled protein would contain only one dye molecule. This is necessary because lysine is very prevalent in protein sequences, and multiple labeling events may affect the hydrophobicity of some proteins such that they may no longer remain soluble under 2-DE conditions. Although a given protein form may exhibit specific labeling efficiencies, these will be the same for labeling with all three dyes, allowing for direct relative quantification. Minimal labeling with CyDye DIGE fluors is very sensitive, comparable to silver-staining or many post electrophoretic fluorescent stains (*ca*. 1 ng, *see* **Subheading 2.2.6**), but with a linear response in protein concentration over four orders of magnitude ***(4)*** (*see* **Note 3**).

For maleimide-labeling of the cysteine sulfhydryls, the overall lower cysteine content in proteins allows for labeling of these residues to saturation without increasing the overall hydrophobicity of the proteins to cause insolubility problems. Saturation labeling is ultimately more sensitive (150–500 picograms, and even more so for proteins with high cysteine content). Its use is not as commonplace, most

likely due to the availability of only Cy3 and Cy5 with this chemistry (*see* **Note 4**), the fact that it is blind to the small but significant population of non-cysteine containing proteins, and the additional optimization of complete cysteine reduction necessary for reproducible labeling. For these reasons, saturation DIGE is usually reserved for experiments where samples are limited, where the advantage of the increased sensitivity out-weigh these additional considerations.

To maximize the information that can be gained from experiments which utilize the DIGE technology, it is imperative that resolution of protein species within gels is optimized. Although single 2-DE runs can resolve proteins with pI ranges between pH 3–11 and apparent molecular mass ranges between 10–200 kDa, higher resolution and sensitivity can be obtained by running a series of medium range (e.g. pH 4–7, 7–11) and narrow range (e.g., pH 5–6) isoelectric focusing gradients with increasing protein loads, leading to an overall more comprehensive proteomic analysis ***(2, 3, 5)*** (*see* **Note 5**). This is analogous to gaining increased resolution and sensitivity in an LC/MS-based strategy by using multiple HPLC columns with different affinity chemistries (e.g., MudPIT ***(6)***). Much of the sensitivity limitation associated with 2-D gels can be attributed to the analysis of unfractionated, whole-cell and whole-tissue extracts. Additional sensitivity can be gained via enrichment for the proteins of interest, such as by analyzing prefractionated or subcellular samples, or immune complexes. However, the additional experimental manipulations required for prefractionation introduce more technical variation into the samples and necessitates increased independent (biological) replicates (which of course can be accommodated with the DIGE internal standard methodology).

The identification of proteins of interest using mass spectrometry can be performed directly from the DIGE gels when protein amounts have been optimized in this way (*see* **Subheading 3.5.,**). Alternatively, some experimental approaches perform the DIGE analysis using "analytical" gels with lower protein amounts, followed by protein excision from a secondary, "preparative" gel with higher protein amounts. This approach has its advantages when dealing with small sample amounts, such is often the case using the Saturation dye chemistries, but is also prone to uncertainties that arise due to the disproportionate amount of protein loading (*see* **Note 6**). The methods presented in this protocol are for optimization of both the DIGE data as well as material for subsequent mass spectrometry using high protein loads.

1.2. Optimizing Statistical Significance

1.2.1. Using the Internal Standard

The ability to coresolve and compare two or three samples in a single gel is attractive because it allows for direct relative quantification for a given protein without any interference from gel-to-gel variations in migration and resolution, removing the need for running replicate gels for each sample (similar to stable

isotope LC/MS-based strategies) ***(44–47)***. This approach has limited statistical power, however, since confidence intervals are determined based on the overall variation within a population (*see* **Subheading 3.6.2.,**).

Many researchers new to DIGE technology are not immediately aware of the increased statistical advantage and multiplexing capabilities of DIGE when combining this approach with a pooled-sample mixture as an internal standard for a series of coordinated DIGE gels ***(7).*** This design will allow for repetitive measurements (vital to any type of experimental investigation), and in such a way as to control both for gel-to-gel variation and provide increased statistical confidence. Importantly, these replicates should be from independent experiments (biological replicates) rather than multiple samples from the same experiment (technical replicates) (*see* **Subheading 1.2.2.,**). In this way, statistical confidence can be measured for each individual protein based on the variance between multiple measurements, independent of the variation in the population. Incorporating independently prepared replicate samples into the experimental design also controls for unexpected variation introduced into the samples during sample preparation.

This more complex and statistically powerful experimental design is accomplished by using one of the three dyes (usually Cy2) to label an internal standard which is comprised from equal aliquots of protein from all of the samples in an experiment. The total amount of the Cy2-labeled internal standard is such that an equal aliquot can be coresolved within each DIGE gel that also contains an individual Cy3- and Cy5-labeled sample from the experiment. Since this standard is composed of all of the samples in a coordinated experiment, each protein in a given sample should be represented in the mixture and thus serve as an unique internal standard for that protein (*see* **Note 7**). Direct quantitative comparisons are made individually for each resolved protein between the Cy3- or Cy5-labeled samples and the cognate protein signal from the Cy2-labeled standard for that gel (without interference from gel-to-gel variation), enabling the calculation of standardized abundance for every spot matched across all gels within a multigel experiment. The individual signals from the internal standard are also used to normalize and compare between each in-gel direct quantitative comparison for that particular protein from the other gels. Using the Cy2-labeled standard in this fashion, therefore, allows for more precise and complex quantitative comparisons between gels, including independent (biological) sample repetition (**Fig. 1**).

Importantly, the internal standard experimental design allows for the identification of significant changes that would not have been identified if the analyses were performed separately, even when using Cy3- and Cy5-labeled samples on the same DIGE gel ***(8).*** This experimental design also allows for multivariable analyses to be performed in one coordinated experiment, whereby statistically

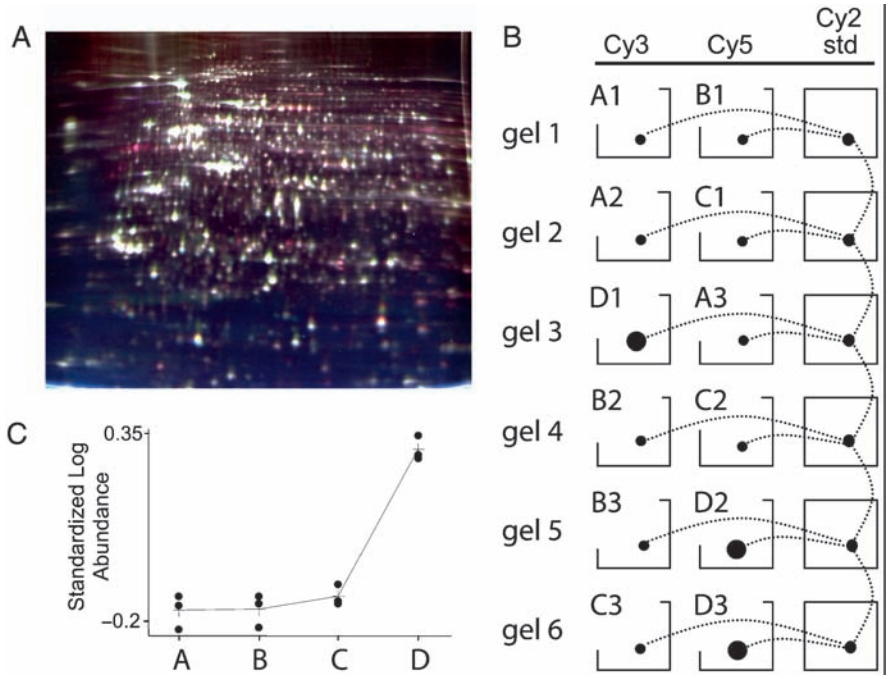

Fig. 1. Illustration of DIGE and experimental design using the mixed-sample internal standard. **(A)** Representative gel from a 6-gel set containing three differentially labeled samples: Cy2-labeled internal standard, Cy3-labeled sample #1, and Cy5-labeled sample #2. The individual protein forms all coresolve in this one gel, but these three independently labeled populations of proteins can be individually imaged using mutually exclusive exitation/emission properties of the CyDyes. **(B)** Schematic of the sample loading matrix indicating gel number, Cydye labeling and three replicates (indicated as "1, 2, and 3") of the four conditions being tested (A, B, C, and D). Within the boxed regions representing each labeled sample is depicted a theoretical protein that is upregulated in condition D. Dotted lines illustrate how the protein signals from each sample are directly quantified relative to the Cy2 internal standard signal for that protein without interference from gel-to-gel variation, and how the Cy3:Cy2 and Cy5:Cy2 intra-gel ratios are normalized between the 6 gels. **(C)** A graphical representation of the normalized abundance ratios for this theoretical protein change. Adapted from ***(5).***

significant abundance changes can be quantitatively measured simultaneously between several sample types (e.g., different genotypes, drug treatments, disease states), with repetition and without the necessity for every pair-wise comparison to be made within a single DIGE gel ***(9, 10)*** (*see* **Note 8**).

1.2.2. Assessing Intersample Variation

Even under the best-controlled situations there is always room for technical variation in sample preparation. Moreover, there will always be some degree of biological "noise" that represents fluctuations in protein expression that fall into the normal range. In the majority of cases, however, biological variation usually outweighs technical variation. Clinical proteomic experiments are especially hampered by biological noise that describes the variation between patient samples that is not associated with disease. The largest proportion of this variation comes from biological diversity, but a significant amount may also come from variable collection and storage of biological samples. It is of vital importance to identify changes in protein expression that describe the biological processes under investigation rather than variation derived from technical or biological noise.

In order to gain the more robust data sets necessary to be able to draw accurate conclusions, it is therefore of paramount importance to collect and store samples using very stringent and closely adhered to protocols. For clinically related samples it is also necessary to assess the biological variation within the population being tested and also within a single individual. Interindividual variation has been the focus of several studies ***(11, 12)*** and determining a typical diversity within a single patient (i.e. taking longitudinal samples and assessing variability in protein abundance) and between patients will determine the minimum number of patient samples required for an experiment. This is an essential step before embarking on any large-scale and potentially costly DIGE experiment. Without this type of pretest, the results of underpowered experiments run the risk of being peppered with false information (both false positives and negatives).

As with all complex technologies, the DIGE technique itself is subject to technical variation which will be laboratory specific to a greater or lesser extent. However, the amplitude of this variation is generally outweighed by the biological variation associated with a typical sample set ***(13).***

1.2.3. Univariate Statistical Analyses

To date, the majority of published quantitative proteomics studies using the DIGE technology have applied a univariate test, such as a Student's t-test or Analysis of Variance (ANOVA), to identify protein species with significant changes in expression ***(14).*** These tests calculate the probability (p) that the samples being compared are the same and therefore any apparent change in expression occurs by chance alone. An expression change is considered significant if the calculated p-value falls below a prescribed significance threshold, typically 0.05 (whereby 1 in 20 tests may give a change in expression by chance). For more stringent analyses, a p-value of 0.01 is often used as the significance threshold.

When employing these tests on DIGE datasets there are several factors that must be considered if correct assumptions are to be made from ensuing analyses. Student's t-tests and ANOVA assume that the data achieved is normally distributed and that any variance is homogeneous. The measurement and correction of systematic bias within DIGE experiments has been the subject of several studies which chart methods to optimize normalization of data sets ***(15–17).***

Another important consideration is that of false discovery rate (FDR) which could arise as a result of statistical tests such as the ones described above. These tests involve the simultaneous and independent testing of thousands of protein features. The probability of a false-positive being recorded for each test is such that a substantial number of false positives may accumulate. There are several approaches to determine the FDR and adjust *p*-values to compensate for this, the most widely used to date being the Benjamini and Hochberg method, whose use in conjunction with DIGE data has been described by Fodor et al. ***(15).***

1.2.4. Multivariate Statistical Analyses

Discovery phase proteomics often produce large lists of proteins that are identified as changing significantly in the experiment, many of which may well be false-positives. Another complementary approach to overcome issues surrounding univariate tests is the application of additional multivariate statistical analyses to these datasets, which can help to filter out false-positives that result from whole-sample outliers (i.e., sample mis-classification and/or poor sample preparation technique). These analyses, such as Principal Component Analysis (PCA), partial least squares discriminate analysis (PLS-DA) and unsupervised hierarchical clustering (HC) (*see* **Figs. 2** and **3**) have recently been applied to DIGE datasets ***(5, 18–26).*** Raw and normalized data can be exported from most DIGE software solutions (e.g., DeCyder, Progenesis), and several multivariate analyses are now part of an extended data analysis software module as part of the DeCyder suite of software tools (GE Healthcare) which was specifically developed for DIGE analysis (*see* **Subheading 3.6.,**). Similar capabilities can also be found in newer versions of the Progenesis software (Non-Linear Dynamics) and Delta2D [Decodon].

These multivariate analyses work essentially by comparing the expression patterns of all (or a subset of) proteins across all samples, using the variation of expression patterns to group or cluster individual samples. Technical noise (poor sample prep, run-to-run variation) and biological noise (normal differences between samples, especially present in clinical samples) is almost always associated with any analytical dataset of this nature, and may well override any variation that arises due to actual differences related to the biological questions being tested. Unsupervised clustering of related samples, therefore, adds additional confidence that a "list of proteins" changing in a DIGE experiment are not arising stochastically ***(5).***

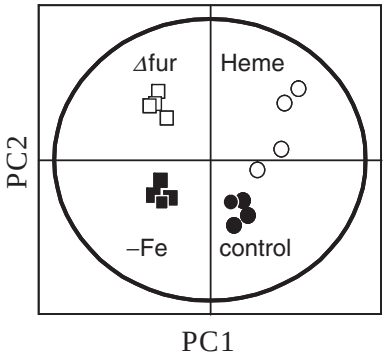

Fig. 2. Illustration of the use of Principal Component Analysis. DIGE was used to analyze changes in Staphylococcus proteins in reponse to genetic and chemical alterations affecting iron utilization. Adapted from ***(18)***.

1.3. DIGE in the Clinical Setting

Although the potential for DIGE to address clinical studies is only beginning to be addressed (for example, see ***(23, 24)***), many studies have been published demonstrating the feasibility and benefit of DIGE/MS using small patient cohorts for preliminary studies in colon ***(8),*** liver ***(27–29),*** breast ***(30, 31),*** esophageal ***(32, 33),*** and pancreatic cancers ***(34),*** as well as other important clinical studies such as SARS ***(35).*** Many studies also explore the important benefit of procuring samples using laser capture microdissection (LCM) for a highly enriched population of the cells under study ***(10, 24, 36–38).*** These LCM studies necessitate the use of the saturation chemistry owing to the increased sensitivity but limited multiplexing power, and typically require secondary preparative gels with higher protein loads to enable protein identification by mass spectrometry.

The study of Suehara et al. ***(23)*** represents the utility of a multivariable DIGE/MS analysis with an extended sample set pertinent for a clinical study. Eighty soft-tissue sarcoma samples comprising seven different histological backgrounds were analyzed. Using the saturation DIGE fluors, individual samples were labeled with Cy5 and multiplexed with a pooled-sample internal standard (labeled in bulk with Cy3) for each DIGE gel. Using high-resolution 2-D gel separations and a combination of multivariate statistical tools (support vector machines, leave-one-out cross-validation, PCA and HC), these studies identified a small subset of proteins including tropomyosin and HSP27 that were able to discriminate between the different classes of tumors. HSP27 in particular was part of a subclass of discriminating proteins that could distinguish between leiomyosarcoma and malignant fibrous histiocytoma (MFH), as

well as correlate with patient survival between low-risk and high-risk groups. HSP27 has long been associated with prognosis in MFH as well as in other human carcinomas ***(39).***

This chapter assumes a solid understanding in 2-D gel electrophoresis, and will focus on the design and implementation of the DIGE method using the pooled-sample internal standard methodology and the minimal dye chemistry for Cy2, Cy3 and Cy5, with notes provided for saturation labeling chemistry.

2. Materials

2.1. Cell lysis buffers

1. TNE: 50 m*M* Tris-HCl pH 7.6, 150 m*M* NaCl, 2 m*M* EDTA pH 8.0, 2 m*M* DTT, 1% (v/v) NP-40.
2. RIPA buffer: 50 mM Tris-HCl pH 8.0, 150 mM NaCl, 1% NP-40, 0.5% deoxycholic acid, 0.1% SDS.
3. 2-D gel electrophoresis lysis buffer: 7 M urea, 2 M thiourea, 4% CHAPS, 2 mg/mL DTT, 50 mM Tris-HCl pH 8.0.
4. ASB14 lysis buffer: 7 *M* urea, 2 *M* thiourea, 2% amidosulfobetaine 14, 50 m*M* Tris-HCl pH 8.0.

Note: Depending on the sample, it may also be necessary to add protease inhibitors (Complete protease inhibitor cocktail tablets. Roche Diagnostics) and phosphatase inhibitors (sodium pyrophosphate (1 m*M*), sodium orthovanadate (1 m*M*), beta-glycerophosphate (10 m*M*) and sodium fluoride (50 m*M*)) to the chosen lysis buffer (*see* **Subheading 3.1**).

2.2. SDS-Polyacrylamide Gel Electrophoresis (PAGE)

1. Immobilized pH gradient strips and accompanying ampholyte mixures can be purchased from a number of commercial vendors. Strip lengths vary from 7 cm to high-resolution 24 cm strips, and pH ranges vary from wide-range (e.g. pH 3–11) to high-resolution narrow-range (e.g. pH 5–6) strips.
2. Bind silane working solution (50 mL): 40 mL ethanol, 1 mL acetic acid, 50 µL bind silane solution (GE Healthcare), 9 mL water (*see* **Note 9**).
3. 4x separating gel buffer: 1.5 M Tris-HCl pH 8.8.
4. 30% acrylamide:bis-acrylamide (37.5:1), N,N,N,N -Tetramethyl-ethylenediamine (TEMED), and ammonium persulfate.
5. 10x SDS-PAGE running buffer (1 L): 30.25 g Tris-base, 144.13 g glycine, 10 g SDS (0.1%).
6. Fixing solution for SyproRuby staining (1 L): 100 mL methanol, 70 mL acetic acid, 830 mL water. SyproRuby stain is available form several commercial sources and can be substituted by other fluorescent total-protein stains such as Deep Purple (GE Healthcare), LavaPurple (Fluorotechnics), or Flamingo Pink (BioRad).
7. 2nd dimensional equilibration buffer: 6 M urea, 50 mM Tris-HCl pH8.8, 30% glycerol, 2% SDS, trace bromophenol blue.

8. Water-saturated butanol (*see* **Note 10**).
9. Dithiolthreitol (store dessicated).
10. Iodoacetamide (store dessicated, keep in the dark).

2.3. DIGE Labeling

1. N,N-dimethyl formamide (DMF) (*see* **Note 11**).
2. Labeling (L) buffer: 7 M urea, 2 M thiourea, 4% CHAPS, 30 mM Tris-base (do not pH, but ensure that pH of final solution is between 8.0–9.0), 5 mM magnesium acetate (*see* **Note 12**). Alternatively, 4% CHAPS can be replaced with 2% ASB14, especially in cases where membrane rich samples are being utilized.
3. Rehydration (R) buffer: 7 M urea, 2 M thiourea, 4% CHAPS, 2 mg/mL DTT (13 mM; 2 %).
4. Cyanine dyes with NHS-ester chemistry for minimal labeling (Cy2, Cy3, Cy5), and with maleimide chemistry for saturation labeling (Cy3 and Cy5) are available from GE Healthcare as dry solids.
5. Quenching solution (for minimal labeling): 10 mM lysine.
6. Dithiothreitol reduction stock solution: 200 mg/mL DTT.

3. Methods

DIGE is a powerful technique for quantitative multivariable differential-expression proteomics. However, the quality of the data will only be as good as the quality of the underlying 2-D gel electrophoresis technology upon which it is based. The main focus of this chapter is to provide detailed notes on the DIGE technology, however, some key considerations to successful high-resolution 2-D gel electrophoresis are also provided. This section describes methods associated with labeling using minimal CyDyes.

3.1. Sample Preparation

The key to success for any analytical measurement begins with robust sample preparation. This not only includes the buffers and materials used, but also the nature of the samples and the way in which they are procured. The addition of exogenous materials (such as DNAse, RNAse), or allowing for uncontrolled manipulation of the sample (such as conditions that may lead to proteolysis) can severely hamper and sometimes completely prevent an analysis. Care should be taken to ensure against common laboratory contaminants (e.g., mycoplasma for tissue culture) that if present may be detected as significant changes using DIGE, either due to the presence in a subset of samples, or by responding to the experimental perturbation.

1. Prepare protein extracts using any method of preference. The appropriate amount of protein can be subsequently precipitated prior to resuspension in the CyDye labeling buffer (*see* **Subheading 3.2**). Ensure against proteolysis and loss of posttranslational modifications (e.g., phosphorylation) as this is of monumental importance.

Care should be taken not to use reagents that will resolve on the 2-D gel, such as soybean trypsin inhibitor. Small molecule inhibitors such as aprotinin, leupeptin, pepstatinA, antipain, AEBSF, sodium orthovanadate, okadaic acid and microcystin, among others, are far better choices.

2. Lyse cells using standard lysis buffers such as TNE, RIPA buffers, or even the buffers used for 2-D gel electrophoresis. All of these buffers have the capability of producing high-resolution samples for 2-DE. In most cases, the presence of reagents that would otherwise interfere with CyDye labeling (such as those that contain primary amines) will be removed prior to labeling by protein precipitation (*see* **Subheading 3.2**).
3. Sonicate cells if necessary to improve sample quality. Sonication improves sample quality by disrupting nucleic acids which are subsequently removed by sample cleanup (*see* **Subheading 3.2**) along with phospholipids. Both of these non-proteinaceous ionic components can obliterate the resolution during isoelectric focusing.
   Short bursts with a tip-sonicator are suggested. It is important to keep the system chilled, especially in the presence of urea-containing samples that should never be heated (*see* **Note 12**).
4. Determine the protein concentration of the sample using a system that is compatible for the buffer that the proteins are extracted in. CHAPS and thiourea in the buffers used for DIGE, although adequately chaotropic, interfere with either the Bradford or BCA assays, making the data inaccurate and unreliable. In these cases, aliquots should be precipitated prior to quantification in a suitable buffer, or the use of a detergent compatible assay should be utilized.
5. Aim to use a protein concentration between 1–10 mg/mL. Too dilute and it will be difficult to quantitatively recover proteins following precipitation clean-up (*see* **Subheading 3.2**); too concentrated and it will be difficult to accurately dispense the appropriate volume for the experiment. Freeze/thawing should also be kept to a minimum; freezing samples in 1 mL aliquots or less will usually suffice.

3.2. Sample Clean Up.

The desired amount of sample to be used in the experiment should be precipitated prior to labeling. This both removes non-proteinaceous ions from the sample (e.g., nucleic acids, phospholipids) that can interfere with IEF, and also transfers the proteins into a labeling buffer optimized for CyDye labeling and subsequent IEF. Determine how much total protein will be on each gel, and precipitate ½ of that amount for each sample to be run on that gel. This is straightforward for a two-component separation, but also works out for the multigel experiments where 1/3 of the total protein amount on each gel comes from the pooled-sample internal standard (*see* **Table 1**). Precipitate only what is needed for each sample for the experiment; too much material may create pellets that are difficult to resolubilize completely.

Many precipitation methods are available, the following is a MeOH/$CHCl_3$ protocol that works well for DIGE, and can be easily performed in 1.5 mL tubes (adapted from ***(40)***):

Table 1
Experimental Design for CyDye Labeling Using a Pooled-Sample Internal Standard

	Samples						
	Gel 1		Gel 2		Gel 3		
	Control-1	Treated-1	Control-2	Treated-2	Control-3	Treated-3	pool
Precipitated amount	150 µg	150 µg	150 µg	150 µg	150 µg	150 µg	
L-buffer	24 µL	24 µL	24 µL	24 µL	24 µL	24 µL	
Aliquot	16 µL	16 µL	16 µL	16 µL	16 µL	16 µL	8 µL (x6)
Cy2							6 µL
Cy3	2 µL		2 µL			2 µL	
Cy5		2 µL		2 µL	2 µL		
	30 min on ice in the dark						
Lysine (quench)	2 µL	2 µL	2 µL	2 µL	2 µL	2 µL	6 µL
	10 min on ice in the dark						
Total vol	20 µL	20 µL	20 µL	20 µL	20 µL	20 µL	60 µL
	For each gel, combine the quenched Cy3-and Cy5-labeled samples and add 1/3 of the quenched Cy2-labeled pooled mixture						
	20 + 20 + 20 µL		20 + 20 + 20 µL		20 + 20 + 20 µL		
2x R-buffer	60 µL		60 µL		60 µL		
total	120 µL		120 µL		120 µL		
R-buffer	to V_f		to V_f		to V_f		

This table illustrates a typical DIGE labeling experiment, as described in **Subheadings 3.2** and **3.3.**

1. Bring up predetermined amount of protein extract to 100 µL with water.
2. Add 300 µL (3-volumes) water.
3. Add 400 µL (4-volumes) methanol
4. Add 100 µL (1 volume) chloroform
5. Vortex vigorously and centrifuge; the protein precipitate should appear at the interface.
6. Remove the water/MeOH mix on top of the interface, being careful not to disturb the interface. Often the precipitated proteins do not make a visibly white interface, and care should be taken not to disturb the interface.
7. Add another 400 µL methanol to wash the precipitate.
8. Vortex vigorously and centrifuge; the protein precipitate should now pellet to the bottom of the tube.
9. Remove the supernatant and briefly dry the pellets in a vacuum centrifuge.
10. Resuspend the pellets in a suitable amount of CyDye labeling buffer (L-buffer, see **Table 1**).

An alternative widely used precipitation method is as follows:

1. Add 5 volumes of cold 0.1 *M* Ammonium acetate in methanol.
2. Leave at −20°C for 12 hr or overnight
3. Centrifuge at ~3000 rpm (1400 × g) for 10 min at 4°C and remove the supernatant.
4. A pellet of protein should be visible at this stage
5. To wash the pellet, add 80% 0.1 *M* ammonium acetate in methanol and mix to resuspend the protein.
6. Centrifuge at 3000 rpm (1400 × g) for 10 min at 4°C and remove the supernatant.
7. To dehydrate the pellet add 80% acetone and resuspend the pellet by mixing.
8. Centrifuge at 3000 rpm (1400 × g) for 10 min at 4°C and remove the supernatant.
9. Dry pellet for 15 min by leaving open tube in a laminar flow cabinet.

3.3. DIGE Experimental Design.

1. Start with a preliminary gel. All experiments should start with a preliminary gel on representative samples to ensure equivocal protein amounts between samples, and that the highest resolution and sensitivity are obtained before embarking on a multigel DIGE experiment (*see* **Notes 13** and **6**). The preliminary gel will also show any problems with the sample preparation that may be corrected by adjusting the procurement methods (*see* **Subheading 3.1**). This step can also be used to optimize the maximal amount of protein can be loaded without adversely affecting resolution.
   The preliminary gel needs only to test one or two of the samples of a much larger experiment. This gel can simply be stained with a total protein stain (*see* **Subheading 2.2.6**) to visually inspect the resolution and sensitivity. Alternatively, the gel can contain two different samples prelabeled with Cy3 and Cy5 and coresolved (*see* **Note 14**).
2. Choose a suitable pH gradient for IEF. Precast isoelectric focusing strips are commercially available from several vendors. The widest length is currently 24 cm, providing the highest resolving power for a given pH range. Medium-range isoelectric focusing gradients (e.g., pH 4–7) offer the best trade-off between overall resolution and sensitivity. Subsequent experiments can then be designed to resolve proteins in the basic range (pH 7–11) and in narrow pI ranges with commensurate increases in protein loading to gain access to the lower abundant proteins in a given sample (*see* **Note 5**). In this way a more comprehensive picture of the proteomes under study can be obtained.
3. Incorporate a pooled-sample mixture internal standard on every DIGE gel in a coordinated experiment. This internal standard, usually labeled with Cy2, is composed of an equal aliquot of every sample in the entire experiment, and therefore represents every protein present across all samples in an experiment. The use of this pooled-sample internal standard on every DIGE gel in a coordinated experiment allows for the facile comparison of independent sample replicates with increased statistical confidence. This experimental design also enables the simultaneous quantitative comparison between multiple variables in a coordinated experiment (**Fig. 1**).
4. Plan out which samples will be labeled with which dyes ahead of time. For minimal dye-labeling chemistry (*see* **Subheading 3.4**), each gel will contain two individual

samples labeled with either Cy3 or Cy5, and an equal amount of the pooled-sample internal standard. The example outlined in **Table 1** is for a two-component comparison repeated in triplicate, with 300 µg total protein loaded onto each of three gels. In this case, 150 µg of each sample should be precipitated (*see* **Subheading 3.2**), resuspended in L-buffer and then split 2:1. Two-thirds of each sample (100 µg) will be individually labeled with either Cy3 or Cy5. The remaining 1/3 of each sample will be pooled together and labeled en masse with Cy2 to serve as an internal standard. By following this, there will be enough of the Cy2-labeled internal standard to have an equal amount as the Cy3 or Cy5 samples loaded onto each gel (*see* **Note 15**).

3.4. CyDye Labeling

All steps are performed on ice. The following protocol is for sample loading via rehydration of IPG strips, and assumes incorporation of a pooled-sample internal standard to coordinate many samples across multiple DIGE gels simultaneously. The steps are summarized in **Table 1** (*see* **Note 16**).

1. Resuspend precipitated sample in 24 µL labeling (L) buffer. Remove 8 µL (1/3 of sample) and place into a new tube that will contain the pooled-sample internal standard (8 µL from all of the other individual samples will be pooled into this tube) (*see* **Note 17**).
2. CyDyes are purchased as dry solids and should be reconstituted to 10x stock solutions (1 nmol/µL) in fresh DMF. Dilute stock solutions of CyDyes 1:10 in fresh DMF to a final working concentration of 100 pmol/µL. (*see* **Note 11**).
3. Label each sample (50–250 µg) with 2–4 µL (200–400 pmol) of either Cy3 or Cy5 working dilution for 30 min on ice in the dark. Label the pooled-sample mixture with 2–4 µL (200–400 pmol) of Cy2 working dilution for every equivalent amount of sample present in the pooled standard as compared with the individually labeled samples. That is, if 100 µg of each sample is labeled with 200 pmol of Cy3 or Cy5, then 50 µg of each of these samples is present in the pooled standard, and 200 pmol of Cy2 is used for every 100 µg of pooled standard (*see* **Table 1** and **Note 18**).
4. Quench reactions with 2 µL of 10 mM lysine for 10 min on ice in the dark.
5. For each gel, combine the quenched Cy3-and Cy5-labeled samples and add 1/3 of the quenched Cy2-labeled pooled mixture.
6. To each tripartite mixture, add an equal volume of 2x R-buffer and incubate on ice 10 min. 2x R-buffer is R-buffer supplemented with an additional 2 mg/mL DTT using the 200 mg/mL DTT stock solution. DTT is omitted from the L-buffer to prevent unfavorable interaction with the CyDyes. Adding an equal volume of 2x R-buffer to the quenched reactions provides the reducing agents to the total reaction volume at 1x final concentration.
7. Add R-buffer (1x DTT concentration) to a final volume suggested by the manufacturer for the given IPG strip length (e.g., 450 µL for 24 cm strips). Add the appropriate volume of IPG buffer ampholines to 0.5% final (v/v) for isoelectric focusing. Proceed with rehydration of dehydrated immobilized pH gradient (IPG)

strips for >16 hr and proceed with isoelectric focusing (*see* **Subheading 3.5.3** and **Note 19**).

3.5. 2-D Gel Electrophoresis and Poststaining

As a result of the minimal labeling, quantification with the CyDyes is carried out on only 2–5% of the proteins that are labeled, and the labeled portion of the protein may migrate at a higher apparent molecular mass than the majority of the unlabeled protein due to the added mass and hydrophobicity of the dyes (exacerbated in lower M_r species). To ensure that the maximum amount of protein is excised for subsequent in-gel digestion and mass spectrometry, minimally labeled 2-D DIGE gels are poststained with a total protein stain (*see* **Subheading 2.2.6**). Accurate excision is also ensured by preferentially affixing the 2nd dimension gel to a presilanized glass plate during gel casting so that the gel dimensions do not change during the analysis. (*see* **Notes 20** and **21**)

These methods assume the use of the Ettan 2-D electrophoresis system (GE Healthcare), but are easily adaptable to other commercially available systems. It also assumes usage of high resolution 24 cm × 20 cm gels.

1. Special gels for 2nd dimension SDS-PAGE. Using low-fluorescence glass plates, pretreat one plate for each gel with 3–5 mL bind silane working solution, carefully wiping the entire surface of the plate with a lint-free wipe. Leave treated plates covered with lint-free wipes for several hours to allow for sufficient out-gassing of fumes (that may contain bind silane) before assembling gel plates and casting of 2nd dimensional SDS-PAGE gels (*see* **Note 22**).
2. Assemble plates and pour 12% homogeneous SDS-PAGE gel(s) using the appropriate amount of 30% stock acrylamide and 4x separating gel buffer for the volumes needed for the number of gels being poured (*see* **Note 23**). Overlay the gels with water-saturated butanol for several hours to provide a straight and level surface to place the focused IPG strip (*see* **Note 10**).
3. Perform isoelectric focusing (for example using an IPGphor III isoelectric focusing unit, GE Healthcare) of the combined tripartite-labeled samples, brought up to final volume with 1x R-buffer and passively rehydrated into immobilized pH gradient (IPG) strips for >16 hr (*see* **Subheading 3.4**, **step 7**) (*see* **Note 24**).
4. Equilibrate the focused IPG strips into the 2nd dimensional equilibration buffer. During this step, the cysteine sulfhydryls in the focused proteins are reduced and carbamidomethylated by supplementing the equilibration buffer with 1% DTT for 20 min at room temperature, followed by 2.5% iodoacetamide in fresh equilibration buffer for an additional 20 min room temperature incubation (*see* **Note 25**).
5. Place equilibrated IPG strip on top of the SDS-PAGE gels that were precast with low-fluorescence glass plates. Use a thin card or ruler to carefully tamp down the IPG strip to the SDS-PAGE gel, removing air bubbles at the interface (*see* **Notes 26** and **27**).

6. Perform 2nd dimensional SDS-PAGE at constant wattage, using << 1 W/gel for at least 1 h prior to ramping up to < 15 W/gel (*see* **Note 28**).
7. CyDye images are acquired using a fluorescence imager, such as the Typhoon 9400 series (GE Healthcare) equipped with lasers and filters that are compatible with the emission/excitation spectra of the dyes. Imaging is performed through the glass plates using the intact gel cassette (*see* **Note 29**).
8. After imaging the gels, carefully remove the plate that was untreated with bind silane. The gel will remain stuck to the treated plate, and can be stained with an appropriate total-protein dye (*see* **Subheading 2.2, item 6**) "open-faced" in the fixation/staining solutions. For SyproRuby, fix gels for at least 2 hr with fixation solution sufficient to completely cover the gel. Longer fixations are possible without adversely affecting subsequent mass spectrometry. After removing the fixation solution, stain gels overnight in SyproRuby and acquire images using a fluorescence imager (*see* **Notes 21** and **30**).

3.6. DIGE Analysis

3.6.1. Software Algorithms

Many bioinformatics tools are commercially available for the comparison of multiple 2-D gel-separated protein spot patterns. Some free internet-based utilities (e.g., www.lecb.ncifcrf.gov/flicker/) provide simple alternation between two spot-patterns, whereas most of the commercial products contain proprietary algorithms for protein-spot detection, inter-gel matching, protein spot quantification and even utilities for building web-based tools for data dissemination. Many include the ability to average replicate patterns into a single virtual pattern to be used in a comparative study. They are all designed to compare multiple spot patterns and quantify abundance changes for individual proteins between experimental conditions.

Several software packages allow for the analysis of DIGE data; the DeCyder suite of software tools were specifically developed to support the DIGE platform when this technology was first marketed by GE Healthcare, and is therefore used as an example here. The DIA (Differential In-gel Analysis) module of DeCyder is used for direct quantification of protein spot volume ratios between the triply codetected signals emanating from each resolved protein, and can be used for the simplest form of a DIGE experiment for pair-wise comparisons with $N = 1$. It is recommended that these DIA-only experiments should be used for test purposes only. The more advanced and statistically significant DIGE experiments that use the internal standard to cross-compare replicate samples from pair-wise and multivariable analyses ($N > 3$) are handled by the BVA (Biological Variation Analysis) module of DeCyder. In a BVA experiment, the signals emanating from the internal standard are used both for direct quantification within each DIGE gel in a coordinated set (using DIA module), as well as for normalization and protein spot-pattern matching

between gels (*see* **Note 31**). This allows for the calculation of Student's t-test and ANOVA statistics for individual abundance changes (*see* **Subheading 3.6.2**, and **Table 2**). BVA is also used to match patterns between SyproRuby- and CyDye-stained images to facilitate protein excision for subsequent mass spectrometry (*see* **Notes 20, 21,** and **30**).

3.6.2. Experimental Design and Statistical Confidence.

In the simplest form of a DIGE experiment, two or three samples are separately labeled with one of the three dyes and separated in the same gel for direct pair-wise comparisons. In this case, the software first normalizes the entire signal for each Cy-dye channel and then calculates the protein spot volume ratio for each protein pair. A normal distribution is modeled over the actual distribution of protein pair volume ratios, and two standard deviations of the mean of this normal distribution represent the 95th percent confidence level for significant abundance changes.

This $N = 1$ type of experiment has limited statistical power, since the 95th percentile confidence interval is determined based on the overall distribution of changes within the population (*see* **Note 32**). Many more changes in abundance of much lesser magnitude can be detected with much greater statistical confidence (Student's t-test and ANOVA, **Table 2**) by incorporating independent replicate samples into the experiment (*see* **Note 33**). The number of replicates required in a study depends on the amount of variation in the system being investigated. Increasing the number of replicates will increase confidence in smaller changes in expression. The number of gel replicates that are needed for the experiment to have sufficient sensitivity to detect expression changes can be determined using power calculations ***(41)***.

With replicate samples, the Student's t-test and ANOVA statistics are measuring the significance of the variation of a specific protein change, independent of the overall distribution of abundance changes in the population. Incorporating replicate samples into the experimental design also controls for unexpected variation introduced into the samples during sample preparation. This design not only allows for the identification of abundance changes that are consistent across multiple replicates of an experiment, but can also identify significant abundance changes that would not have been identified even if the analyses were performed using Cy3- and Cy5-labeled samples on the same gels, but without the pooled-sample internal standard to coordinate them ***(8)***.

3.6.3. Multivariate Statistical Analysis

Univariate analyses such as the Student's t-test and ANOVA (analysis of variants) have traditionally been used in DIGE experiments to provide a list of statistically significant changes in protein abundance. The application of multivariate

Table 2
Statistical Applications of DeCyder Biological Variation Analysis (BVA) and Extended Data Analysis (EDA) modules

Average ratio	Calculated for each protein spot-feature between two groups or experimental conditions. Derived from the log standardized protein abundance changes that were directly quantified within each DIGE gel relative to the internal standard for the protein spot-feature.
Student's T-test	Univariate test of statistical significance for an abundance change between two groups or experimental conditions. P-values reflect the probability that the observed change has occurred due to stochastic chance alone. With DIGE, p-values of <0.01 are often observed. Assumes normal distributions of protein abundance. Can be performed either unpaired or paired.
One-Way ANOVA	Tests for differences in standardized abundance of a given protein across all groups of a multicomponent analysis. Indicates that one group is significantly different from the other groups in the experiment.
Two-Way ANOVA	Tests for differences in standardized abundance of a given protein between multiple groups with the same condition, where multiple conditions are analyzed.
Principal Component Analysis (EDA only)	Reduces the dimension of the variables in a multidimensional space. The first principal component (PC1) divides the dataset along an axis describing the most variance in a system, with the orthogonal second component (PC2) accounting for the second greatest source of variation.
Hierarchical Clustering (EDA only)	Compares groups based on similarity of the collective expression patterns of individual proteins, often displayed in an expression matrix (heatmap). Similarity between groups is proportional to the lateral distance depicted as a branched dendrogram,
K-means (EDA only)	Used to classify proteins into a predefined number of bins based on similarity.
Self Organizing Maps (EDA only)	Similar to K-means, but also clusters nearest neighbors (based on exression patterns) in a 2-D map.
Gene Shaving (EDA only)	Used to identify groups of proteins that have similar expression profiles. Unlike K-means, proteins can belong to more than one group provided there is high coherence within each group.
Discrimnant Analysis (EDA only)	Identifies proteins that can discrimate between groups based on a variety of classifier schemes, including cross validation, feature selection, partial least squares, K-nearest neighbors.

statistical analyses (as outlined in **Subheading 1.2.4**) allow for the assessment of changes on a global scale, and can bring added insight to the usual "list of proteins" generated. Most software packages allow for the export of raw and normalized protein spot-volumes to allow for these additional statistical tests and data manipulations; in addition the DeCyder suite of software tools now

provides an Extended Data Analysis (EDA) module that includes many of these tools (**Table 2**). These tools are now becoming more evident in recent DIGE publications (***5, 18, 22–24, 26, 42***). Although these multivariate analyses are especially beneficial when analyzing a DIGE experiment that contains three or more conditions, they can also useful in two-condition comparisons to detect sample outliers, fouled samples or even poor experimental design.

Fig. 2 illustrates an example of PCA applied to a DIGE dataset comprised of four experimental conditions each measured in quadruplicate. PCA simplifies multidimensional datasets by reducing the variation down to the two or three most significant sources of variation. In this example, the first principle component (PC1) accounts for 62.3% of the variation amongst 156 proteins of interest, with the second principle component (PC2) accounting for an additional 12.5% of the variation. Each sample datapoint describes the collective expression profile for the subset of 156 proteins, and PC1 and PC2 orthogonally divide the samples into quadrants based on these two largest sources of variation within DIGE dataset. In this case, 75% of the variance between these proteins clusters the samples into the proper categories (adapted from ***(18)***).

Fig. 3 is taken from a 2-D DIGE study which determined the change in protein abundance in mouse liver over a 24-hr period. In this study proteins were harvested from groups of mice on a second cycle after transfer from synchronized light (12 hr light : 12 hr dim red light) to free running conditions (constant dim red light). Proteins were extracted from each liver and pooled from six mice per four-hr time point. Hierarchical clustering (by average distance correlation) was used to investigate the expression of 49 novel circadian proteins. This gave a range of phase groups with 10 proteins peaking during the subjective day and 39 proteins distributed between two clusters which were most abundant during the subjective night (adapted from ***(26)***).

Finally, additional information may be gleaned by mapping proteins found to be changing by DIGE to existing biological pathways and networks. Many software solutions and services are becoming available for this type of extended analysis. Although additional validation is necessary to establish biological significance, the mapping of members of a "list of proteins" to established pathways and networks can provide validating support for the proteins observed by DIGE alone. In some cases, it can also indicate potential proteins associated with the biological question(s) that were not accessible in the DIGE analysis. For example, Friedman et al. ***(5)*** recently reported the use of network/pathway mapping for proteins found by DIGE/MS in MCF10A cells overexpressing the HER2 receptor after treatment with TGF-β. The majority of proteins identified with DIGE/MS mapped to a network of pathways involving TGF-β1 as a major hub, but also included an intercalating pathway involving p53 that effected many proteins that were independently identified in the DIGE/MS experiments. This

insight linking new players to those identified with DIGE/MS led to the further investigation of a direct role for p53 in the expression of the tumor suppressor maspin ***(43).***

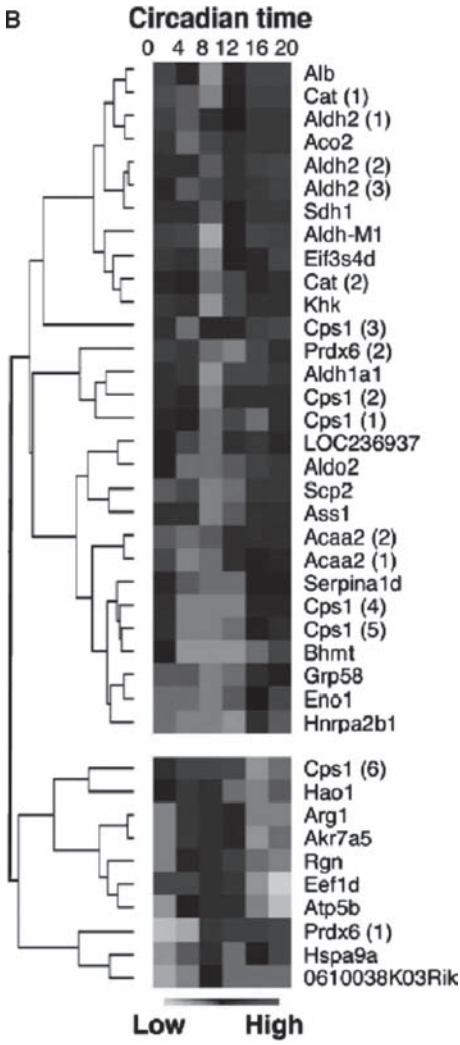

Fig. 3. Hierarchical clustering (by average distance correlation) of representative novel circadian proteins detected by 2-D-DIGE of soluble protein extracts from mouse liver. Pale gray represents low levels of protein expression, black represents intermediate levels, and dark gray represents high levels of expression. (From ***26***).

4. Notes

1. 2-DE has traditionally been a popular method for differential-expression proteomics on a global scale, but until recently, these strategies lacked the ability to directly quantify abundance changes in the same fashion as in stable isotope LC/MS-based strategies ***(44–46)***. This has been mainly due to the inability to directly correlate migration patterns and protein staining between gel separations (gel-to-gel variation). Stable isotopes have been used in gel-based proteomics as well, whereby different proteomes have been separately labeled with different stable isotopes (e.g., growing cells using 14N vs. 15N-labeled medium) prior to mixing and running together through the same 2-DE separation ***(47)***. In this case, abundance changes can be monitored during the mass spectrometry stage on individual proteins, but requires the in-gel digestion and mass spectrometry on every protein present to discover the subset of proteins that is changing.
2. Both hydrophobicity and molecular weight influence how proteins migrate during SDS-PAGE, yielding information on apparent molecular mass.
3. In comparison, commonly used silver or colloidal coomassie blue (c. 5–10 ng sensitivity) stains typically exhibit a dynamic range of less than two orders of magnitude (***4***, ***48***). The CyDye labeling system is compatible with the downstream processing commonly used to identify proteins via mass spectrometry and database interrogation, which involves the generation of tryptic peptides within excised gel plugs. Trypsin cleaves the peptide bonds the C-terminal side of lysine and arginine residues, but peptide generation is mostly unhindered as so few lysine residues are modified by dye labeling.
4. DIGE experiments can still be performed using the internal standard methodology with only two CyDyes, but twice as many gels are required to analyze the same number of samples compared with the three-dye minimal labeling scheme. With saturation labeling, one dye is used to label the internal standard, and the other is used to label individual samples. A dye-swap scheme is not necessary in this case because the individual samples are always labeled with the same CyDye.
5. The use of hydroxyethyl disulfide (commercially available as "DeStreak reagent"), combined with anodic cup-loading, should be used for enhanced resolution for isoelectric focusing above pH 8 (***49***).
6. Running every DIGE gel with the maximal amount of protein (without adversely effecting first-dimension resolution) not only enables detection of lower abundance proteins, but also provides more material for subsequent protein identification using mass spectrometry. This makes every gel in a coordinated DIGE experiment a "pick-able" gel, without the need to run subsequent preparative gels with increased protein load that then have to be carefully matched to a lower-abundant, analytical gel. When combined

with narrow range isoelectric focusing, maximizing the protein amount also allows interrogation of the lower abundant proteins in a sample.

7. If one sample within a study has very skewed protein distributions compared with others, then many of the "novel proteins" within this sample will effectively be diluted out in the pool. Such a sample outlier can be easily identified using the multivariate statistical analyses described.
8. Repetition not only enables the identification of subtle differences with statistical confidence, it is also vital to control for non-biological variation. In most cases biological variation will outweigh technical variation, therefore only biological replicates are necessary. Thus it is important that each replicate sample is derived from an independent experiment, ideally performed on different occasions as perhaps using different batches of medium. The independent samples can then be analyzed coordinately using the pooled-sample internal standard methodology. See Table 1 for an example of this design.
9. All solutions should be prepared using water that has a resistivity of 18.2 MΩ-cm; this is referred to as "water" throughout the text.
10. Mix equal parts butanol and water and shake vigorously. Let the two phases separate overnight, and use the butanol phase for overlay. Butanol that is not completely water-saturated can extract water from the top of the gel. A more recent improvement is to use a 0.1% SDS solution in a conventional spray bottle, used to carefully spray a fine mist over the top of the gels to thoroughly cover the top of the gel (the gel/overlay interface will not be as obvious).
11. DMF can degrade, producing amines which can react with the NHS-ester CyDyes. DMF stocks should be kept fresh (< 3 months) and anhydrous to ensure optimal labeling conditions.
12. For buffers that contain urea, care should be taken to ensure the urea is fresh and free of the natural breakdown product isocyanate, which will carbamylate free amines and thereby neutralize the protonatable epsilon-amine groups of lysines residues. This is problematic for several reasons, the foremost being the fact that this gives rise to artificial charged-train isoforms in the first dimension isoelectric focusing. Heating samples above 37°C should also be avoided, as this facilitates the conversion to isocyanate. Any buffer component which contains a primary amine, such as pharmalytes, ampholytes, HEPES buffers etc. should be avoided as these components may react with the CyDyes thus reducing their affective concentration.
13. For example, 500 µg of material may be loaded onto a pH 4–7 24 cm IPG strip), but due to the overall distribution of proteins in the sample, as well as a sometimes unusually high abundance of a subset of proteins, may result in much less material actually resolving between the electrodes. A good rule to follow is to load the desired amount based on the protein concentrations, and then adjust the load by eye as necessary.

14. This is DIGE in its most simplistic form, and can show differences between the samples without interference from gel-to-gel variation, but provides limited statistical power to help distinguish true biological variation from background such as artificial noise introduced during sample preparation.
15. Employing a dye-swapping approach will control for any dye-specific effects that may result from preferential labeling or different fluorescence characteristics of acrylamide at the different wavelengths of excitation for Cy2, Cy3 and Cy5, especially at low protein spot volumes. This is easily incorporated into any DIGE analysis where repetitive samples are used (along with the internal standard to compare across multiple DIGE gels).
16. For saturation chemistry, general methods and considerations are the same as for the minimal chemistry, but there are several unique features to also consider for the saturation chemistry. First, careful optimization of the labeling conditions must be carried out for each new sample set to ensure complete reduction of cysteine residues. Insufficient labelling will lead to multiple protein features in the second dimension due to MW and hydrophobicity shifts. Overlabeling results in side reactions with the epsilon-amine groups of lysine side chains, but since the maleimide dyes do not carry compensatory charge, this results in the overall loss of a charge which creates a series of isoelectric forms in the first dimension ("charge trains"). Labeling buffer should not contain any components with free thiols, as these will react with the satCyDyes.
17. L-buffer volume can be increased if necessary for complete resolubilization, although 100–250 μg or more should resolubilize readily in this volume. The volume of labeling buffer used for resolubilization should not exceed 40 μL per sample when using cup-loading for sample entry to ensure that the final volumes will not exceed the capacity of the cup-loading (c. 100–150 μL).
18. These methods are provided assuming that all gels to be run will be used both for analytical (quantification) as well as preparative (providing material for subsequent mass spectrometry) purposes. Current recommendations from the manufacturer are to label 50 μg of sample with 400 pmol CyDye. Sufficient amount of unlabelled sample can be added to the quenched reactions to achieve final protein amounts to facilitate subsequent mass spectrometry. Alternatively, many have found that the ratios can be adjusted to label increasing amounts of sample (up to 200 μg with 200 pmol dye) without adversely affecting the overall labeling reaction (presented here).
19. If samples are to be introduced using anodic cup-loading, simply bring this mixture up to 100 μL in R-buffer and proceed with cup-loading. R-buffer can always be supplemented with additional DTT using the 200 mg/mL DTT stock solution. In the presence of Destreak reagent for focusing in pH ranges above pH 8, the addition of equal volume 1x R-buffer should provide sufficient amount of DTT without interfering with the Destreak reagent.

20. Comparison of minimally labeled protein 2-D maps with unlabeled protein maps is generally not a problem, as the addition of only one dye molecule does not generally prevent the facile matching of small alterations in protein mobility between the 2–5% labeled protein and the remaining unlabeled protein that will provide enough material for mass spectrometry.
21. Poststaining is not necessary with Saturation DIGE, since an unlabeled population with potentially different migration characteristics will not exist.
22. This treatment binds the gel to one of the glass plates and therefore prevents shrinking/swelling during the poststaining and protein excision processes, thereby facilitating accurate robotic protein excision. Nothing should be placed on top of wipes that are covering bind silane-treated plates, as this may leave impressions that are detected during the scanning phase. Assembly and casting too soon may create a binding surface on the opposite glass plate, preventing the gel to be subsequently poststained and picked. Automated protein excision can be facilitated for certain systems by placing fluorescent alignment reference targets on the plate, which can be performed at this stage.
23. A stacking gel is not required for 2-D gel electrophoresis, as the proteins are effectively "stacked" to the height of the IPG strips. SDS is also not essential in the separating gel, as the SDS associated with the proteins during the equilibration step, and present in the running buffer, is sufficient (although many traditionally use it in the separating gel). Using 2x concentration running buffer in the upper buffer chamber can produce higher quality separations in some circumstances.
24. Samples of similar nature should always be focused simultaneously for optimal reproducibility. Focusing programs vary for some pH gradients. A typical program for many ranges is 500 V for 500 V-hr, stepping to 1000 V for 1000 V-hr, followed by a final step to 8000 V until > 50 V-hr have been reached. Check recommendations from specific vendors. Using the ceramic manifold tray adaptor is recommended.
25. Volume of equilibration buffer should be large to ensure sufficient removal of ampholines and other components of the 1st dimensional run.
26. Carefully wash out any remaining liquid on top of the SDS-PAGE gel. Prewet the IPG strip with1x running buffer and place the strip between the gel plates with the plastic-backing adhering to the inside surface of one of the glass plates. The prewetted running buffer will facilitate the manipulation of the IPG strip down the inside surface of the plate and on top of the SDS-PAGE gel.
27. An agarose overlay, used by many protocols, is not absolutely necessary to ensure proper contact between the IPG strip and the 2nd dimensional SDS-PAGE gel. Using a thin card or ruler to carefully tamp down the IPG strip to the gel is usually sufficient and removes the added problems associated with the overlay, such as trapped air bubbles in the solidified agarose.

28. Running gels at less than 1 W/gel can improve resolution in the high molecular weight regions of the 2nd dimension gel. Use wattage appropriate for the 2nd dimensional unit being used. Many different gel units can accommodate increased power by compensating for the increased heat.
29. Absorption/emission maxima in DMF are 491/506 for Cy2, 553/572 for Cy3, and 648/669 for Cy5; although care must be taken to scan in regions of each spectrum that do not contain absorbance or emission in the other spectra, which may mean using a non-maximal region of a given spectrum.
30. Comparison of the 2-D spot maps between saturation-labeled samples and minimal labeled or unlabeled samples is impossible, as proteins containing multiple cysteine residues may appear as significantly larger M_r species when labeled with the saturation dyes, which of course cannot be predicted without first knowing the protein identity.
31. Almost all software packages for 2-D electrophoresis involve matching of protein spot-patterns between gels. For DeCyder, it is used in the BVA module to match the quantitative data obtained from the triply coresolved protein signals from each gel in the DIA module (where gel-to-gel variation does not come into play). Manual verification of the matching is almost always required with any software package.
32. There are many "all-or-none" type of experiments where the single gel comparison may be valid, and subtle changes are not expected. Nevertheless, using independent replicates and the pooled-sample internal standard methodology is still needed to control for non-biological sample preparation error.
33. The multigel approach allows many data points to be collected for each group to be compared. Protein features of interest can be selected by looking for significant change across the groups. Student's t-test and Analysis Of Variance (ANOVA) probability scores (p) indicate the probability that the observed change occurred due to stochastic, random events (null hypothesis). Probability values < 0.05 are traditionally used to determine a statistically significant difference from the null hypothesis. As this represents 50 potential false-positives for 1,000 resolved proteins, confidence intervals within the 99th percentile ($p < 0.01$) are arguably more valid, and can be attained using DIGE (5, 8, 18, 50–54).

Comparing 2D Electrophoretic Gels Across Internet Databases: An Open Source Application

Peter F. Lemkin, Gregory C. Thornwall, and Jai A. Evans

1. Introduction

In ***(1–4)*** and in the second edition of this book ***(5),*** we described a Web-based computer-assisted visual method called Flicker for comparing two two-dimensional (2D) protein gel images across the Internet using a Java applet. In the second edition of this book ***(6),*** Flicker was described as a stand-alone application. The flicker method was originally developed in the GELLAB 2D-gel analysis system ***(7–11).*** The applet version was used for Web-based analysis using a Web-browser.

The Java stand-alone application can run on a user's computer, where it can access images from the Web but can easily access the user's images data on their local computer. Flicker is available as open source on http://open2Dprot.sourceforge.net/Flicker where the executable program and the source code is also available. Some of the code was derived from the old Flicker applet program and some from the MicroArray Explorer ***(12)*** –an open-source data-mining tool for microarray analysis http://maexplorer.sourceforge.net/. The Open2Dprot protein expression analysis system http://open2Dprot.sourceforge.net/ was partly derived from Flicker, MicroArray Explorer, and GELLAB code and concepts.

Because Flicker can analyze a user's data on his or her computer independent of the Internet, this gives the user the ability to perform real-time comparisons of 2D-gel image data with gel images residing on the user's local file system, on remote Internet databases on the Internet, or a combination of both sources.

This approach may be useful for comparing similar protein samples created in different laboratories to help putatively identify or suggest possible protein spot identification. The gels should be run under similar pH and molecular weight ranges if possible. Although available for over three decades, 2D polyacrylamide gel electrophoresis (2D-PAGE) is still used ***(13–14)*** even considering

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

the now common use of mass spectrometry ***(13,25–26)*** and protein microarrays ***(13,21–22)*** for protein identification and biomarker discovery as part of the researcher's toolkit ***(13).***

Advances, such as IEF "zoom" fractionation gels ***(23),*** are commonly used ***(24)*** to divide the protein sample by pH range or immunoaffinity subtraction with LC ***(18),*** greatly increase the resolution and numbers of spots able to be discriminated by subsequent 2D-gel electrophoresis. Another increasingly common image comparison technique uses 2 to 6 cyanine dyes using dye multiplexing to label multiple control and experimental samples run in the same gel such as GE Healthcare's (formerly Amersham's) DIGE ***(13,25–26)*** and scanned with system's like Perkin Elmer's ProExpress ***(27).*** Multiple scans of the same gel using different color filters can then be color mapped to see the contributions of the different samples. This is useful if one has control over the experimental design when determining the reference gel, set of control gels, and experimental gels. Advances in DIGE (DeCyder™) EDA software now allow comparison of multiple images run on the same apparatus ***(26).*** However, these advances do not completely solve the problem of trying to putatively compare one's own sample against an Internet reference gel where they have identified protein spots.

A number of 2D-gel databases that contain gel images are available on the Web for various types of tissues. Proteins are identified for some of the spots in a subset of these databases. Both WORLD-2DPAGE and 2D Hunt on the http://www.expasy.org/ server can be used to find Web URL addresses for a number of 2D protein gel databases. Google searches are also used and we link to these sites in the Help menu. Many of these databases contain 2D-gel images with identified proteins. Some of these databases let you identify spots in their gels by clicking on a spot in their gel image shown in your Web browser. It then queries their Web server database to determine if the spot you pointed to is in that database and report its identity if found. These "clickable" 2D-gel map images are often published using a common federated database (DB) schema ***(28–29).*** One of the more interesting databases is SWISS-2DPAGE ***(28–31),*** accessible from the Expasy site. It has a large number of tissues with over 30 gel databases including a wide range of human tissues, mouse, *E. coli*, *aribidopsis*, *dictyostelium*, and yeast. Their site also has a series of IEF zoom fractionated gels for *E. coli*.

We have incorporated links to these SWISS-2DPAGE database gel map images so they may be loaded and accessed directly from Flicker after having putatively matched a spot in your gel with one in the SWISS-2DPAGE gels. If you have loaded one of these active map gel images in Flicker and enabled the database access, then clicking on a spot in that image will pop up a Web page as it tries to look it up the spot in the SWISS-2DPAGE database. If a SWISS-2DPAGE data entry exists for the spot coordinates you have selected, then it will report the corresponding protein or tell you it cannot be found.

By comparing one's own experimental 2D-gel image data with gel images of similar biological material from these from Internet reference databases, it opens up the possibility of using the spots in these reference gels to suggest the putative identification of apparently corresponding spots in your gels. The image analysis method described here allows scientists to more easily collaborate and compare their gel image data over the Web.

How Can We Compare Two Gels?

When two 2D gels from different laboratories are to be compared, simple techniques may not suffice. There are several methods for comparing two gel images: (1) put the images side by side and visually compare them; or (2) slide one gel (autoradiograph or stained gel) over the other while backlighted; or (3) build a 2D-gel quantitative computer database from both gels after scanning and quantitatively analyzing these gels using a 2D-gel database system; and (4) run DIGE dye multiplexing ***(25)*** to label different samples in the same gel or across gels ***(26)***. A variant of this last method is to spatially warp two gels to the same geometry and then pseudocolor them differentially. These methods may be impractical for many investigators since in the first case the physical gel or autoradiograph from another laboratory may not be locally available. The first method may work for very similar gels with only a few differences. The second method will work better for gels that are not so similar but that have local regions that are similar. The third method may be excessive if only a single visual comparison is needed because of the costs (labor and equipment) of building a multigel database solely to answer the question of whether one spot is probably the same spot in the two gels. The fourth method may also not be practical if you want to compare your sample against an existing reference gel.

The Flicker Program

We describe a computer-based image comparison technique called flicker that has been used for years in finding differences in star maps in astronomy.

The Flicker program runs on most computers. It is started as one would any program after it is downloaded from the Flicker server and installed (*see* **Method 1**). One gel image may be read from any Internet 2D-gel database (e.g., SWISS-2DPAGE, etc.), the other may reside on the investigator's Web server where they were scanned or copied, or the two gel images may be from either Web server source.

Figure 1 shows the Flicker application after it has been started with some demo gels. You interact with the program by clicking or dragging the mouse in the left or right images, adjust parameter scrollers (upper right), set interaction modes (checkboxes upper left), keyboard short-cut commands, and primarily pull-down menu commands.

Notation in This Paper

We use the notation (<*menu name*> | <*command*>) throughout this paper to indicate the these menu commands. The <m*enu name*> indicates one of the

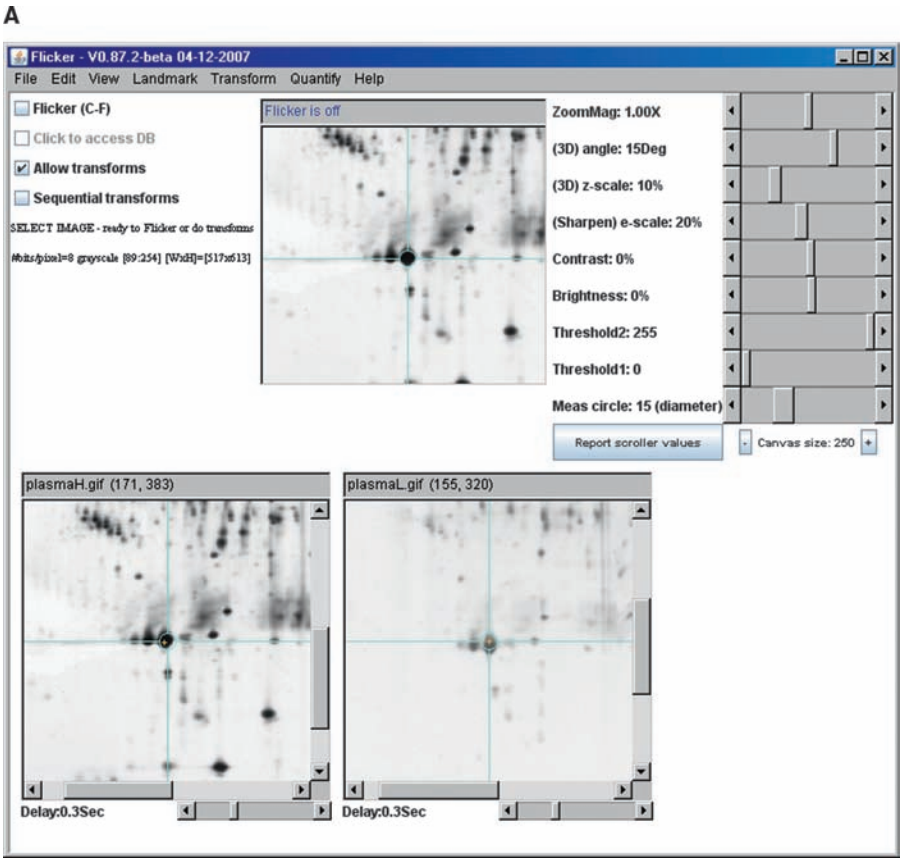

Fig. 1. Screen view of initial Flicker program. **(A)** shows the pull-down menus at the top used to invoke file operations, editing, view selection, landmarking, image transforms, spot quantification, and help. A set of scroll bars on the right determines various parameters used in some of the transforms. The File menu options include opening a new gel image. Checkboxes on the left activate flickering and active gel map access if the data supports it. A set of status lines appear below the checkboxes and indicate the state of operation and various other messages. The flicker image is in the upper middle of the frame when it is enabled. The two labeled human blood plasma gel images are shown in the bottom scrollable windows that may be positioned to the region of interest. These windows also have associated flicker time-delays used when flickering. Image *plasmaH* is an IPG non-linear gradient gel from SWISS-2DPAGE in Geneva and *plasmaL* is a carrier-ampholyte linear gradient gel from the Merril Lab at NIMH. Transformed image results are shown in the same scrollable windows. The four checkboxes are: **Flicker** (C-F) to enable/disable flickering; **Click to access DB** checkbox enables/disables access to a Web server that is associated with a clickable image DB if it exists for the selected image; **Allow transforms** checkbox enables/disables image transforms; **Sequential transforms** checkbox enables/disables using the last image transform output as input for the next image transform. The parameters used in various transforms

B

Fig. 1. (continued) are adjusted directly by first selecting an image and then adjusting its values. You can popup the scrollable report window using the **Report scroller values** button. These parameters are saved when you save the state. You can change the size of the three image windows by using the **"+"** and **"–"** buttons**. (B)** The popup scrollable report window shows a log of all text output that appears in the status lines. It may be saved to a text file on the local disk.

pull-down menus: File, Edit, View, Landmark, Transform, Quantify, Help. The <*command*> indicates one of the commands in that menu. **Table 1** summarizes the menu commands. Some of the commands have alternative keyboard shortcuts

Table 1
Summary of Commands Available in Flicker Nenu

Submenus are indicated by underlining the name of the menu and adding the '->' symbol. Checkboxes are indicated by the □ prefix to the command. Shortcuts are indicated by a (C-<key>) at the end of the command.

File menu – *to load images, load demo images, active map urls, to load/save the Flicker .flk state, update (from the server): program, DB/Flk*DB.txt database files*

  Single images -> – load single user gel image to selected image
  List user's images by directory
Open active map image -> – load active gel image from Internet(Swiss-2DPAGE)
Open recent images -> – load an image you have used recently
Assign active image URL – to one of the open images to make it active

——

Open state file – restore the Flicker state of previously saved session
Save state file – save the Flicker state in current .flk state file
SaveAs state file – save the Flicker state in new .flk state file

——

Update -> – download and update your program and data from server
  Flicker program – to get the most recent release
  Active Map Image database – get latest active maps database
  Demo Images database – get latest demo images database
  Add user's active images DB by URL

——

Save Transformed image – of selected image as .gif file if transformed
SaveAs Overlay image – the current overlay image
Reset images – to the initial state when they were loaded
Abort transform – abort any active image transforms

——

Quit – exit the program, saving the .flk state of Flicker in the process

Edit menu - *to change various defaults*

  Canvas size -> – change the size of 3 image canvases and overall Flicker window
    Increase size (C-Numpad '+') - increase the canvas size
    Decrease size (C-Numpad '–') - decrease the canvas size
  Set colors -> – set default colors for the overlays
    Target colors – to change the target color
    Trial object colors – to change the trial object color
    Landmarks colors – to change the color of landmarks
    Measurement color – to change the color of measurements
    Guard Region color – to change the color of the guard region

(continued)

——

□ Use linear else log of TIFF files > 8-bits – take log of tiff data if > 8-bits
□ Enable saving transformed images when do a 'Save(As) state'
□ Use protein DB browser, else lookup ID and name on active images

——

Auto measure, protein lookup in active server and Web page popup – set access
Select access to active DB – select protein report for active protein queries
Use SWISS-2DPAGE DB access
Use PIR UniProt DB access
Use PIR iProClass DB access
Use PIR iProLink DB access

——

Reset default view – sets all view options to the defaults
Clear all 'Recent' images entries – clears the list of recently accessed images
View menu - *to change the display overlay and popup report window options*
m Flicker images (C-F) – toggle flickering on and off
Set overlay options – select one or more image overlay options
□ View landmarks – add landmarks to the overlay display in images
□ View target – add target to the overlay display images
□ View trial object – add trial object to the overlay display images
□ View Region Of Interest (ROI) - add ROI to the overlay display images
Set measurement options – select one or more image measurement options
□ View measurement circle – add measurement circles to overlay display images
□ Use 'Circle' for measurement spot locations
□ Use '+' for measurement spot locations
□ Use 'spot number'for spot annotations – e.g., *#1, #2*, …, etc.
□ Use 'spot ID'for spot annotations – e.g., *actin, APO-A1*, etc.
Set gang options – select one or more ganged images (left and right) options
□ Multiple popups – make multiple popup windows instead of reusing one
□ Gang scroll images – move left and right images scrolling together
□ Gang zoom images – zoom left and right images scrolling together
□ Add guard region to edges of images – this allows comparing edges of images
□ Display gray values (C-G) – show gray values of cursor trial object
□ Show report popup – display the report popup window again if needed
Landmark menu - *to define landmarks for spatial image warping*
Add landmark (C-A) – add trial objects (in images) as landmark
Delete landmark (C-D) – delete the last landmark defined
Show landmarks similarity – compute a LSQ error similarity measure of the two sets of landmarks
Set 3 predefined landmarks for demo images (C-Y)
Set 6 predefined landmarks for demo images (C-Z)
Transform menu - *contains various image processing transforms for selected image(s)*
Affine Warp – warp selected image using 3 pairs of landmarks

(continued)

Pseudo 3D transform – do pseudo 3D scaling based on image intensity

——

Sharpen Gradient – gradient + gray scale sharpen selected image
Sharpen Laplacian – Laplacian + gray scale sharpen selected image
Gradient – gradient of the selected image
Laplacian – Laplacian of the selected image
Average – average selected image
Median – median of selected image
Max 3×3 - max of 3×3 neighborhood of selected image
Min 3×3 - min of 3×3 neighborhood of selected image

——

Complement – complement selected image
Threshold – threshold the selected image by gray values in (T1:T2)
Contrast Enhance – Contrast enhance selected image
Histogram equalize – histogram equalize selected image

——

Original color - Restore original data for selected image
Pseudo color - compute pseudo color scaling for selected image
Color to grayscale - compute NTSC RGB to grayscale transform for selected image (gray = red*0.33 + green*0.50 + blue*0.17)

——

Flip Image Horizontally – flip image horizontally selected image
Flip Image Vertically – flip image vertically selected image

——

Repeat last transform (C-T) - repeat last transform, if any
□ Use threshold inside (T1:T2) filter - filter by pixels inside the range (T1:T2), otherwise pixels outside of (T1:T2))

Quantify menu - *contains OD calibration, background and foreground measurements*

Measure circle -> – measure intensity/density within circle
Capture background (C-B) – background measurement at current position
Capture measurement (C-M) – report object measurement at current position
Circle size -> – define the circlular mask size by radius in m 1×1 to m 11×11 pixels subregions

——

Clear measurement – clear measurement data
Edit selected spot(s) 'id' fields from spot list(s) (C-I)
Edit selected spot(s) from spot list(s) (C-E)
Delete selected spot from spot list (C-K)

——

List spots in the spot list for selected image – list measured spots
List spots in the spot list (tab-delimited) – same but can cut& paste data
List 'id'-paired annotated mean norm. spots in both spot lists (tab-delim.)
List 'id'-paired annotated spots in both spot lists (tab-delimited)

(continued)

———

Lookup Protein Ids & Names in spot list from active map server (sel'td image)

———

Clear spot list (ask first) for selected image

Print data-window -> - print numeric pixel data around image pixel

Show data window of selected pixel (C-V)

Set print window size – either 5×5, 10×10, … or 40×40

Set print data radix – either decimal, octal, hex, or optical density

Calibrate -> - Calibrate grayscale as optical density or other units

Optical density by step wedge – set calibration by ND step wedge in gel image

Use demo Leukemia ND step wedge preloaded data – for use in demo

———

Optical density by spot list – set OD values by mean spot list measurements

Region of Interest (ROI) -> - region of interest operations

Set ROI ULHC (C-U) - define upper left hand corner of ROI

Set ROI LRHC (C-L) - define lower right hand corner of ROI

Clear (ROI) (C-W) - delete ROI

Show ROI grayscale histogram (C-H) – show grayscale histogram of ROI pixels

Capture measurement by ROI (C-R) - measure integrated density inside the computation region ROI. Use the circular mask mean background for background correction

□ Use sum density else mean density - use sum of the density else mean density within the region

□ List-of-spots else trial-spot measurement mode (C-J)

Help menu - *popup Web browser documentation on Flicker from the server*

Flicker Home – pop up Flicker home page open2Dprot.sourceforge.net/Flicker

Reference Manual – pop up the reference manual for Flicker application

How-to use controls -> – pop up the reference at particular sections

Vignettes -> – pop up short vignettes showing how-to-do tutorials

Version on the web site – show current version available on the Web site

About – show details on Flicker application

———

Book chapter on Flicker (2005) – popup 2005 PDF of book chapter

Old flicker applet documentation ->

Flicker applet home page – popup the home page for old Flicker applet

EP97 Paper – popup the Electrophoresis '97 paper Flicker applet

Poster 1 – pop up poster describing Flicker applet

Poster 2 – pop up poster describing Flicker applet

Poster 3 – pop up poster describing Flicker applet

Poster 4 – pop up poster describing Flicker applet

2D gel web resources ->

SWISS-2DPAGE – pop up SWISS-2DPAGE home page

WORLD-2DPAGE – pop up Expasy World-2DPAGE of federated gel databases

2D-HUNT – pop up Expasy's 2D-Hunt for finding gel Web sites

Google 2D search – pop up Google search for finding gel Web sites

activated by using the *Control key* with another key and are indicated as Control-<*key*> or C-<*key*> (e.g., C-A). The checkbox menu commands are indicated with a □ prefix. Checkbox commands may be toggled on and off.

The gels in the two lower left and right images are specified by the user with the FlickerFiles menu. Gel images may be loaded from: the local computer (File | Open image file), or any Internet site with GIF, JPEG, TIFF or PPX images (with .gif, .jpg, .tiff or .tif, or .ppx GELLAB-II format ***(9)*** file extensions) using the (File | Open image URL) command. In addition, the installation provides a few demonstration images (File | Open demo images) that loads pairs of comparable images. You may also specify active gel images from Web servers as described below.

When Flicker starts, it creates additional submenu entries in the (File | Open user images | Pairs of images | …) and (File | Open user images | Single images | …) submenus that are the names of the user's images they copied to the Flicker Images/ subdirectory. The user can load images using those commands.

Flicker is also capable of interacting with federated 2D-gel databases to retrieve data on individual protein spots if one of the gels is a federated gel having an associated clickable gel map database. After aligning gels in Flicker, you enable federated database access in Flicker and then click on a spot in the gel belonging to the federated database (*see* **Fig. 2**). This causes a Web page to pop up with information from the federated server describing that protein. We provide menu entries (File | Open active map image | …) to let you load one of the SWISS-2DPAGE gel images.

You may load a gel image in the lower left or right image windows. First click on the image you want to load the new image. Then select the active gel image to you want using the entry (File | Open active map image | …) pull-down menu (e.g., select (… | SWISS-2DPAGE Human | Plasma)). Next, click on the other image and then use the other gel image you want to compare it with using either (File | Open image file) or (File | Open image URL) commands.

The Flicker program is written in Java, a general purpose, object-oriented programming language developed by Sun Microsystems ***(32)*** http://java.sun.com/. Java has become a standard for portable Internet Web applications.

Most often, the original images may be compared directly. However, occasionally, the comparison may be made visually easier by first applying enhancement transforms such as spatial warping, brightness, contrast or other image transforms. Adjusting image brightness and contrast so the two gels have similar ranges will make the image fusion easier for the user when flickering. For gels with a lot of geometric distortion, it is useful to adjust the geometry of one gel so that the geometry of the local region being compared approximates that of the other gel. By local geometry, we mean the relative positions, distances, and angles of a set of spots in corresponding regions.

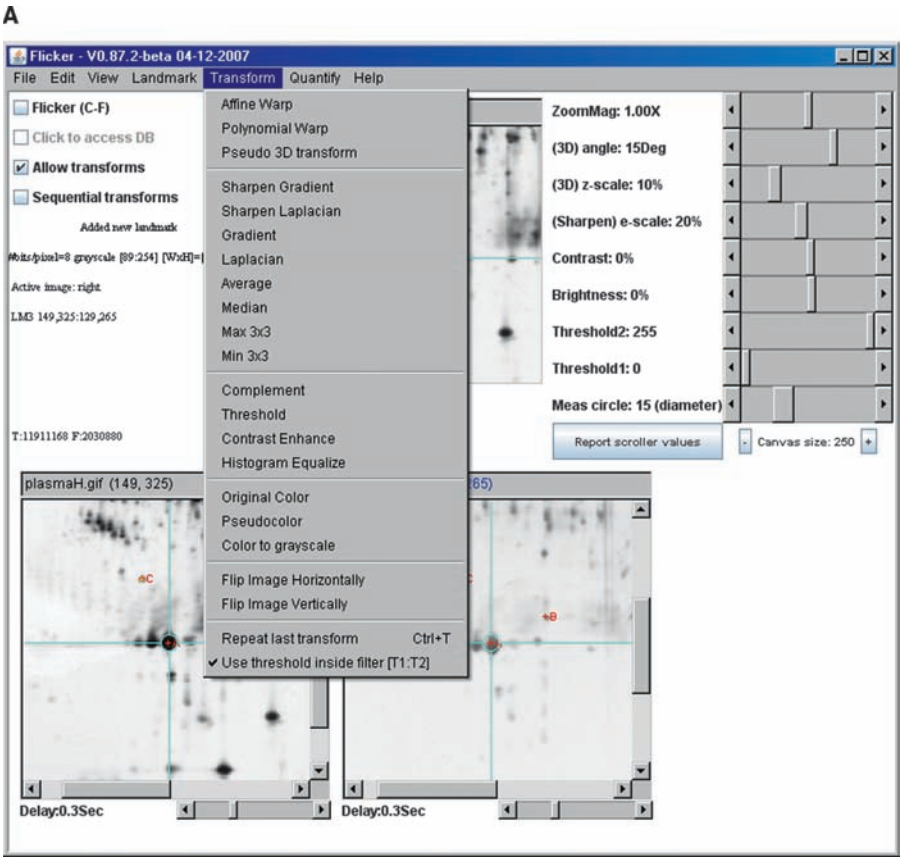

Fig. 2. Screen view of the landmarks used for the affine transform of the human plasma gel images. **(A)** The transform warps the geometry of a local region defined by the three landmarks so it more closely resembles the geometry of the corresponding local region in the other gel. Scrollable image windows with 3 "active" landmarks defined in both gel images that were selected interactively in preparation for doing the affine image transform. Corresponding landmark spots are selected so they are defined unambiguously in both gel images. For demonstration purposes, the command (Landmarks | Set 3 predefined landmarks for demo gels) will set up the 3 landmarks shown in this figure. **(B)** After defining the 3 landmarks, use the (Transform | Affine warp) command.

One technique to correct geometry differences is called spatial warping. When performing spatial warping, corresponding regions of interest are **(1)** first marked by the user (we call this "landmarking") with several corresponding points in each gel image (3 for affine warping and 6 for poly warping), and **(2)** then one of the two gel images is warped to the geometry of the other gel

B

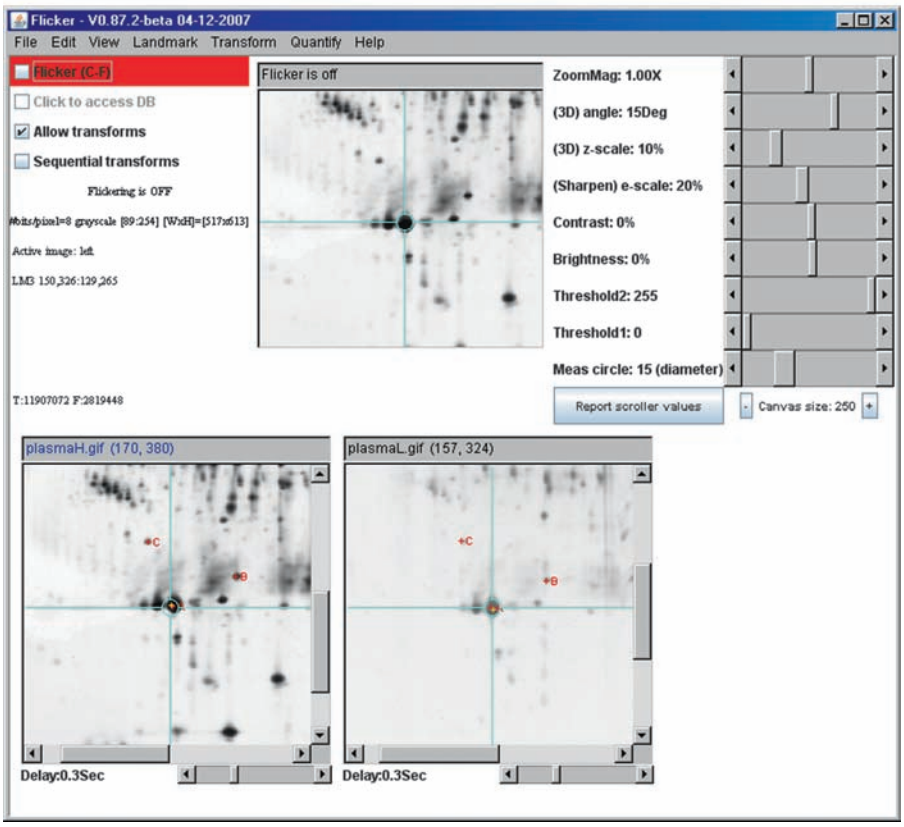

Fig. 2. (continued)

(see equations 1 and 2). A landmark is a corresponding spot that is present in both gels. Landmarks are defined by clicking on the spot to mark and selecting the (Landmark | Add Landmark (C-A)) command. The warping is performed by first selecting the image to warp by clicking on it, and then and selecting the (Transform | Affine Warp) command. Landmarking and warping are described in more detail below.

Spatial warping doesn't change the underlying grayscale values of the synthesized warped image to the extent that would cause local structural objects to appear and disappear and thus spot artifacts might be created. Instead, it samples pixels from the original image to be transformed and places them in the output image according to the geometry of the other input image. After warping is finished, gels may then be compared visually by flickering.

1.1. Image Flickering

The basic concept of using flickering as a dynamic visualization technique is simple. If two images may be perfectly aligned then one could simply align them by overlaying one over the other and shifting one image until they line up. However, many images such as 2D PAGE gels have rubber-sheet distortion (i.e., local translation, rotation, and magnification). This means there is more distortion in some parts of the image than in others. Although it is often impossible to align the two whole images at one time, they may be locally aligned piece-by-piece by matching the morphology of local regions.

If it appears that a spot and the surrounding region do match, then one has more confidence that the objects are the same. This putative visual identification is our definition of matching when doing a comparison. Full identification of protein spots requires further work such as cutting spots out of the gels and subjecting them to sequence analysis, amino-acid composition analysis, mass spectrometry, testing them with monoclonal antibodies, or other methods.

2.2. Image Enhancement

It is well-known that 2D gels often suffer from local geometric distortions making perfect overlay impossible. Therefore, making the images locally morphologically similar while preserving their grayscale data may make them easier to compare. Even when the image subregions are well aligned, it is still sometimes difficult to compare images that are quite different. Enhancing the images using various image transforms before flickering may also help. Some of these transforms involve spatial warping, which maps a local region of one image onto the geometry of the local region of another image while preserving its grayscale values. Another useful operation is contrast enhancement that helps when comparing light or dark regions by adjusting the dynamic range of image data to the dynamic range of the computer display. Other transforms include image sharpening and contrast enhancement. Image sharpening is performed using edge enhancement techniques such as adding a percentage of the gradient or Laplacian edge detection functions to the original grayscale image. The gradient and Laplacian have higher values at the edges of objects. In all cases, the transformed image replaces the image previously displayed. Other functionality is available in Flicker and is described in the **Methods** and **Notes** subheadings of this chapter, **Table 1,** and on the Web server.

1.3. Image Processing Transforms

As mentioned, there are a number of different image transforms that may be invoked from the Transform menu. You may display the transformed image, use it as input to another transform, or save it as a .gif file on your local computer. When you save the state, you may also save the transformed images.

1.3.1. Affine Spatial Warping Transform

The spatial warping transforms require defining several corresponding landmarks in both gels. As we mentioned, one gel image can be morphologically transformed to the geometry of the other using the affine or other spatial warping transformations. These transforms map the selected image to the geometry of the other image. It does not interpolate the gray scale values of pixels – just their position in the transformed image. As described in **(1–2, 4–6),** this might be useful for comparing gels that have some minor distortion, comparing local regions, gels of different sizes or gels run under slightly different conditions. Flicker uses the affine transform as an inverse mapping as described in ***(33).*** Let $(u_{xy}, v_{xy}) = f(x,y)$, where (x,y) are in the output image, and corresponding (u,v) are in the input image. Then, in a raster sweep through the output image, pixels are copied from the input image to the output image. The affine transformation is given in **Eqs. 1–2:**

$$u_{xy} = ax + by + c \tag{1}$$

$$v_{xy} = dx + ey + f \tag{2}$$

When the affine transform is invoked, Flicker solves the system of 6 linear equations for coefficients (a,b,c,d,e,f) using three corresponding landmarks in each gel.

1.3.2. Pseudo-3-D Transform

As described in **(1–2, 4–6),** the Pseudo-3-D transform is a forward mapping that generates a pseudo 3-D relief image to enhance overlapping spots with smaller spots seen as side peaks. The gel size is width by height pixels. The gray value determines the amount of y shift scaled by a percentage z_{scale} (in the range of 0 to 50%). Pseudo perspective is created by rotating the image to the right (left) by angle theta (in the range of –45 to +45 degrees). The transform is given in **Eqs. 3–5** for image of size width X height, shift in the horizontal dimension computed as d_x.

$$d_x = \text{width} \sin(\theta) \tag{3}$$

$$x' = (d_x \text{ (hight - y)/hight}) + x \tag{4}$$

$$y' = y\text{-}z_{scale} * g(x,y) \tag{5}$$

where $g(x,y)$ is in the original input image and (x',y') is the corresponding position in the output mapped image. Pixels outside of the image are clipped to white.

The Pseudo-3-D transform is applied to both images so that one can flicker the transformed image.

1.3.3. Edge Sharpening

Edge sharpening may be useful for sharpening the edges of fuzzy spots. The sharpened image function g´ *(x,y)* is computed by adding a percentage of a 2-dimensional edge function of the image to original image data *g(x,y)* as shown in equation **(6).** The edge function increases at edges of objects in the original image and is computed on a pixel by pixel basis. Typical "edge" functions include the 8-neighbor gradient and Laplacian functions that are described in **(1–2, 4–6)** in more detail. The e_{scale} value (in the range of 0 to 50%) is used to scale the amount of edge detection value added.

$$g'(x,y) = (e_{\text{scale}} * \text{edge}(x,y) + (100 - e_{scale}) * g(x,y))/100. \quad (6)$$

2. Materials

The following lists all items necessary for carrying out the technique. Since it is a computer technique, the materials consist of computer hardware, software and an Internet connection. We assume the user has some familiarity with computers and the World Wide Web.

1. A Windows PC, MacIntosh with MacOS-X, a Linux computer or a Sun Solaris computer having a display of at least 1024 × 768 resolution. At least 30 Mb of memory is required and more is desirable for comparing large images or performing many transforms. If there is not enough memory, it will be unable to load the images, the transforms may crash the program or other problems may occur. An Internet connection is required to download the program from the http://open2Dprot.sourceforge.net/Flicker Web site (*see* **Note 1**). New versions of the program will become available on this Web site and can be uploaded to your computer using the various Update commands described in the Notes section or from the Downloads Web page. If you will be using the active gel image maps associated with federated 2D-gel databases, then you *will* need the Internet connection for accessing those (e.g., SWISS-2DPAGE) databases. You do *not* need the Internet for local image comparisons.
2. You should have Java (JDK or JRE version 1.5.0 or later) installed already on your computer. If you do not, you can download it from java.sun.com for free and install it yourself.
3. When you install Flicker, it creates several subdirectories: *Images/* (containing the demonstration images), *DB/* (containing startup database files), and *FlkStartups/* (containing any startup files you create when you do a (File | SaveAs state file). The DB/ files are: *FlkDemoDB.txt* which describes the demo images, *FlkMapDB.txt* which describes the gel images and their corresponding active image map URLs, and

FlkRecentDB.txt which lists recently accessed images. An empty database file *FlkRecentDB.txt* contains the file names and active gel map URLs, if any, of the recently accessed images. The program is in *Flicker.jar* is the Java Archive File for Flicker that is executed when you run Flicker. It also uses *jai_core.jar*, the core Java runtime from SUN's Java Advanced Imaging (JAI at java.sun.com) and *jai_codec.jar* that is the JAI tiff file reader from SUN's Java Advanced Imaging JAI at reader. For Windows users, there is a Flicker.exe file that you can click on to run the program. Otherwise, there are two script files *Flicker-startup.bat* (for Windows) and *Flicker-startup.sh* for Unix/Linux or Mac OS-X that run it through the Java interpreter.

4. The Internet is a good source of 2D-gel images. You can find them by searching WORLD-2DPAGE and 2D Hunt on the http://www.expasy.org/ server or a Google search to find other Web 2D protein gel image databases. Links to these databases are available in the (Help | 2D gel Web resources) submenu.
5. We currently distribute Flicker so that it uses up to 96 megabytes of memory. If you want to run it with more or less memory, you will need to edit the startup files *Flicker-startup.bat* or *Flicker-startup.sh* you use to set it to a value in the range of 30 Mb to 1784 Mb. Both of these startup files contain the command

   java -Xmx96M -jar Flicker.jar

   So to increase the startup memory, change the 96 M to some larger value (e.g., to increase it to 500 megabytes, change -Xmx96M to –Xmx500M).

3. Method

We now describe the operation of the Flicker from the user's point of view. You first install Flicker. Then run it with either the demonstration images, your own images or images from the Internet. Then you simply flicker the gel images. If necessary, to improve the image comparability, use image enhancement transforms first before then flickering the two images.

3.1. Installing Flicker from the Web Server

Click on the *Download* link on the http://open2Dprot.sourceforge.net/Flicker Web site. The following method can be used to download the Zipped Flicker-dist installation package and install it as described below.

Go to the Web site's *Files mirror* under the Flicker releases. Look for the most recent release named "*Flicker-V.XX.XX-dist.zip*" such as *Flicker-V0.87.2-dist.zip*. These zipped files include the program, required jar libraries, demo data, and Windows batch and Unix shell scripts. Download the zip file and put the contents where you want to install the program. Note that there is a *Flicker.exe* for Windows (created with launch4j.sourceforge.net). You might make a short-cut to this file to make it easier to find when starting the program. Alternatively, you can use the sample *Flicker-startup.bat* or *Flicker-startup.sh* scripts to run the program explicitly via the java interpreter. Note that this method assumes that you have Java installed on your computer and that it is at *least* JDK (Java Development

Kit) or JRE (Java Runtime Environment) version 1.5.0. If you don't have this, you can download the latest version free from the java.sun.com Website.

The following is a short procedure that summarizes the procedure for downloading and installing Flicker.

1. In the Table of Contents on the left on the home page, click on "Files mirror" under "Source Code".
2. Under latest file releases, where it has the header "Package", click on the "open2Dprot" below that.
3. This will refresh the page and if you scroll down, it will show "Flicker files".
4. Select the "+" on this to list the files. Pick the one with the highest version number called something like *Flicker-V0.87.2-dist.zip* file.
5. Click on that to download it.
6. Put it where you want to install it and unpack it. There is a *Flicker.exe* file (for Windows) as well as .bat and .sh file scripts.
7. If you have images to compare, you can copy them or subfolders of images into the Image folder in the distribution directory.

To start Flicker in Windows, click on the startup icon for *Flicker.exe*. You can also start it in Windows by clicking on the *Flicker-startup.bat* file. For Unix systems including MacOS-X, you can start Flicker from a command line file by specifying the path to *Flicker-startup.sh*. Normally it comes up with the two demonstration human plasma 2D-gel images (*plasmaH.gif* - an IPG gel from SWISS-2DPAGE on the left) and (*plasmaL.gif* – a carrier ampholyte gel from Dr. Carl Merril/NIMH on the right).

If you have your own gels (JPEG, GIF or TIFF formats), you can try loading them. But first you must copy the files or folders of files to the *Images/* folder where you installed Flicker. Then use the (File | Open user images | …) commands to load the images. There is currently no way to load images stored in a relational database. You may want to limit resolution by first decreasing their size using an image editing program like Adobe PhotoShop, shareware program ThumbsPlus (www.cerious.org), or open source programs like Gimp (www.gimp.org). Large very high-resolution images that are 20 Mb to 40 Mb will not work well. We suggest reducing the size to about 1 K×1 K for good interactivity if you have any problems with running out of memory or very sluggish response. These image-editing programs can also be used for converting other formats to JPEG, GIF or TIFF formats that Flicker can read.

3.2. Graphical User Interface for Flickering

Fig. 1 shows the initial screen of the Flicker program. Pull-down menus at the top invoke file operations, edit preferences, view overlay options, landmarking, image transforms, and help commands. Scroll bars on the side determine various parameters used in the transforms. The two images to be compared are

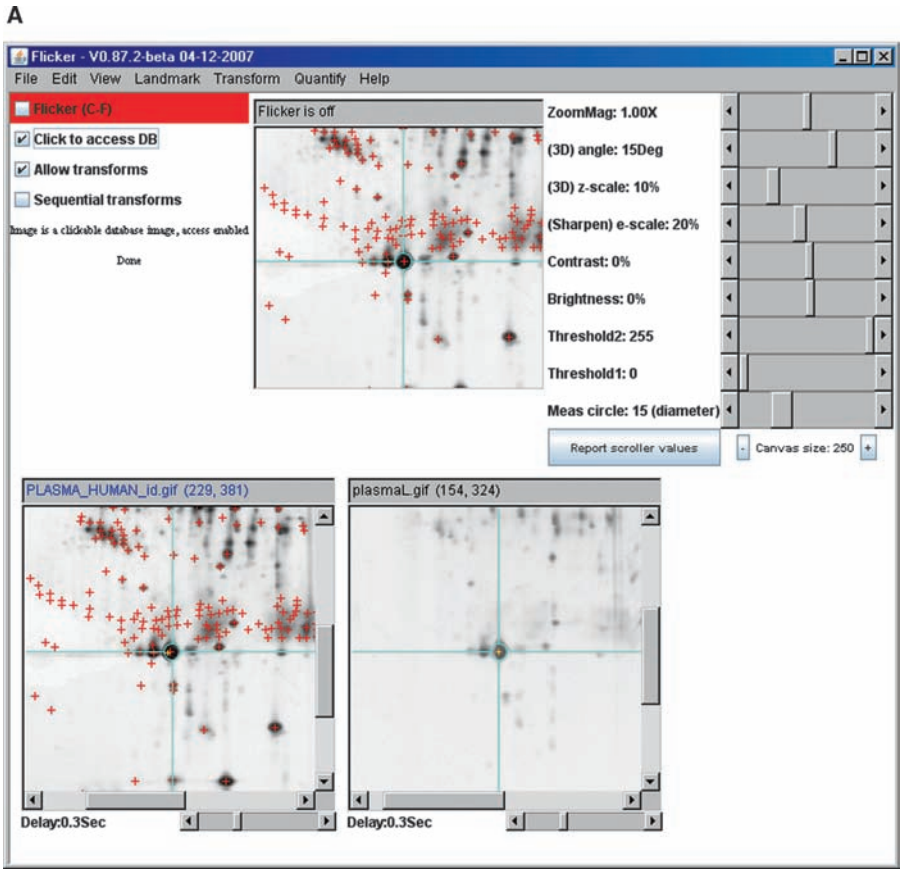

Fig. 3. Screen views of clickable active gel compared with another gel. **(A)** We have loaded the active SWISS-2DPAGE human plasma gel (*PLASMA_HUMAN_id*) in the left image and the *plasmaL* gel in the right image. Spots that appear in SWISS-2DPAGE are indicated with red "+" symbols. We then aligned the images using flickering. We then selected the **Click to access DB** checkbox. Finally, we clicked on the indicated spot in the left gel to determine the putative identification of the corresponding spot in the right gel. **(B)** The SWISS-2DPAGE window then popped up as a result of clicking on that spot in the left image and indicates the putative protein identification of the visually corresponding spot in the right gel. The *plasmaH* image is the same gel as *PLASMA_HUMAN_id* but without the graphic overlays. You can load these same gels using the (File | Open demo images | Human Plasma gels | (SWISS-2DPAGE vs Merril) - clickable) command, which should be used when you are connected to the Internet.

loaded into the lower scrollable windows. A flicker window appears in the upper middle of the screen. Checkboxes on the left activate flickering and control display options. A group of status lines below the checkboxes indicate the state

B

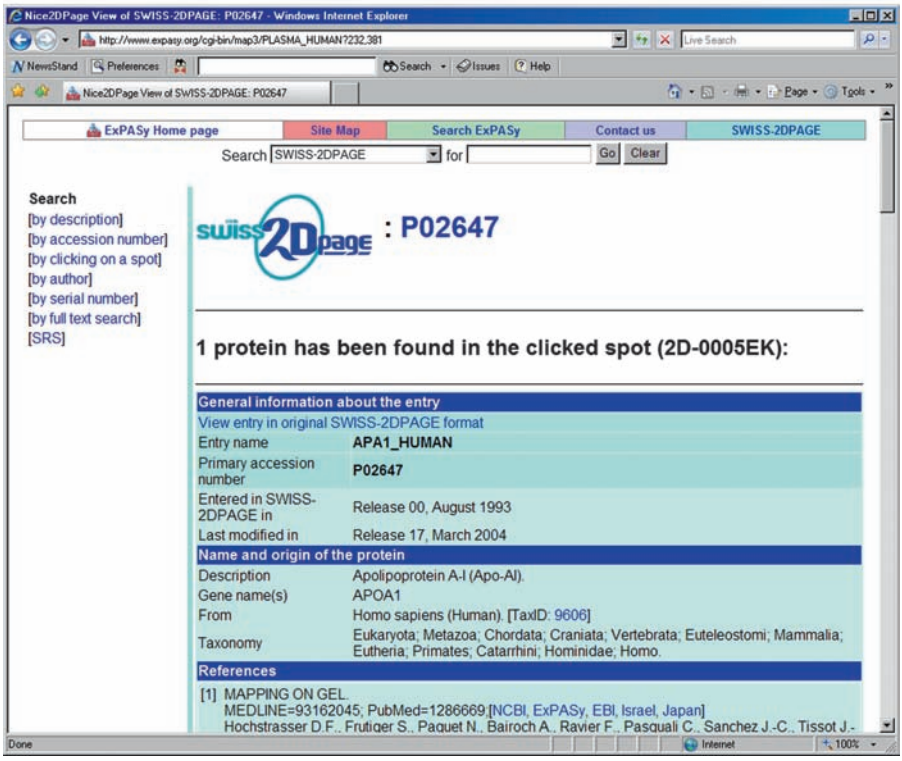

Fig. 3. (continued)

of operations. **Table 1** shows the summary of the commands in the pull-down menus.

Only part of an image is visible in the scrollable windows. These subregions are determined by setting horizontal and vertical scroll bars. Another, preferred, method of navigating the scrollable images is to click on the point of interest while the CONTROL key is pressed. This will re-center the scrollable image around that point. This lets the user view any subregion of the image at high resolution. These images may be navigated using either the scroll bars or by moving the mouse with the button pressed in the scrollable image window. Then, each image in the flicker window is centered at the point last indicated in the corresponding scrollable image window.

Note that if you are near the edge of the image when you do this, it will may not scroll the image properly. To fix this problem you can add a "guard region" around the edge of the image using the (View | □ Add guard region to edges of images). This is useful for aligning spots that are along the edge of the images while flickering.

The guard region's color can be changed via the Edit menu (Edit | Set colors | Guard region color). The guard region requires more memory that is why the default is to have the guard region default to off.

A flicker window is activated in the upper-middle of the screen when the "Flicker" checkbox is selected. Images from the left and right scrollable images are alternatively displayed in the flicker window. The flicker delay for each image is determined by the adjusting the scroll bar below the corresponding scrollable image window. Various graphic overlays may be turned on and off using the various view "overlays" selected in the (View | <sub-menus> …) checkbox menu commands.

Clicking on either the left or right image selects it as the image to use in the next transform. However, clicking on the flicker image window indicates the next transform you might use should be applied to *both* left and right images. You can change the selected image by just clicking on any of the images.

You can increase or decrease the size of the three image windows by using the (Edit | Canvas size | Increase size (C-keypad '+')) and (Edit | Canvas size | decrease size (C-keypad '–')) commands. This will resize the main window accordingly. Alternatively, and easier to do, is to click on either the left-arrow (shrink) or right-arrow (enlarge) buttons on the **Canvas size** scroller on the middle right edge of the Flicker application window.

3.3. Loading Images

As mentioned in the introduction, gel images may be loaded into the left or right selected image from: (a) the local computer using the (File | Open image file) command or (b) any Internet site using the (File | Open image URL) command. You may load pairs of demonstration images that come with Flicker, and are installed in the *Images/* directory. Use the (File | Open demo images | …) command to load them into the left and right images. The demos include a few samples that may be useful for initially learning the system. They include: two human plasma gels - an IPG SWISS-2DPAGE gel vs a carrier ampholyte gel (Merril/NIMH); some human leukemias (AML, ALL, CLL, HCL) from Lester et.al. ***(10–11).***

You may specify active gel images from the Web using the (File | Open active map image | **…**) to let you load one of the Swiss-2DPAGE gel images into the left or right selected image. This list of active images is defined by the tab-delimited *FlkMapDB.txt* file read by Flicker when it is started. "Power users" could edit this file (use Excel and save as tab-delimited) to add active map entries pointing to other federated 2D-gel Web databases. The *FlkMapDB.txt* file is provided with your download installation in the *DB/* directory.

Gel images are loaded into the lower left or right images. First click on the left or right image you want to replace. Then, select the active gel image to you want using the entry (File | Open active map image | …) pull-down menu (e.g., select (… | SWISS-2DPAGE Human | Human Plasma)). Next, click on the other image

and then open the other gel image you want to compare it with using either (File | Open image file) or either (File | Open image URL) commands.

3.4. Adding Your Own Image Data to the User Images/Database

There is another way for users to add many of their gel images without editing the *DB/FlkDemoDB.txt* file. When you place your image data directories in the *Images/* directory, Flicker will discover them when it starts and add them to the demo menu. It works as follows:

1. You copy or move one or more of your directories of with the images you want to use with Flicker in the *Images/* folder.
2. When Flicker starts, it creates additional submenu entries in the (File | Open user images | Pairs of images | …) and (File | Open user images | Single images | …) submenus that are the names of the user's directories.
3. The first submenu contains unique combinations of pairs of all images within each of the user's directories. Selecting one of these entries will load the pair of images into the left and right Flicker image windows.
4. The second menu command lets you select the right or left Flicker image, and then load a single image from any of the user image directories into that Flicker image window. This would be useful if you wanted to compare one of your images with one of the Internet reference gels.

3.4.1. Flickering

When flickering two images with the computer, one aligns putative corresponding subregions of the two rapidly alternating images. The flicker window overlays the same space on the screen with the two images and is aligned by interactively moving one image relative to the other using the cursor in either or both of the lower images. Using the mouse, the user initially selects what they suspect is the same prominent spot or object in similar morphologic regions in the two gel images. The images are then centered in the flicker window at these spots. When these two local regions come into alignment, they appear to pulse and the images fuse together. At this point, differences are more apparent and it is fairly easy to see which spots or objects correspond, which are different, and how they differ. We have found that the user should be positioned fairly close to the flicker window on the screen to optimize this image-fusion effect (i.e., it does not work as well standing back more than a few feet from the screen).

3.4.2. Selecting the Proper Time Delays When Flickering

The proper flicker delays, or time each image is displayed on the screen, is critical for the optimal visual integration of image differences. We have also found that optimal flicker rates are dependent on a wide variety of factors including: amount of distortion, similarity of corresponding subregions,

complexity and contrast of each image, individual viewer differences, phosphor decay-time of the display, ambient light, distance from the display, and so on. We have found the process of flickering images is easier for some people than for others.

When comparing a light spot in one gel with the putative paired darker spot in the other gel one may want to linger longer on the lighter spot to make a more positive identification. Because of this, we give the user the ability to set the display times independently for the two images (typically in the range of 0.01 second to 1.0 second with a default of 0.30 second) using separate Delay scroll bars located under each image. If the regions are complex and have a lot of variation, longer display times may be useful for both images. Differential flicker delays with a longer delay for the light gel are useful for comparing light and dark sample gels. This lets you stare at the lighter spots to have more verification that they are actually there.

3.5. Image Processing Methods

As mentioned, there are a number of different image transforms that may be invoked from the menus. These are useful for changing the geometry, sharpness, or contrast making it easier to compare potentially corresponding regions. As we go through the transforms we will indicate how they may be used. Some affect one image while some affect both. Flickering is deactivated during image transforms to use most computational power for doing the transforms.

The TRANSFORM menu has a number of commands that include warping, grayscale transforms and contrast functions. The two warp method selections: "Affine Warp and "Poly Warp" are performed on only one image (the last one selected by clicking on an image). The "Pseudo-3-D" transform makes a 3-D image with the "peaks" created proportional to gray level. Unlike the warp transforms, the grayscale transforms are performed on both images. These include: "SharpenGradient", "SharpenLaplacian", "Gradient", "Laplacian", "Average", "Median", "Max3×3" and "Min3×3". The contrast functions are "Complement" and "ContrastEnhance". You can transform image color images to grayscale using the "Color to grayscale" command, and generate a false color image from a grayscale using the "Pseudo color" command. You can flip the image using "Flip image horizontally" or "Flip image vertically" commands.

3.5.1. Landmarks: Trial and Active

The affine transform requires that three active landmarks be defined before it can be invoked. A trial landmark is defined by clicking on an object's center anywhere in a scrollable image window. This landmark would generally be placed on a spot. Clicking on a spot with or without the CONTROL key pressed still defines it as a trial landmark. After defining the trial landmark in both the

left and right windows, selecting the (Landmark | Add Landmark (C-A)) command to define them as the next active landmark pair and identifies them with a red letter label (+A, +B, +C, …) in the two scrollable image windows. The (Landmark | Delete Landmark (C-D)) command is used for deleting the last landmark you defined.

3.5.2. The Affine Transform for Spatial Warping

The two warping transforms, affine (see **Eqs. 1** and **2**) and polynomial, require 3 and 6 landmarks respectively. Attempting to run the transform with insufficient landmarks will cause Flicker to notify you that additional landmarks are required. The image to be transformed is the one last selected. You must select either the left or right image. **Fig. 2a** shows the landmarks the user defined in the two gels before the affine transform. **Fig. 2b** shows the transformed image. Then, recenter the transformed image before you flicker. After the transform, the landmarks can be lined up perfectly, and adjacent spots will line up better.

3.5.3. Pseudo-3-D transform

As described in **(1–2, 4–6)** and as shown in **Eqs. 3–5,** the Pseudo-3-D transform generates a pseudo 3D relief image to enhance overlapping spots with smaller spots seen as side peaks. The gray value determines the amount of "*y*" shift scaled by a percentage (set by scroll bar z_{scale} (in the range of 0 to 50%). Pseudo perspective is created by shifting the image to the right or left by setting by scroll bar "angle" degrees (in the range of −45 to +45 degrees). Negative angles shift it to the right and positive angles to the left. The image to be transformed is the one last selected. If neither was selected (i.e., you clicked on the flicker window), then both images are transformed.

3.5.4. Edge Sharpening

Edge sharpening may be useful for improving the visibility of the edges of fuzzy spots. You can select either a Gradient or Laplacian edge sharpening function using the "SharpenGradient" or "SharpenLaplacian" operation in the TRANSFORM menu where the image to be transformed is the one last selected. The Laplacian filter generates a "softer" edge than the Gradient. You can set the scroll bar e_{scale} value (in the range of 0 to 50%) to scale the amount of edge detection value added. The image to be transformed is the one last selected. If neither was selected (i.e., you clicked on the flicker window), then both images are transformed.

3.5.5. Putative Identification of a Spot in One Gel by Comparison with Federated Database Gel Map

Open an active gel image in the lower left or right window. First click on the window you want to load the new image. Then, select the active gel image to

you want using the entry (File | Open active map image | …) pull-down menu (e.g., select (… | SWISS-2DPAGE Human | Plasma)). Next, click on the other image and then use the other gel image you want to compare it with using one of the other (File | Open …) commands

At this point flicker the two images so that you can make a putative guess on which spot you are interested in your gel corresponds to which spot in the active map gel. Then shut off flickering by turning off the "Flicker" checkbox. Then turn on the "Click to access DB" checkbox. Then click on the spot in the active map image which will pop up a Web browser window indicating the SWISS-2DPAGE web page for that spot if it is in their database.

4. NOTES

1. Status of the Flicker application.

As of the time of the submission of this chapter, most of the functionality available in the former Java applet (1–2, 4–6) is fully functional in the stand-alone application. The current state of Flicker is documented on the Web server. A future release of Flicker will contain a spot quantification capability with the ability to calibrate the image (either from the calibration information in the image itself if available, or from a scanned neutral density step wedge scanned with the image), estimate background density, and estimate spot intensity with a background subtraction. Documentation is available on the Web site. This documentation may also be invoked from the "Help" submenus.

The original Flicker program was converted from a Java applet to a Java application by Peter Lemkin and Greg Thornwall with help from Jai Evans. Code was added from the open source MicroArray Explorer (http://maexplorer.sourceforge.net/) program. The new Flicker program uses the Mozilla 1.1 open source license and is available on the open source Web server http://open2Dprot.sourceforge.net/Flicker/.

You can update your program and data files using the various Update options in the Files menu. The (File | Update | Update Flicker Program) command downloads and installs the latest *Flicker.jar* file. The (File | Update | Update active Web maps DB) command downloads and installs the latest active Web maps database *DB/FlkMapDB.txt* file. The (File | Update | Update Demo images DB) command downloads the latest demo images into the *Images/* directory.

2. Hints on measuring spots.

There are some disadvantages in comparing gels visually. It is useful for doing a rough comparison and there is currently no simple way available to do adequate quantitative comparison (as can be done with existing 2D-gel computer database systems) that use automatic spot segmentation and global normalization methods. However, you can look at the gray value of the cursor in

the left or right image if you enable the (View | μ Display gray values in image title (C-G)) menu option. The program also allows single-spot quantification with optical density calibration. These limitations should be kept in mind when using the technique.

In the mean time, if your gels and scanner are reasonably linear so that grayscale approximates protein concentration, you can use the simple grayscale method that can be used for the ballpark estimates of density. You can do this either of two ways: by measuring the area under a circular mask (you can set the radius), or the area inside a rectangular Region of Interest (ROI). Note that unless the spot fits well inside of the mask or ROI, you will not get a very accurate measurement. Both methods can subtract an optional background value you can capture and so can give intensity corrected for background if defined.

To set the measurement circle region size (1×1, 3×3, 5×5 …, or 11×11), select the image you will work on and the adjust the Meas Circle slider on the right.. Click on a background region near where you want to measure a spot's density within a circular mask. Then select the (Quantify | Measure by circle | Capture background (C-B)) command. Then click on the center of the spot you want to estimate and select the (Quantify | Measure by circle | Capture measurement (C-M)) command. This will compute and display background corrected data that appears in the report window as:

```
plasmaH.gif (201,392) totBkgrd: 1557gray, meanBkgrd: 21 gray
CircleMask: 5X5 area: 73 pixels
(1) plasmaH.gif (214,376)
        Tot(Meas-Bkgrd):    9418.000   gra
        TotMeas: 10975.000 (39.000:227.000) gray
        TotBkgrd: 1557.000 (201,392) (16.000:28.000) gray
        mnDens: 154.577, mn(Dens-Bkgrd): 132.648, mnBkgrd: 21.930 gray
        CircleMask: 5X5 area: 73 pixels
```

The (View | Set measurement view options | □ View measurement circle) displays the background and foreground measurement circles if enabled with "**B**" and "**M**" labels. Set the (View | □ Use sum density else mean density) menu option to specify that it report either total region density or mean density.

You also can measure intensity inside a rectangular ROI regions you set by using both the (Quantify | Region of Interest (ROI) | Set ROI ULHC (C-U)) and the (Quantify | Region of Interest (ROI) | Set ROI LRHC (C-L)) commands. Use the (View | □ View Region Of Interest (ROI)) to display the ROI as a rectangle from the ULHC to the LRHC (upper left-hand corner and lower right-hand corner). You can measure the integrated density of the (Quantify | Region of Interest (ROI) | Capture measurement by ROI (C-R)) command. If you set it, the (C-R) command will subtract the background computed by the area times the mean background using the (Quantify | Measure by circle | Capture background (C-B)) command.

This will compute and display background corrected data that appears in the report window as:

```
Setting ULHC (163,370) of ROI: left image
Setting LRHC (181,389) of ROI: left image
(1) plasmaH.gif (181,389) Tot(Meas-Bkgrd): 44989.309 gray
      TotMeas:   49271.000   (13.000:238.000)
      TotBkgrd: 4281.690 at (133,429) (9.000:20.000) gray
      ROI:   (163:181,  370:389)
```

When grayscale calibration is added in a future version, then the measurements will be in terms of the calibration rather than grayscale.

The intent of applying image transforms is to make it easier to compare regions having similar local morphologies but with some different objects within these regions. Image warping prior to flickering is intended to spatially warp and rescale one image to the geometric "shape" of the other image so that we can compare them at the same scale. This should help make flickering of some local regions on quite different gels somewhat easier. Of the two warping transforms, affine and polynomial, the latter method handles nonlinearities better. For those cases where the gels are similar, the user may be able to get away with using the simpler (affine) transform. For demonstration purposes, if you are using the demo *plasmaH* and *plasmaL* gels, the (Landmark | Set 3 predefined landmarks for demo gels (C-Y)) and (Landmark | Set 6 predefined landmarks for demo gels (C-Z)) define 3 and 6 corresponding landmarks for these gels that may be used with the affine and polynomial warping transforms respectively.

In cases where there is a major difference in the darkness or lightness of gels, or where one gel has a dark spot and the other a very faint corresponding spot, it may be difficult to visualize the light spot. By differentially setting the flicker display-time delays, the user can concentrate on the light spot using the brief flash of the dark spot to indicate where they should look for the light spot. We have found differential-flicker to be very helpful for deciding difficult cases. Adjusting one image so that its brightness and contrast are approximately that of the other image also helps when flickering. You change the image brightness and contrast using the Shift/Drag mouse control described below.

3. Additional hints on image transforms.

Other transforms including image sharpening may be useful in cases where spots are very fuzzy, as might be the case when comparing Southern blots. When two corresponding local regions of the two images are radically different so the local morphologies are not even slightly similar (e.g., when high MW regions of

gels that are run differently such as: IPG vs. non-IPG, gradient vs. nongradient SDS), then even using these transforms may not help that much.

4. Saving and restoring the Flicker state.

Flicker gives you the option of saving the current state of your session including the images your are looking at and the parameter values of the sliders, etc. To save the current state, use the (File | Save (or SaveAs) state file) command. This creates a file with a .flk file extension in the installation *FlkStartups/* folder (default *FlkStartup.flk)*. If you have used the Flicker Web site Java installer (ZeroG.com) for installing Flicker, then it lets you click on a specific *.flk* you have previously saved to restart it where you left off. While running Flicker, you can also use (File | Open state file) command to change it to another state.

5. Mouse control of images.

The following mouse and key-modified mouse operations control various actions.

Pressing the mouse in either the left or right image selects it. If flickering is active, then it will move the flicker image center for the selected image to that position. A little yellow "+" indicates the position you have selected. If the **Click to access DB** checkbox is enabled and the image has an associated active map database server associated with it, then it will request the spot identify when you click on a spot from the map database..

Dragging the mouse is similar to pressing it. However, only pressing it will invoke a clickable database. It also displays the cursor coordinates in the image title.

Control/Press will position the selected image so that the point you have clicked on will be in the center of the crosshairs. If you are near the edge of the image, it will ignore this request.

Shift/Drag activates the brightness/contrast filter with minimum brightness and contrast in the lower left hand corner.

6. Checkbox control of flickering and database access.

There are four checkboxes in the upper left part of the window that control commonly used options.

Flicker checkbox enables/disables flickering.

Click to access DB checkbox enables/disables access to a Web database server that is associated with a clickable image - if it exists for the selected image. Turning on this option will disable flickering.

Allow transforms checkbox enables/disables image transforms.

Sequential transforms checkbox enables/disables using the last image transform output as input for the next image transform (image composition) if **Allow transforms** is enabled.

7. Keyboard shortcut controls

There are several short-cut key combinations that can be use to perform operations instead of selecting the command from the pull-down menus. The notation **C-<***key***>** means to hold the Control key and then press the following <*key*>.

C-A add landmark (you must have selected both left and right image trial objects) (see Landmark menu)

C-B capture background intensity value for current image under a circular mask (see Quantify menu)

C-D delete landmark - the last landmark defined (see Landmark menu)

C-E edit selected measured spot (click on spot to select it) (see Quantify menu)

C-F toggle flickering the lower left and right images into the upper flicker window (see View menu or the ☑**Flicker (C-F)**)

C-G toggle displaying gray values in the left and right image titles as move the cursor (see View menu)

C-H show grayscale ROI histogram. Popup a histogram of the computation region ROI (see Quantify menu)

C-I define or edit selected measured spot(s) annotation 'id' field (see Quantify menu)

C-J toggle the spot measurement mode between list-of-spots measurement mode and the single spot trial-spot measurement mode (see Quantify menu)

C-K delete selected measured spot (click on spot to select it (see Quantify menu)

C-L define the lower right hand corner (LRHC) of the region of interest (ROI) and assign that to the computing window (see Quantify menu)

C-M measure and show intensity under a circular mask for current image. Report background-corrected value if background was defined (see C-B shortcut and Quantify menu). An alternative way to measure spots is to hold the **ALT-key** when you press the mouse to select the spot. This combines spot selection and measurement in one operation.

C-R measure and show intensity under a the computing window defined by the ROI (see commands (**C-U**) and (**C-L**)) for the current image. Report background-corrected value if circular mask background was defined (see (**C-B**) shortcut and Quantify menu)

C-T repeat the last Transform used, if one was previously performed else no-op (see Transform menu)

C-U define the upper left hand corner (ULHC) of the region of interest (ROI) and assign that to the computing window (see Quantify menu)

C-V show data-window of selected pixel in the popup report window.

C-W clear the region of interest (ROI) and computing window (see Quantify menu)

C-Y set 3 predefined landmarks for demo gels for Affine transform (see Landmark menu)

C-Z set 6 predefined landmarks for demo gels for Polywarp transform (see Landmark menu)

C-Keypad "+" increase the canvas size for all three images (see Edit menu)

C-Keypad "-" decrease the canvas size for all three images (see Edit menu)

8. Reporting the status in the popup status window.

Information is display in several places in Flicker.

a. There are two status lines in the upper left part of the main window. The output into these status lines is also appended to the Report window (c).
b. The selected image (clicking on the left or right image) changes its title to blue from black. If neither image is selected, then both titles are black.
c. A report popup window is created when Flicker is started. It may be temporarily removed by closing it. You can get it back at any time by selecting (View | Show report popup). All text output is appended to this window. The Clear button clears all text. The SaveAs button lets you save the text in the window into a local text file.

9. Sliders for defining parameters.

The following sliders are in the upper right part of the window and are used for adjusting parameters in the various image transforms.

ZoomMag (X) to zoom both left and right images from 1/10X to 10X by a transform

(3D) angle (degrees) used in the pseudo 3D transform

(3D) z-Scale (%)used in the pseudo 3D transform

(Sharpen) e-Scale(%) used in the sharpening transforms

Contrast (%) set by Shift/Drag to change the image contrast

Brightness (%) set by Shift/Drag to change the image brightness

Threshold1 (grayscale or od) is the minimum grayscale value to show pixels otherwise they are shown as whites

Threshold2 (grayscale or od) is the maximum grayscale value to show pixels otherwise they are shown as white

Meas circle (diameter in pixels) size of the measurement circle for selected image

10. Local database files.

When Flicker is installed, several tab-delimited (spreadsheet derived) *.txt* files are available in the ***DB/*** directory (located where the *Flicker.jar* file is installed). These *DB/Flk*DB.txt* files are read on startup and are used to setup the (**File | Open … image | …**) menu trees.

DB/FlkMapDB.txt - contains instances of Web-based active image maps with fields: (*MenuName, ClickableURL, ImageURL, BaseURL, DatabaseName*)

DB/FlkDemoDB.txt - contains instances of pairs of images in the local Images/ directory and contains fields:

(*SubMenuName, SubMenuEntry, ClickableURL1, ImageURL1, ClickableURL2, ImageURL2, StartupData*)

DB/FlkRecentDB.txt - contains instances of recently accessed non-demo images with fields:

(*DbMenuName, ClickableURL, ImageURL, DatabaseName, TimeStamp*)

11. Files required that are included in the download.

The following files are packaged in the distribution and installed when you install Flicker.

Flicker.jar is the Java Archive File for Flicker that is executed when you run Flicker

jai_core.jar is the core Java runtime from SUN's Java Advanced Imaging (JAI) at sun.com

jai_codec.jar is the JAI tiff file reader from SUN's Java Advanced Imaging JAI at sun.com

DB/ is a directory containing the set of tab-delimited DB files *Flk*DB.txt* read at startup

Images/ is a directory holding demo .gif, .tif, and .ppx sample files

FlkStartups/ is empty directory to put the startup *FlkStartup.flk* files

Flicker-startup.bat is a Windows .bat batch script startup file

Flicker-startup.sh is a Unix/MacOS-X command line script startup file

12. Image transform and brightness-contrast display model.

There are several display models for combinations of using image transforms, zooming, and brightness contrast filtering. Zooming is an image transform and you can de-magnify as well as magnify. These transforms and filtering are applied to the left and right windows and also are shown in the flicker window. Two checkboxes in the upper left of the main window control transforms: "Allow transform" enables/disables transforms, and "Sequential transforms" allows using the previous transform as the input to the next transform, i.e., this lets you implement image composition.

This description applies independently to the left and right images. The original image is denoted *iImg*. If you allow transforms and are also composing image transforms, you may optionally use the previous transformed output image (denoted *oImg*) as input to the next image transform. The output (either *iImg* or *oImg*) is then sent to the *output1*. Then *output1* may be optionally zoomed to output2 by being sent to the zoom transform (iff the magnification is different from 1.0X). Then *output2* may be optionally contrast-adjusted by being sent to the brightness-contrast filter (if it is active as specified by dragging the mouse in the selected window with the SHIFT-key pressed). The *output2* of the brightness-contrast filter is denoted as *bcImg*. If you have never used the

zoom or brightness-contrast filtering since loading an image, then *zImg* and *bcImg* are not generated and hence not used in the displayed image. This will speed up display refresh as you navigate the windows.

a. If no transforms or brightness-contrast filtering is used on the selected image

(no transforms)
iImg → output1

b. The image may be optionally transformed from the original image (*iImg*)

(transform)
iImg → oImg → output1

c. Image transforms may be optionally composed from the original image or from the sequential composition of image transforms on the selected image

(sequential transforms)

iImg → Transform → oImg → output1

d. The image may be optionally zoomed if the magnification is not 1.0X

(zoom)
output1 → zImg → output2

or

(no zoom)
output1 → output2

e) The brightness-contrast filter may be optionally applied to the image

(B-C filter)
output2 → bcImg → display

or

(no B-C filter)
output2 → display

Quantification of Radiolabeled Proteins in Polyacrylamide Gels

Wayne R. Springer

1. Introduction

Autoradiography is often used to detect and quantify radiolabeled proteins present after separation by polyacrylamide gel electrophoresis (PAGE) (*see* Chapter 56). The method, however, requires relatively high levels of radioactivity when weak β-emitters, such as tritium, are to be detected. In addition, lengthy exposures requiring the use of fluorescent enhancers are often required. Recent developments in detection of proteins using silver staining ***(1, 2)*** have added to the problem because of the fact that tritium emissions are quenched by the silver ***(2)***. Since for many metabolic labeling studies, tritium labeled precursors are often the only ones available, it seemed useful to develop a method that would overcome these drawbacks. The method the author developed involves the use of a cleavable crosslinking agent in the polyacrylamide gels that allows the solubilization of the protein for quantification by scintillation counting. Although developed for tritium ***(3)***, the method works well with any covalently bound label, as demonstrated here with ^{35}S. Resolution is as good as or better than autoradiography (***3*** and **Fig. 1**), turnaround time can be greatly reduced, and quantification is more easily accomplished.

2. Materials

Reagents should be of high quality, particularly the sodium dodecyl sulfate (SDS) to obtain the best resolution, glycerol to eliminate extraneous bands, and ammonium persulfate to obtain proper polymerization. Many manufacturers supply reagents designed for use in polyacrylamide gels. These should be purchased whenever practical. Unless otherwize noted, solutions may be stored indefinitely at room temperature.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

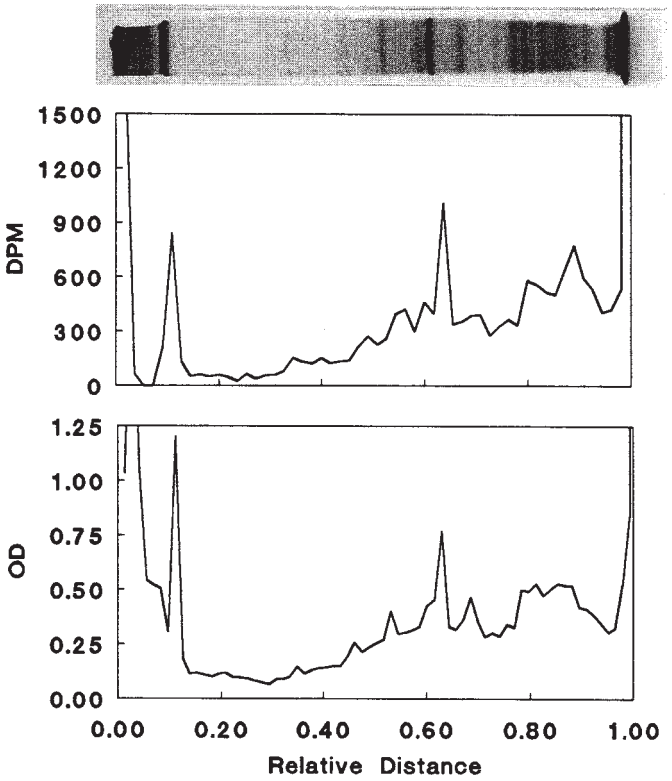

Fig. 1. Comparison of an autoradiogram, densitometry scan, and radioactivity in gel slices from a mixture of labeled proteins separated by PAGE. Identical aliquots of ^{35}S-methionine-labeled proteins from the membranes of the cellular slime mold, *D. purpureum,* were separated using the methods described in **Subheading 3.1.** One lane was fixed, soaked in Fluoro-Hance (Research Products International Corp., Mount Prospect, IL), dried, and autoradiographed (photograph). Another lane was cut from the gel, sliced into 1-mm pieces, solubilized, and counted using a Tracor Mark III liquid scintillation counter with automatic quench correction (TM Analytic, Elk Grove Village, IL) as described in **Subheading 3.3.** The resultant disintigrations per minute (DPM) were plotted vs the relative distance from the top of the running gel (**top figure**). The autoradiogram (photograph) was scanned relative to the top of the running gel using white light on a Transidyne RFT densitometer (**bottom figure**).

2.1. SDS-Polyacrylamide Gels

1. Acrylamide-DATD: Acrylamide (45 g) and *N,N′*-dialyltartardiamide (DATD 4.5 g) are dissolved in water to a final volume of 100 mL. Water should be added slowly and time allowed for the crystals to dissolve.
2. Acrylamide-*bis*: Acrylamide (45 g) and *N,N′*-methylenebis(acrylamide) (*bis*-acrylamide, 1.8 g), are dissolved as in item 1 in water to a final volume of 100 mL.

3. Tris I: 0.285 *M* Tris-HCl, pH 6.8.
4. Tris II: 1.5 *M* Tris-HCl, pH 8.8, 0.4% SDS.
5. Tris III: 0.5 *M* Tris-HCl pH 6.8, 0.4% SDS.
6. Ammonium persulfate (APS) solution: A small amount of ammonium persulfate is weighed out and water is added to make it 100 mg/mL. This should be made fresh the day of the preparation of the gel. The ammonium persulfate crystals should be stored in the refrigerator and warmed before opening.
7. *N,N,N′,N′*-tetramethylethylenediamine (TEMED) is used neat as supplied by the manufacturer.
8. 10X Running buffer: Tris base (30.2 g), glycine (144.1 g), and SDS (10.00 g) are made up to 1 L with distilled water.
9. Sample buffer: The following are mixed together and stored at 4°C: 1.5 mL 20% (w/v) SDS, 1.5 mL glycerol, 0.75 mL 2-mercaptoethanol, 0.15 mL 0.2% (w/v) Bromophenol blue, and 1.1 mL Tris I.

2.2. Silver Staining of Gels

All solutions must be made with good-quality water.

1. Solution A: methanol:acetic acid:water (50:10:40).
2. Solution B: methanol:acetic acid:water (5:7:88).
3. Solution C: 10% (v/v) glutaraldehyde.
4. 10X Silver nitrate: 1% (w/v) silver nitrate stored in brown glass bottle.
5. Developer: Just before use, 25 µL of 37% formaldehyde are added to freshly made 3% (w/v) sodium carbonate.
6. Stop bath: 2.3 *M* Citric acid (48.3 g/100 mL).

2.3. Solubilization and Counting of Gel Slices

1. Solubilizer: 2% sodium metaperiodate.
2. Scintillation fluid: Ecolume (+) (ICN Biomedical, Inc., Irvine, CA) was used to develop the method. *See* **Subheading 4**. Notes. for other scintillants.

3. Methods

The general requirements to construct, prepare, and run SDS-PAGE gels as described by Laemmli ***(4)*** are given in Chapter 11. Presented here are the recipes and solutions developed in the author's laboratory for this particular technique. For most of the methods described a preferred preparation of a standard gel can be substituted, except for the requirement of the replacement of DATD for bis at a ratio of 1:10 DATD: acrylamide in the original formulation.

3.1. SDS-Polyacrylamide Gels

Sufficient medium for one 8 × 10 × 0.75 to 1.0-cm gel can be made by combining stock solutions and various amounts of acrylamide-DATD and water to achieve the required percentage of acrylamide (*see* **Note 1**) by using the

quantities listed in **Table 1**. The stacking gel is that described by Laemmli ***(4)*** and is formed by combining 0.55 mL of acrylamide-*bis* with 1.25 mL of Tris III, 3.2 mL of water, 0.015 mL of APS, and 0.005 mL of TEMED.

1. For both the running and the stacking gel, degas the solutions by applying a vacuum for approx 30 s before adding the TEMED.
2. After the addition of the TEMED, pour the gels, insert the comb in the case of the stacking gel, and overlay quickly with 0.1% SDS to provide good polymerization.
3. Prepare protein samples by dissolving two parts of the protein sample in one part of sample buffer and heating to 100°C for 2 min.
4. Run gels at 200 V constant voltage for 45 min to 1 h or until the dye front reaches the bottom of the plate.

3.2. Silver Staining

The method used is that of Morrissey ***(1)***.

1. Remove gels from the plates, and immerse in solution A for 15 min.
2. Transfer to solution B for 15 min and then solution C for 15 min, all while gently shaking.
3. At this point, the gel can be rinsed in glass-distilled water for 2 h to overnight (*see* **Note 2**).
4. After the water rinse, add fresh water and enough crystalline dithiotreitol (DTT) to make the solution 5 µg/mL.
5. After 15 min, remove the DTT, and add 0.1% silver nitrate made fresh from the 1% stock solution. Shake for 15 min.
6. Rapidly rinse the gel with a small amount of water followed by two 5–10 mL rinses with developer followed by the remainder of the developer.
7. Watch the gel carefully, and add stop bath to the gel and developer when the desired darkness of the bands is reached.
8. Store the stopped gel in water until the next step.

Table 1
Recipe for Various Percentages of SDS-PAGE Gels

	Percentage of Acrylamide		
Stock Solution	7.5%	10%	12.5%
Acrylamide-DATD	0.96 ml	1.33 ml	1.66 ml
Tris II	1.50 ml	1.50 ml	1.50 ml
Water	3.50 ml	3.13 ml	2.80 ml
APS	0.03 ml	0.03 ml	0.03 ml
TEMED	0.003 ml	0.003 ml	0.003 ml

3.3. Slicing and Counting of Gel Slices

1. Remove individual lanes from the gel for slicing by cutting with a knife or spatula.
2. Cut each lane into uniform slices, or cut identified bands in the gel (*see* **Note 3**).
3. Place each slice into a glass scintillation vial, and add 0.5 mL of 2% sodium metaperiodate solution.
4. Shake the vials for 30 min to dissolve the gel.
5. Add a 10-mL aliquot of scintillation fluid to the vial, cool the vial, and count in a refrigerated scintillation counter (*see* **Notes 4–6**).

4. Notes

4.1. SDS-Polyacrylamide Gels

1. Acrylamide-DATD gels behave quite similarly to acrylamide-bis gels, except for the fact that for a given percentage of acrylamide, the relative mobility of all proteins are reduced in the DATD gel. In other words, a DATD gel runs like a higher percentage acrylamide*bis* gel.

4.2. Silver Staining

2. The water rinse can be reduced to 1 h, if the water is changed at 10–15 min intervals. The author found in practice that the amount of DTT was not particularly critical, and routinely added the tip of a microspatula of crystals to approx 30 mL of water.

4.3. Slicing and Counting of Gel Slices

3. The method seems relatively insensitive to gel volume, as measured by changes in efficiency (***3***) over the range of 5–100 mm^3 for tritium and an even larger range for 14C or ^{35}S. Larger pieces of gel can be used if one is comparing relative amounts of label, such as in a pulse chase or other timed incorporation, but longer times and more metaperiodate may be required to dissolve the gel. Recovery of label from the gel is in the 80–90% range for proteins from 10–100 kDa (***3***). In most cases, the label will remain with the protein, but in the case of periodate-sensitive carbohydrates on glycoproteins, it may be released from the protein. This, however, does not prevent the quantification. It just does not allow the solubilized labeled protein to be recovered for other manipulations.
4. It is necessary to cool the vials in the counting chamber before counting in order to eliminate occasional chemiluminescence. The cause of this phenomenon was not explored, but one should determine whether this occurs when using other scintillants or counters.
5. **Figure 1** shows the results of a typical experiment using ^{35}S-methionine to label proteins metabolically from the cellular slime mold, Dic*tyostelium*

purpureum, and quantify them using the method described or by autoradiography. As can be seen, the resolution of the method is comparable to that of the autoradiogram (*see* **ref. *3*** for similar results using tritium). The time to process the lane by the method described here was approx 8 h, whereas, the results of the autoradiogram took more than 3 d to obtain. Examination of the stained gel suggests that, if one were interested in a particular protein, it would be fairly easy to isolate the slice of gel containing that protein for quantification. This makes this method extremely useful for comparing incorporation into a single protein over time as in pulse/chase experiments ***(3)***.

6. The author has found that as little as 400 dpm of tritium associated with a protein could be detected ***(3)***, which makes this method particularly useful for scarce proteins or small samples.

Differential ProteoTope Radioactive Quantification of Protein Abundance Ratios

Wojciech Wozny, Gerhard P. Schwall, Chaturvedula S. Sastri, Slobodan Poznanović, Werner Stegmann, Christian Hunzinger†, Karlfried Groebe, and Michael A. Cahill

1. Introduction

2D-PAGE remains a widely employed proteomics method because it provides the highest separating resolution of intact polypeptide isoforms that are amenable to subsequent characterization ***(1, 2)***. ProteoTope is a differential radioactive detection method that we developed based upon temporally separated exposures of iodinated proteins on 2D-PAGE gels ***(3, 4)***. We have also developed systems for extremely high resolution 2D-PAGE over 54 cm or longer, which were designed for optimal quantification of radioactively labeled proteins ***(5, 6)***. These methods provide synergistic improvement in data quality for obtaining quality results from limited samples, such as typical valuable clinical tissue samples ***(7–9)***.

Here we provide a comprehensive technical description of differential 2D-radioactive ProteoTope quantification using highly standardized samples from the ABRF PRG2006 study ***(10)***. Our method is a novel application of the widespread Imaging Plate radioactive detection method ***(11, 12)***. The twofold study aims for multiple ABRF study participants were to blindly identify the eight unknown standard proteins in the two sample mixtures, and to determine a best estimate of their relative amounts in each sample by multiple measurements of mixtures of the two samples at a ratio of 1:1 ***(10)***. 2D-PAGE and ProteoTope differential radioactive imaging provided excellent relative quantification data of even subtle differences between the two samples. However our inverse symmetrical replicate experimental design and precise relative quantifications revealed that the quantities of proteins in both samples were apparently altered during sample resolubilization in our laboratory. Thus this case study demonstrates

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

both the excellent quantification of limited protein samples achievable by differential radioactive imaging, and the requirement for stringently optimized sample-specific handling protocols which were not developed for this one-off time-restricted experiment.

2. Materials

2.1. Samples, Resolubization, and Labeling

1. The study was performed blind on unknown standard lyophilized samples provided by the ABRF (*see* **Note 1**), and as summarized in **Table 1.**
2. Resolubilization buffer: 2% SDS, 10 m*M* Tris pH 7.4 (*see* **Note 2**).

2.2. Protein Iodination

1. Chloramine T.
2. ^{125}I specific activity >600 GBq/mg Iodide, no added carrier.
3. ^{131}I specific activity ~740 GBq/mg Iodide, no added carrier.
4. Zeba Desalting Spin Columns, 500 µL, Pierce.
5. Tributylphosphine (TBP), Fluka.
6. Bromophenol blue (BPB), Sigma.
7. Radioactive counters suitable for measuring ^{125}I & ^{131}I.
8. Lead shielding suitable to protect the operator from radiation.
9. Iodination Buffer: 8 *M* Urea, 4% CHAPS, 0.1 *M* Tris pH 7.4 (conveniently stored in 500 µL aliquots at −20°C).
10. Elution Buffer: 8 *M* urea, 2 *M* thiourea, 4% CHAPS, 4 µg/µL Tryptone (trypsinized yeast extract proteins).
11. Radiation safety equipment as specified by your authorized radiation safety officer, such as lead blocks with sufficient holes bored to hold all labeling reactions.

2.3. Isoelectric Focussing (IEF)

1. Isoelectric focusing (IEF) buffer: 7 *M* urea, 1% Triton-X-100, 10% glycerin, 2 *M* thiourea, 4% CHAPS, 1% DTT, 0,8% IPG-Buffer pH 3–10 (GE Healthcare).
2. Immobiline DryStrips (Immobilized pH gradients: IPGs), pH 3–10 linear gradient (GE Healthcare).
3. 1 % BPB solution in MilliQ water (stored in 100 µL – 200 µl aliquots at −20°C).

2.4. Equilibration

1. Equilibration buffer: 6 *M* urea, 30% glycerol, 4% SDS, 0.05 *M* Tris-HCl pH 8.8, 2% iodoacetamide. 4 m*M* TBP is added immediately prior to use.
2. Disposable rehydration/equilibration tray with Lid, 24 cm, Biorad.

2.5. SDS-Polyacrylamide Gel Electrophoresis (SDS-PAGE)

1. 30% Acrylamide/ 0,8% Bis-acrylamide-stock solution (C. Roth, Catalogue Nr 3029.1).
2. 1.5 *M* Tris-HCl, pH 8.8. (May be autoclaved for long term storage).

Table 1
Nominal sample description

	1*	2*	3*	4*	5*	6*	7*	8	9	10	11
	MW	pI	Mixture A	Mixture B	Mixture A	Mixture B	Nominal Ratio	Mixture A	Mixture B	Mixture A	Mixture B

			83.9	83.9				126.1	101.4		

*SSNominal values from the ABRF *(**10**)*.
Columns 1–7 (asterisked) were taken from information supplied by the ABRF after the results were announced (***10***). Columns 8 and 9 show the nominal amount of each protein present in the 5 µg radiolabeling reactions, and columns 10 and 11 show the nominal amounts of each protein loaded per 2D PAGE gel, assuming 100% yields.

3. 10% sodium dodecyl sulfate (SDS) stock solution in MilliQ water.
4. 10% ammonium persulfate (APS) solution. (Mix fresh each time by weighing crystalline APS and adding 9 times that weight of MilliQ water).

2.6. Gel drying & lamination

1. 4 × vacuum Gel Dryers (Speed Gel SG210D, ThermoSavant).
2. Plastic kitchen foil.
3. 3 m*M* blotting paper.
4. Laminating Pouch Film large enough for your gels (for ISO-DALT gel we used 216 × 303 mm, 80 microns; Bürobedarf Keller, Marktredwitz, Germany)
5. A laminating device and foils large enough for your gels (Filux LM1250HC DIN A3, Topversand24 GbR, 26135 Oldenburg, Germany)
6. Radiation safety equipment as approved by your radiation safety officer for the process.

2.7. Image Acquisition

1. 20× Fuji Imaging Plates (IPs) for 21–22 h (BAS-MS 2325; raytest GmbH, Straubenhard, Germany).
2. 20 × IP imaging cassettes for IP exposure (raytest GmbH, Straubenhard, Germany).
3. Fuji FLA-3000 R Bioimager and accompanying computer (raytest GmbH, Straubenhard, Germany).
4. IP erasing capacity for 20 IP plates (we use an own-made apparatus).
5. Suction device to remove IPs from the cassettes (optional) (raytest GmbH, Straubenhard, Germany).
6. Copper and lead lined cabinet (safe) to expose the IPs (optional) (raytest GmbH, Straubenhard, Germany).

2.8. Image Deconvolution

1. A computer program capable of image deconvolution. We use the own-developed "select_deconv_v1.1.pl" program (ProteoSys AG)

3. Methods

3.1. Sample Resolubilization and Protein Labeling

1. The desiccated samples were dissolved directly into 40 µL of 10 mM Tris, 2% SDS, pH7.4 with 5 min shaking at 95°C (*see* **Note 2**). Protein content was assumed to be 80 µg/40 µl based upon the ABRF sample description.

3.2. Protein iodination

1. Into eight reaction tubes place 60 µL Iodination Buffer.
2. Design your own experimental replicates as appropriate. For the described ABRF study experiment: Transfer 2.5 µL (5 µg) of the redissolved sample A into four of the reaction tubes, and transfer 2.5 µL of sample B into the other four reaction tubes. This establishes inverse duplicates samples for eight iodination reactions:

^{125}I-A1, ^{131}I-A1, ^{125}I-A2, ^{131}I-A2, ^{125}I-B1, ^{131}I-B1, ^{125}I-B2 and ^{131}I-B2 (*see* **Notes 3** and **4**).

3. Transfer 3,7 MBq of ^{125}I to each tube of sample A or B that is to be labeled with ^{125}I from the previous step (^{125}I-A1, ^{125}I-A2, ^{125}I-B1, and ^{125}I-B2). Then transfer 3,7 MBq of ^{131}I to the other tubes (^{131}I-A1, ^{131}I-A2, ^{131}I-B1, and ^{131}I-B2). (*see* **Note 5**).
4. Start the reaction by adding 3.5 µL of 100 m*M* Chloramine T (20X concentrated stock solutions: reaction conditions 5 m*M*).
5. Reaction time is 5 min at RT.
6. The reaction is stopped by adding 2 µL of 1 M TBP in 2-propanol (*see* **Note 6**).
7. The labeled proteins are purified by Spin columns (*see* **Note 3**).
8. Remove the bottom seal of the column and loosen (do not remove) the cap.
9. Place the column in a 1.5–2.0 mL microcentrifuge collection tube.
10. Centrifuge at 1,500 × *g* for 1 min to remove storage solution.
11. Place a mark on the side of the column where the compacted resin is slanted upward. Place the column in the microcentrifuge with the mark facing outward in all subsequent centrifugation steps.
12. Add 300 µL of elution buffer on top of the resin bed. Centrifuge at 1,500 × *g* for 1 min to remove buffer.
13. Repeat the previous step three additional times, discarding buffer from the collection tube.
14. Place the column in a new collection tube, remove the cap, and apply the sample to the top of the compacted resin bed. Load sample directly to the centre of the resin bed. Carefully touch the pipette tip to the resin to expel all sample.
15. Centrifuge at 1,500 × *g* for 2 min to collect the sample.
16. Discard the desalting column after use.
17. Measure radioactivity of the resulting protein solutions.
18. Calculate the amount of iodine incorporated into proteins (*see* **Notes 7** and **8**) to assess the labeling yield (*see* **Note 9**).
19. All procedures should be approved by your radiation safety officer.

3.3. Isoelectric Focusing (IEF)

The methods of 2D-PAGE are so well established that these are described only in general reference to the steps employed. It is assumed that each laboratory has existing 2D-PAGE methods and equipment available and operating. For general methodical 2D-PAGE references see ***(13–16)*** or reference ***(17)*** from the Methods in Molecular Biology series. Samples were analyzed by 2D-PAGE according to the regime of **Fig. 1A** (*see* **Note 4**).

1. Prepare 20 Eppendorf tubes and 20 loading mixtures as follow:
2. Add 200 µL IEF buffer to each vessel.
3. Add 90 kBq of the appropriate ^{125}I-labelled protein and ^{131}I-labelled to each well according to the scheme of **Table 2.** Adjust the volume with IEF buffer up to 350 µL. Add 2.8 µL of IPG buffer pH 3–10 linear. Be sure to use a new disposable tip each time.

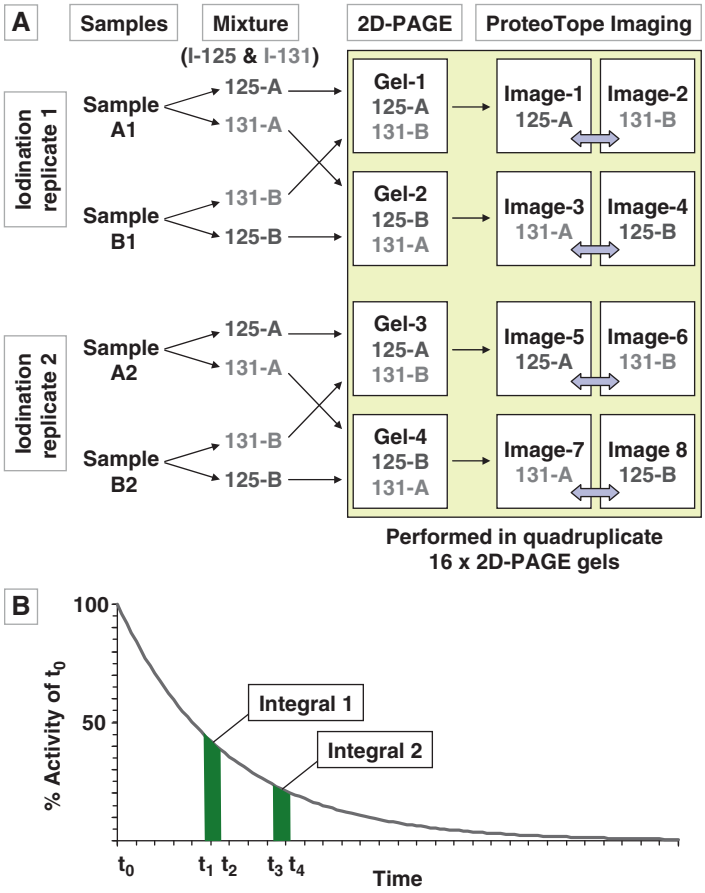

Fig. 1. Schematic depiction of ProteoTope analysis in this study. (**A**) Experimental ProteoTope Inverse Replicate and Tracer Gel Design employed for quantitative analytical multiplex. In this study the design for boxed gels 1–4 was performed in quadruplicate to generate 16 × 2D-PAGE gels, pH 3–10 linear. Each sample is separately iodinated in duplicate with each of two radioactive iodine isotopes: ^{125}I (dark) and ^{131}I (light). The radioactively labeled proteins were mixed together and coelectrophoresed on inversely labeled replicate 2D-PAGE gels as shown. The individual signals from each radioisotope were measured by ProteoTope and mutually calibrated to give equal BSA intensities in each channel of a respective gel. Double headed arrows represent multiplex image generation. The experimental design provides 16 independent estimates of the abundance ratio of proteins in particular spots between the samples, and includes all variables introduced by sample handling and electrophoretic conditions. (**B**) A schematic depiction of the integrals between t1 and t2, and t3 and t4 (being time intervals after t0), used to calculate decay factors that are provided in **Table 2**.

4. Prepare 20 IEF Rehydration tubes. The tubes should be made of 5 mL disposable pipettes (606107, Greiner Bio-One GmbH). Cut each pipette at the ends to obtain 22 cm long tubes.
5. Place into each tube Immobiline dry strip 18 cm, pH 3–10, gel side down.
6. Put the cup (Caps, 12504, Moss Plastic Parts) at one end of each tube. Label the tubes as Loading mixture.
7. Apply the Loading mixtures into appropriate strip. Carefully pipette the mixture between the gel side of the strip and the wall of the tube. Avoid introducing bubbles (*see* **Fig. 2**). Close the tube with the cap.
8. Incubate horizontally (gel side down) overnight at RT.
9. Rinse the rehydrated IPG strips with water, blot lightly onto filter paper soaked with water and place them gel side up in the strip aligner tray of a Multiphor IEF device.
10. Cut paper electrode strips (ca 15–20 mm wide and approx. 130 mm long for the IPG-Phor from Macherey-Nagel Filterpaper MN 440. Soak the paper strips with water and blot excess water with clean blotting paper, then place the wet paper electrode strips over the ends of IPG strips so that the electrode strip overlaps onto about 5 mm of the IPG gel.
11. Install electrodes so that they press down roughly in the middle of the paper electrode strips.
12. Switch on the water cooling system to maintain constant temperature at 25°C.
13. With the power supply limited to 2 mA and 5 W, electrophorese the samples for 1 h at 150 V, 1 h at 300 V, 0.5 h at 600 V, 0.5 h 1500 V, 0.5 h at 2000 V, 1 h at 3500 V, 10 h at 6000 V (*see* **Note 5**).
14. All procedures should be approved by your radiation safety officer.

3.4. Equilibration

1. After the completion of IEF, incubate each individual IPG for 30 min, in 5 mL Equilibration Buffer, while gently shaking. Use disposable equilibration trays (*see* **Note 3**).
2. All procedures should be approved by your radiation safety officer.

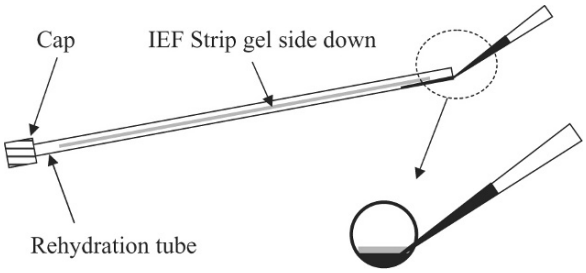

Fig. 2. Loading of rehydration mixture.

3.5. SDS-Polyacrylamide Gel Electrophoresis (SDS-PAGE)

1. 20 × 12% acrylamide SDS gels were electrophoresed in one ISO-DALT chamber, loading two gels per ISO-DALT slot, for 3 h at 50 V, and 110 V overnight with temperature regulated to 20°C.
2. All procedures should be approved by your radiation safety officer.

3.6. Gel Drying and Llamination

1. Separate the 2D-PAGE gels from one of the glass plates, systematically removing the glass plate from the same side of all gels. The aim is to process all gels in the same orientation so that all resulting gel images will have the same orientation. If some gels are processed in the wrong orientation the images can still be later manually rotated or mirrored by computer.
2. Place a piece of blotting paper on top of the gel, conveniently precut to about 23 × 30 cm (*see* **Notes 3** and **10**).
3. Invert the glass plate and paper, so that the paper is underneath the glass and gel, then gently remove the glass plate.
4. Place plastic kitchen foil over the gel, fully covering all potential sources of radioactivity.
5. Place the gel, paper down and plastic up, on top of two sheets of blotting paper on a gel dryer. (Up to four ISO-DALT gels can fit onto one gel dryer.)
6. Dry the gels at 80°C under vacuum for at least 45 min up to 90 min (*see* **Note 11**) on the Savant gel dryer (*see* **Note 5**).
7. Place the gels, dried onto one sheet of paper, into 0.08 mm plastic protective layer laminating foils, paying careful attention that the orientation of all gels is the same. Obviously, avoid contaminating the outside of the plastic! These will later be in direct contact with the IPs and you cannot afford a contamination of the IPs with ^{125}I, which has a half-life of 60 days.
8. Seal the gel in the laminating foil using the lamination device. The seal should ideally be perfect and airtight. At this stage the gels are ready for imaging.
9. All procedures should be approved by your radiation safety officer.

3.7. Image Acquisition

1. Erase 20 IP plates (*see* **Note 12**).
2. Place the gels into an IP exposure cassette, paper side down and gel side up, once more paying attention that the orientation of all gels is identical (*see* **Note 13**).
3. Gently place a freshly pre-erased IP into the cassette, white/phosphor side down and contacting the upturned gel surface of the laminated gel, also paying attention that the edges are flush with the edges of the exposure cassette in one corner. Be careful not to bend the IP or touch the white surface with your fingers (*see* **Note 12**).
4. Close the cassette, noting the exact time for each different IP to give the individual t1 values analogous to those from **Table 2** (*see* **Note 14**).
5. Expose for 21–22 h (*see* **Note 15**).

6. After the exposure is complete, open the IP exposure cassette under conditions of low light (*see* **Note 16**). Record the exact time the exposure is terminated to give t2 from **Table 2.**
7. Carefully remove the exposed IP from the cassette containing the laminated gel and transfer the IP to the imaging device for scanning (*see* **Note 17**). Pay attention to the consistent and exact orientation of all IPs with respect to the IP stage (*see* **Note 18**).
8. Place the IP stage with IP into the Imager, which has been switched on for sometime beforehand to warm up the lasers (*see* **Note 19**).
9. Scan on a Fuji FLA-3000 R Bioimager at 0.2 mm resolution using the IP filter selection and grid setting height = 1125, width = 1250 of the BASReader software (Version 3.01) (*see* **Note 20**).
10. When the images are acquired the IP may be removed. Remove the IP stage from the imager and take the IP off it by sticking your gloved finger through the hole in the stage taking care once more not to touch the white surface with your bare fingers or to bend the IP.
11. The IP may then be erased.
12. Acquisition of the first scan images is complete.
13. After waiting at least two weeks (*see* **Note 21**) to permit differential decay of the ^{125}I and ^{131}I (half lives of 59.41 days for ^{125}I and 8.04 days for ^{131}I) on the labeled proteins, repeat this entire exposure and imaging process to generate the second scan images (*see* **Note 22**). Remember to record t3 (commencement of the second exposure) and t4 (termination of the second exposure) from **Table 2** for each individual exposure.

3.8. Image deconvolution

1. Expositions in this study were commenced on 10 November 2005 and 1 December 2005 according to the regime of **Table 2.**
2. The signal distribution of ^{125}I and ^{131}I on the gel images is deconvoluted by solving simultaneous equations with a computer algorithm to generate images of the two individual isotopes on each gel (*see* **Notes 23** and **24**). An example set of images for gel 1 from **Table 2** is depicted in **Fig. 3.**

3.9. Image processing and spot detection

Quantitative image processing was performed with the PIC/GREG software package (Fraunhofer-Institut für Angewandte Informationstechnik, Sankt Augustin, see http://www.fit.fraunhofer.de/projekte/greg/index_en.xml). There are multiple commercially available software products suitable for 2D-PAGE image processing. The signal intensities of deconvoluted images for each isotopic channel were calibrated to produce a best-fit 1:1 ratio for albumin spots for each gel according to sample information provided by the ABRF ***(10)***. Therefore final abundance ratio estimates were relative to the assumed albumin ratio. (Note that this is not our standard normalization method. We usually normalize

[a]The actual time point of t1 for Gel no. 1 was 10 Nov. 2005, 14:16 (hh.mm).

Samples A1, A2, B1, and B2 correspond to replicates of Sample A and Sample B. Gels 1–16 were used to quantify the differential abundances of proteins between samples A and B. Gels 17–20 were labeling controls, and gels 21–24 were preparative gels, loaded with 10 µg of the indicated non-radioactively labeled proteins (cold protein) per gel to be used for mass spectrometric protein identification (not described here). t1 and t2 are given in days after the calibration date of ^{125}I. These represent the start and finish of the first exposure, and are used to calculate Integral 1 for each isotope ^{125}I and ^{131}I, according to the theoretical fraction of radioactive decay between t1 and t2 and as schematically depicted in Fig. 1B. Integral 2 is similarly calculated from t3 and t4. Integrals 1 and 2 are then used to calculate the decay factors (DF) for deconvolution for each isotope as indicated. The decay factors shown correspond to 1/M and 1/N from equation 2 (see Note 23).

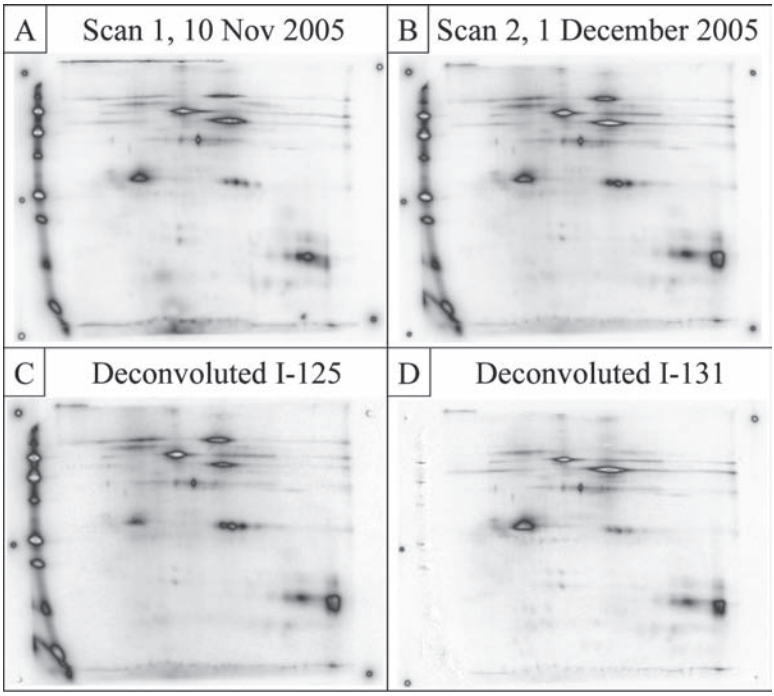

Fig. 3. Deconvolution of gel 1 from **Table 2.** **(A)** The signal obtained from the initial exposure, made for 21 h starting on day 1. **(B)** The signal obtained from the second exposure, made for 22 h starting on day 21. **(C)** The deconvoluted signal from the ^{125}I-labeled sample. **(D)** The deconvoluted signal from the ^{131}I-labeled sample. Deconvolution was performed according to **Eqs. 1** and **2** (*see* **Note 23**) using parameters shown in **Table 2**. Our deconvolution process produces non-linearly scaled TIFF images from the floating point FLA3000 data files.

the total signal volumes for both isotopic channels to each other.) The composite average gel images for sample A and sample B from all 16 gels are shown in **Fig. 4,** as are data depicting the reproducibility of data acquisition for the replicates of different 2D spots for the test proteins.

3.10. Statistical analysis

Quantitative values from PIC/GREG were exported in a spreadsheet and statistics were performed using Excel (Microsoft). The mean values and standard errors are modeled from the $\log_2(I_{sample2}/I_{sample1})$ intensity ratio values, taking advantage of the gel replicates. *P*-values are calculated using a t-test based on the null hypothesis of identical populations unless otherwise specified. The overall result for all spots used for quantitative analysis is shown in **Fig. 6,**

and the comparison of ProteoTope-estimated abundance ratios with those given by the ABRF as nominally correct is shown in Fig. 6 (*see* **Notes 25** and **26**).

4. Notes

1. A technical description of the samples has been published ***(10)***. The samples (one vial of Sample A, one vial of Sample B) from the ABRF arrived in our premises on 31 October 2005. The deadline for submitting results was no later than 9 December 2005. ABRF-PRG2006 was composed of two mixtures, labeled A and B, that contained eight major unknown proteins each of various unknown amounts according to the sample description. The total amount of unknown protein in each sample vial was given as approximately 80 µg. Individual proteins were present on average at

Fig. 4. Master gel and spot quantification. **(A)** A screen shot showing the spot detection made with the PIC/GREG software using the 32 images from all 16 measured 2D gels. The upper left panel shows a master synthetic differential image, with the positions of spots used to estimate the abundance ratios of the eight test proteins in **Fig. 5.** The proteins identified (with SwissProt Accession and number of spots quantified per protein in this study) in order of increasing SDS-PAGE mobility were: GP = Glycogen Phosphorylase B (P00489, $n = 5$); LP = Lactoperoxidase (P80025, $n = 1$); BSA = Bovine Serum Albumin (P02769, $n = 8$); C = Catalase (P00432, $n = 8$); P = Horse Radish Peroxidase (P00433, $n = 4$); BC = Beta Casein (P02666, $n = 4$); CA1 = Carbonic Anhydrase I (P00915, $n = 4$); R = Ribonulclease A (P61823, $n = 4$). Spots were selected for quantification only after unambiguous mass spectrometric identification. All identifications matched the identities supplied by the ABRF (***10***). BA_2369 and BA_2292 are the spots in C below. The lower two panels show the spot segmentation performed by PIC/GREG on the averaged gel images for Sample A **(lower left panel)** and Sample B **(lower right panel)**. These averaged images are synthetically constructed using the 16 warped images generated with both isotopes of iodine for each sample. The upper right panel shows a user interface containing spot parameters for the selected most acidic BSA spot. **(B)** Spot intensity ratios over minimum spot intensity. Logarithms to base 2 of the ratios of spot intensities under conditions A over B minus $\log_2$ of the average intensity ratio of the respective spot $\log_2(I_1/I_2)$ - $\log_2(I_1/I_2)$SpotAvg are displayed for each gel replicate. Data points are plotted as a function of the $\log_2$ of the minimum spot intensity for either Sample **A** or **B** $\log_2(\min(I_1,I_2))$. Symbols indicate the proteins that were identified in the respective spots. The diagram demonstrates that the measurement error in replicate spot quantifications becomes smaller as signal intensities increase. **(C)** Dependency of error on replicate number. The estimated mean spot volumes (with standard errors of means) for the most intense (Spot BA_2292) and least intense (Spot BA_2369) spots for Ribonuclease A are plotted using estimates made from four sets of $n = 4$, two sets of $n = 8$, or one set of $n = 16$ replicates (rplcts), plotted as fold overall mean ratio for the $n = 16$ set (A/B Ratio/Overall Mean Ratio ($n = 16$)). All estimated mean abundance ratios for both spots were within 20% of the mean obtained for n=16 gels. Gel grouping was numerical from **Table 2** (i.e., 1–4, 5–8, 9–12, 13–16, 1–8, 9–16, 1–16).

300 pmol, ranging from approximately 3 to 600 pmol, with ratios of proteins between mixtures A and B that could vary by up to 1:100. Some of the information as presented by the ABRF PRG2006 committee after completion of the study on the abundance of sample proteins is summarized in columns 1–7 of **Table 1.** The overall comparative results of the study for all participants using all experimental methods have been published, where ProteoTope is referred to as "2D radioactivity" ***(10)***.

2. We were the only participant in this study to resolubilize the desiccated protein pellet in an SDS-buffer. This was a one-off real life experiment without method optimization. This method apparently did not resolubilize all desiccated proteins with equal efficiency. We would recommend lysing frozen cryogenically sliced tissue samples into a boiling SDS or a urea-based buffer. For desiccated protein samples a urea buffer is apparently more successful.
3. Be sure to label all reaction vessels and other objects beforehand to avoid unnecessary exposure to radioactivity.
4. The inverse replicate experimental design described here systematically controls for errors that may be introduced by radiolabeling or electrophoretic laboratory steps. Proteins were prepared for 2D-PAGE as described ***(8, 10–12)*** without cysteine alkylation prior to radiolabeling due to schedule constraint and the associated inability to optimize conditions.
5. 1 mm lead shielding can be placed over apparatus to avoid exposure from ^{125}I, however note that gamma radiation from ^{131}I is not effectively impeded by such thin lead sheeting, and so the best protection from radiation exposure is substantial shielding such as a lead brick wall, preferably combined with sufficient physical distance (e.g., leave the room when you are not working). Your radiation safety officer should approve the protocol that you implement.
6. The concentrated form of TBP is explosive in the presence of oxygen, however a 200 mm stock solution is not explosive and can be stored at 4 degrees under inert gas. The stock solution is prepared by diluting the concentrated form (3.93 *M*) in solvent under an inert gas. TBP also is volatile, toxic, and unpleasant smelling ***(18)***, and should be handled in a fume hood.
7. Briefly, iodination reactions with either ^{125}I or ^{131}I were conducted under identical chemical iodine concentrations, using 3.7 MBq of each isotope (^{125}I specific activity >600 GBq/mg Iodide, no added carrier; ^{131}I specific activity ~ 740 GBq/mg Iodide) per 5 µg sample aliquot in a reaction volume of 60 µL by the chloramine T method as described ***(19)***, taking all appropriate radiation safety precautions. Iodine incorporation into proteins was determined to be approximately 800 kBq per labeling reaction, with the yield of iodine incorporated into proteins ranging from 18.6% to 21.1%.

Table 3
Theoretical level of labeling of an 'ideal average' 40 kDa protein and of average tyrosine residues at maximum theoretical specific activity of each isotope

	1 fmol/kBq	2 fmol/800 kBq	3 mol 40 kDa/mol Iodine	4 mol Tyr/mol Iodine
I-125	12,39	9912	13	151
I-131	1,67	1336	94	1123

Column 1 shows the approximate maximum theoretical specific radioactivity per Becquerel of the iodine isotopes used to label proteins, and column two shows the corresponding approximate number of femtomoles of radioactive iodine atoms incorporated into proteins in ideal 5 µg radiolabeling reactions with yield of 800 kBq. Column 3 shows the ratio moles of an "ideal average" 40 kDa protein per mole of incorporated iodine. Column 4 shows the number moles of tyrosine per radioiodinated tyrosine residue in the "ideal sample" (assuming an "average amino acid residue of 110 Da" and a tyrosine amino acid frequency of 0.033 for the "ideal average" 40 kDa protein). In our case, the specific activities of the ^{125}I and ^{131}I isotopes employed were approximately equal, indicating that ^{131}I had decayed through between two and three half-lives at the time of calibration (16% max. theoretical specific activity: a value which decreases by 50% each 8 days), and therefore the chemical labeling stoichiometry achieved for ^{131}I in this experiment was within approximately 23% of that given for ^{125}I above (i.e. 186 mol Tyr/mole iodine corresponding to column 4). Similarly, the specific activity of the ^{125}I employed was within 7% of its maximum theoretical value, and so the labeling stoichiometry of ^{125}I should have been within 7% of that given for ^{125}I in the table (i.e. >140 mol Tyr/mole iodine).

8. To elaborate upon the degree of labeling achieved in this experiment, it may be useful to consider the state of labeling of a population of "ideal average 40 kDa proteins" of random sequence with iodine isotopes of maximum theoretical specific activity as depicted in **Table 3.** Each 5 µg labeling reaction would contain 125 pmol of such "average 40 kDa proteins," which accords well with the nominal sum tallies of 126 pmol and 101 pmol for the experimental sample proteins of columns 8 and 9 from **Table 1**. Assuming that all the iodine present in the yield of radioactive protein was present as labeled tyrosine (an approximately correct yet ideal assumption which ignores nonspecific side reactions and noncovalent affinity of iodine to the protein mixture), approximately every thirteenth "ideal 40 kDa protein molecule" would be iodinated with ^{125}I and each ninetieth 40 kDa protein would be iodinated with ^{131}I under these reaction conditions. This would correspond to approximately every one hundred and fiftieth tyrosine in the mixture being labeled with ^{125}I or less than every thousandth tyrosine being labeled with ^{131}I. Our actual chemical labeling conditions were similar for both isotopes because of

relatively higher proportion of ^{127}I (nonradioactive stable isotope) in the ^{131}I preparation, as described in the legend to **Table 3.** Although these values are more qualitative than quantitative, they illustrate that the labeling conditions employed are conservative in order to reduce the possibility of generating double labeled proteins and corresponding protein chains.

9. As is evident from **Table 3** and **Note 8,** we labeled only a small fraction of the protein molecules present. This is performed to provide a margin of safety for the labeling conditions. To understand this, it is necessary to consider the production of the isotopes in some detail. The iodine is usually produced by irradiating a target of Te in a cyclotron. For instance, in one method to produce ^{125}I an isotopically enriched target of ^{125}Te would be irradiated ($^{125}Te(p,n)^{125}I$). However since the target also contains an often undetermined and batch-specific amount of ^{128}Te impurity, traces of (nonradioactive) ^{127}I are produced simultaneously ($^{128}Te(p,2n)^{127}I$). Furthermore, after irradiation the iodine is washed from the surface of the blank using a solution which inevitably contains some iodine. While the specific activity of commercial iodine products is provided as "carrier free," it is technically impossible to produce an isotopically pure preparation of the radioisotope, and "carrier free" means that no free iodine was deliberately added to the preparation in addition to these necessary and unknown sources, although a multiple molar excess of nonradioactive iodine may be present (this phenomenon is not restricted to iodine isotopes). For instance, whereas the maximum theoretical specific activity of ^{125}I is 642.7 GBq/mg iodide, the product we purchased was rated as >600 GBq/mg. The corresponding values for ^{131}I are 4587 GBq/mg (max. theor.) and 740 GBq/mg (product specification). For a technical description of the processes involved, see Bonardi et al. ***(20)***. For an estimate of the labeling stoichiometries obtained by us, see the legend to Table 3. For most researchers there is no practical way to quantify the isotopic purity of the small highly radioactive mixture that is commercially delivered. When dealing with very small amounts of protein, such as from clinical microdissection samples (***7***), we sometimes experienced smearing (not chain formation) in the basic region of 2D-PAGE patterns due to over-iodination caused by cold iodine in the "no-carrier-added" commercial stocks. Because these samples were extremely valuable, this led us to explore the strategy of sample pooling to generate a critical mass of protein in the labeling reactions, which produced more consistently reliable results over replicate samples (***7***). On the other hand, when sufficient sample is available the labeling conditions can be calibrated for particular batches of iodine and protein to achieve very much higher incorporated specific activity and thereby sensitivity than attained here. In hindsight we could have systematically iodinated the samples in

parallel with tenfold more specifically active iodine in the labeling reactions, which would probably have greatly improved the quantification of glycogen phosphorylase, whose signal was close to background levels in our Sample A gels and which consequently deconvoluted with errors only slightly better than background variation. While the indicative calculations of **Table 3** assume that each tyrosine reacts identically, in practice the electron density contributed to the tyrosine ring by adjacent amino acids may produce sequence-specific differences in reactivities of perhaps up to 100-fold or more in extreme cases (assuming a range of pka values of 2 units for protein tyrosine residues). These would nevertheless only contribute to overlabeling when two or more hyperreactive residues were present in one analyte protein molecule.

10. It is recommended to place 1 µL of a diluted labeled protein *from each reaction mixture used on that gel* onto the border of the blotting paper adjacent to the gel but within the area that will be imaged. The amount of radioactivity required in this signal source will vary depending upon the sensitivity of your imager. It should not saturate the pixel distribution of the imager during the exposure period you choose, yet is useful when >50% saturation is achieved: 60 Bq is a useful guide value. Also place 1 µL of a 1:1 mixture of both labeled proteins (i.e. 30 Bq of protein mixture labeled with each isotope in 1 µL). These optional signals provide useful controls for the deconvolution process later.
11. Unless the gels are perfectly dry they risk shattering into many pieces when the vacuum is removed, or slowly cracking after lamination. When the latter occurs between the first and second imaging scans the images are not superposable, and cannot be deconvoluted! Although these effects can affect every experiment, the consequences are especially severe when working with a large number of gels in a matrix-designed radioactive experiment. As a rule of thumb, the gels are dry when there is no temperature difference apparent between the metal surface of the gel dryer and the drying gel as judged by (disposable gloved) hand contact.
12. DO NOT BEND IPs. The phosphor crystals of the IP are damaged when the IP bends, resulting in less sensitive regions.
13. Because the gels will be exposed twice, and both images must be processed in parallel to generate the individual isotope images, pay attention that the corner of the laminated gel is pressed so that the edges are flush with the edges of the exposure cassette at one particular corner for both exposures.
14. It is highly advisable to expose the same gel with the same IP in the exact same orientation for both scans in your experiment. In case the surface of the IP has been damaged and exhibits differing sensitivities, this can be largely eliminated by imaging the same gel region with the same IP surface in both

scans. Each IP has one corner cut away to help with systematic orientation of the IP with respect to the gel.

15. Exposure in a lead- and copper-lined metal exposure cabinet ("safe") significantly decreases background signals from environmental radiation, permitting the more accurate detection of low intensity signals from the gels. Our version was purchased from raytest GmbH, Straubenhard.
16. You should have the imaging device in a room with low light level, such as drawn blinds or a room without windows. (You will require a few candle power of light to see what you are doing though, such as perhaps the light of the monitor of your PC that runs the FLA3000.) The signal on the IPs is extremely sensitive to light. Only remove the exposed IP from the cassette with the room lights off. The FLA3000 should be able to operate in light while scanning. However we have very occasionally had problems that the sealings of the scanner were not tight and some measurements were interrupted, destroying that exposure and potentially costing a repeat of the whole experiment. So we advise to also keep the room lights off while the imager is scanning.
17. To avoid bending the IP while removing it, a suction device may be useful to lift the plate the first few millimeters **(Fig. 7).**
18. For the FLA3000 the IP has a magnetic backing and is placed into an IP stage for scanning. The IP stage is marked with a grid of letters and numbers. To assist with image orientation, we suggest that the cut corner of the IP should go towards the A9 corner as shown **(Fig. 8).** Make sure that the IP sits squarely in the stage, and that the edges are as close as possible to both sides.
19. Make sure that the IP stage is sitting exactly in the FLA3000. If it is crooked it can destroy the motor of the FLA3000 and/or the IP stage if the stage does not sit flatly as the FLA3000 is trying to move it into the scanning area. Make sure the arrow between "H" & "I" on the IP Stage lines up with the arrow on the FLA 3000 **(Fig. 9).**
20. It may be advisable to make two or more successive measurements without removing the IP stage and IP from the imager if some regions of the gel exhibit saturated pixel intensity. You will need to establish an appropriate systematics of data structure and file nomenclature.
21. We employed only a three week decay period here because of study schedule restraints for the ABRF PRG2006 study. The ability to accurately deconvolute signals containing low intensities of ^{125}I will be increased by permitting longer decay times, whereby the actual number of randomly decayed ^{125}I atoms is given time to approach the theoretically calculated expected number more precisely. Three to five weeks decay period is a practical compromise and should be empirically determined by each laboratory for itself.

22. ProteoTope experiments resemble somewhat the activity of the warrior, with shorter periods of activity interspersed by longer periods of waiting (3–5 weeks) for radioactive decay. However different temporally overlapping experiments can be sequentially coordinated such that the overall throughput is continuous and considerable, and has proved to be adequate for our industrial applications. Although iodine is not a natural component of most proteins, it can be efficiently introduced into proteins from any source by the post harvest labeling method ***(19)***, including clinical human samples. Because the differential images produced for ProteoTope rely on the different decay rates for each isotope (half lives of 59.41 days for ^{125}I and 8.04 days for ^{131}I), the same Imaging Plate can be used for both measurements without the requirement of an absorber as required by the method of Johnstone et al. ***(21)***, and thus there is no source of distortion of the spatial signal distribution or detection efficiency. The vast majority of signal from ^{125}I captured by the Imaging Plate is from the 27 keV and 31 keV photons. The Auger electron is essentially too weak to be detected. For ^{131}I the 364 keV photon does not efficiently interact with the plate crystals, so that the vast majority of signal from this isotope comes from the 810 keV beta particle. Because this beta particle interacts more efficiently with the phosphor crystals than the low energy photons from ^{125}I, the signal detected from ^{131}I is slightly more localized than the more diffuse signal for ^{125}I. However both are favorably comparable in resolution, as evident from our results in this and other cited studies. The precise composition of our imaging plates remains unpublished by the manufacturer, and there is no data available from the manufacturer or distributor on the detection efficiency of the Imaging Plates for the various types of radiation we used. Therefore the discussion of detection efficiencies in this note represents the outcome of empirical observation and deduction. We do not employ ProteoTope to obtain absolute quantitative values, but rather to obtain accurate estimates of differential protein abundances between two samples. There may be some concern that the slightly more diffuse signal pattern generated by ^{125}I may lead to problems in differential quantification between isotope channels. We neglect this since the overwhelming majority of the signal is localized close to the source for both isotopes, and because the signal intensities of the quantified areas for particular spots are normalized to each other after deconvolution of the image channels. The latter effectively corrects any systematic distortion error that might arise because of the different signal distributions for each isotope (signal volumes for the whole gel are effectively normalized across detected spots). The major source of error is statistically related to signal counting acquisition, which is dictated by the amount of radio-

activity present. Fluctuations from ideal exponential decay will result in the signal from one isotope being incorrectly deconvoluted into the channel of the other. Low intensity signals of ^{125}I are most prone to this error. Results are effectively identical whether one employs the spot detection mask for the ^{125}I or ^{131}I channel, however it is advisable to employ the one mask for both channels for calibrated quantification (as was done to generate **Fig. 4**). One could also consider employing an intensity peak-based signal redistribution algorithm on the ^{125}I signal to make it more closely resemble that of ^{131}I, however we have not found that to be necessary and prefer to work with raw distributions which generate fewer opportunities for unforeseen data-processing artifacts to arise. Therefore the simple solution of equations (1) and (2) (*see* **Note 23**) is (A) technically correct to separate the radioactive signals originating from the two respective isotopes by deconvolution, and (B) pragmatically adequate to generate the data quality reported here without subsequently correcting for the marginally different signal distributions of those isotopes.

23. The two resulting images of each gel are used to generate deconvoluted images of the signals for each isotope using simultaneous equations. Briefly, the pixel value of any pixel of the first exposure is expressed in **Eq. 1,**

$$A + B = X \tag{1}$$

and the pixel value of a given pixel of the second exposure is expressed in **Eq. 2**,

$$MA + NB = Y \tag{2}$$

where

A = the signal contribution of radiation type A (e.g., ^{125}I) measured from the first exposure,

B = the signal contribution of radiation type B (e.g., ^{131}I) measured from the first exposure,

M = decay factor for the set-specific radiation type A between the two measurements,

N = decay factor for the set-specific radiation type B between the two measurements.

X = pixel value corresponding to the radiation intensity in the first measurement,

Y = pixel value corresponding to the radiation intensity in the second measurement.

A and B are unknown and to be determined. X and Y are the measured intensities. M and N can be determined by measuring calibration samples if

radioisotopic impurity is suspected, or by calculation based on theoretical decay rates and times of exposures, as performed in this study. The values for A and B can be calculated by simultaneously solving the equation system consisting of Eq. 1 and 2. This function was performed on a pixel by pixel basis using the aligned pixel matrices of both gel images by the own-developed "select_deconv_v1.1.pl" program (ProteoSys AG).

24. The use of the Imaging Plate to produce differential images is not new. Exposure to X-rays of different energies was already used to differentially visualize bone and soft tissue in clinical X-rays by some of the seminal Imaging Plate studies (***3, 4***). Johnstone et al. ***(21)*** used an absorbing sheet between source and Imaging Plate to discriminate between the energies of ^{32}P and either ^{35}S or ^{14}C tocreate differential images of proteins and nucleic acids in gels. In a related strategy,Monribot-Espagne et al. ***(22)*** made two different exposures using Imaging Plates sensitive to either ^{3}H and ^{14}C or only to ^{14}C to obtain differential 2D-PAGE images of proteins labeled with ^{3}H or ^{14}C that had been blotted onto membranes. However these methods have disadvantages relative to the ProteoTope strategy. The use of an absorbing sheet is associated with back-scatter as the beta-particles are deflected by atomic collisions within the absorber leading to altered geometry, altered detection efficiency, and spatial diffusion of the signal. Therefore the size and intensity of the signal measured for a given source with or without absorber is different, resulting in markedly reduced resolution and unaesthetic images (data not shown). The use of an absorber would have been quite advantageous, however we were unable to generate acceptable 2D images with any of them. Despite testing multiple absorbers types of varying thickness including diverse low Z materials (e.g., plastics and carbohydrates) and metals with various Z values, we have never encountered one that would produce data comparable to that shown here, and we therefore continue to employ differential radioisotopic decay rates.

    Both of the analogous imaging methods mentioned above involving differential use of either ^{32}P and ^{35}S/^{14}C, or ^{3}H and ^{14}C isotope pairs suffer from the serious drawback that the chemical labeling of different protein samples is dissimilar because the chemical distribution of the base elements in proteins differs when using ^{3}H, ^{14}C, ^{32}P or ^{35}S as labeling reagents. Therefore two images obtained from the same sample labeled by any two methods exhibits a different 2D-PAGE pattern, as discussed ***(19)***. Accordingly, slight differences between closely related samples as revealed in this study cannot be determined with those methods. By contrast, the ProteoTope strategy offers an efficient solution to the differential imaging of proteins, employing two chemically identical isotopes of radioactive iodine that produce identical 2D-PAGE patterns from the same sample

Fig. 5. Statistical results for each individual spot. The average normalized photostimulated light units (PSL) for each spot in both samples is given as ("A av Norm" and "B av Norm"). Because individual gels vary in intensity these normalized intensities were derived by applying the average of individual abundance ratios from all gels to the average sum signal intensity for each spot in columns AO-AR of spreadsheet "SelectedSpots." The corresponding ratio of A/B for relative protein abundance estimated from each spot is calculated (ratio A/B) with the accompanying 95% confidence interval for that ratio, as shown. Standard deviation (SD) and standard error of the means (SEM) are given in percentage total abundance, with the corresponding P-value for a null hypothesis of equal intensities. The bar diagrams at the right show the percentage signal for A (black bars) and B (light bars). Error bars show SEM.

in the polyacrylamide matrix of dried 2D-gels, with effectively zero post-electrophoretic sample loss.

25. Although our differential ratio estimates were the most accurate 2D-PAGE results submitted to the ABRF study by any participant, and comparable to differential isotope mass spec methods, unfortunately the abundance ratio estimates of some proteins corresponded to those given by the ABRF only within reasonably large error margins for our liking (**Fig. 6**). However the observations discussed below lead us to conclude that the major source of

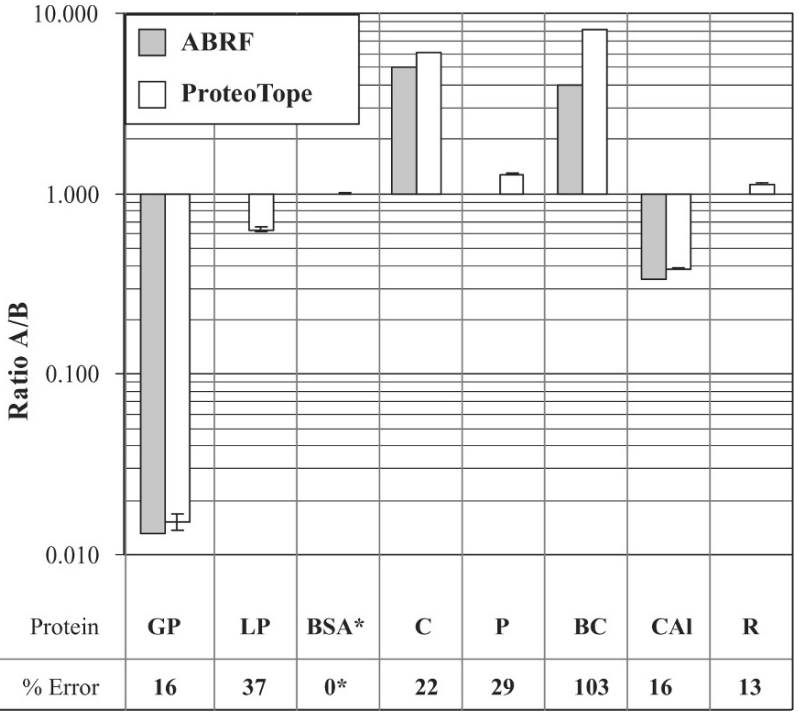

Fig. 6. Comparison of ProteoTope abundance ratios with those given by the ABRF. Abundance ratios submitted for weighted mean estimates from **Fig. 5** (ProteoTope) compared to the abundance ratios published by the ABRF after the study. Error bars show Standard Errors of Means. Protein name abbreviations follow **Fig. 4.** ABRF ratios for A/B (with submitted ProteoTope ratio) were GP, 0.013 (0.015); LP, 1.000 (0.631); BSA, 1.000 (1.000*); C, 5.000 (6.106); P, 1.000 (1.287); BC, 4.000 (8.104); CA1 0.333 (0.385); R, 1.000 (1.129). The absolute percentage errors of the submitted ProteoTope estimates of these ratios relative to the ABRF values are presented underneath the protein name abbreviations (% Error). The asterisk associated with BSA values indicates perfect value of 1:1 because this protein was used to normalize the signals from each radio-isotope across all gels.

discrepancy arose at the point of sample resolubilization, rather than during the quantitative analysis itself. There were two estimates of abundance ratios between Samples A and B that warrant particular discussion in this context: Lactoperoxidase and Beta Casein. For Lactoperoxidase our estimated ratio A/B was 0.63:1 ($P = 4\times10^{-6}$), rather than the ABRF value of 1:1. (We explicitly and categorically have no reason to presume incorrect sample mixing by the ABRF.) This protein exhibited generally weak incorporation of radioactivity relative to that of a silver stained gel of the

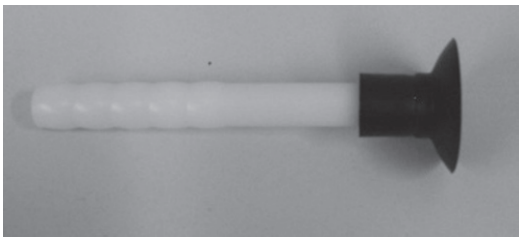

Fig. 7. A suction device to remove IPs from exposure cassettes without bending them. The handle is a hollow tube. Suction is created by hole at the blocking the upper (left in the image) end with a finger. This provides sufficient force to lift the IP high enough out of the cassette that its edges can be accessed with the fingers. The suction device was purchased from raytest GmbH.

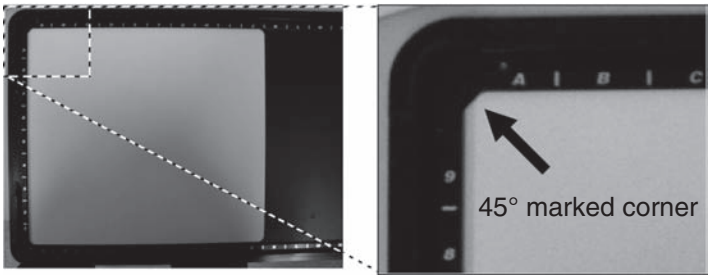

Fig. 8. Recommended orientation of the Fuji IP in the FLA3000 IP stage. The left panel shows an IP in the IP stage ready for scanning. The right panel shows an enlargement of the upper left corner, where the diagonally removed corner of the IP is oriented. Both edges of the IP should be exactly flush with the walls of the IP stage.

Fig. 9. Positioning the FLA3000 IP stage into the FLA3000 imager. The small arrow between H & I on the reverse of the IP stage should align with the large arrow on the FLA3000 imager.

same samples ***(10)***, which was reflected by the rather large 95% confidence limits of **Fig. 5** (0.473 – 0.808). However, in light of the result for Beta Casein, we conclude that the abundance of this protein had probably been altered in at least one sample in some manner prior to taking the sample aliquots for the radiolabeling step.

For Beta Casein our estimate of the A/B abundance ratio contained >100% error relative to the nominal ABRF value (weighted average estimate 8.104:1 compared to ABRF value 4:1). None of the 95% confidence limits for any of our four quantified spots approach a ratio of 4 **(Fig. 5)**, and a t-test against the null hypothesis of a 4:1 ratio shows a highly significant difference ($P = < 0.00001$). Because of our rigorous experimental design **(Fig. 1A)** we can therefore be statistically quite confident that the abundance of this protein was altered in at least one sample between the time the samples were mixed in the laboratory of the ABRF and the time that the two identical aliquots were taken from each resolubilised sample before iodination in our laboratory. Note that the alteration(s) did not occur during or after radio-iodination of the samples (during the ProteoTope analysis itself), which would have increased the measured variability and reduced the significance of the results. There is no other (persuasive) argument for the reproducible estimation of these observed abundance ratios being obtained after labeling the proteins with two different radioiodine isotopes used in eight labeling reactions across sixteen inverse replicate gels **(Fig. 1A).** It must be emphasized that although the estimates of abundance ratios that we submitted were associated with undesirably high deviations from the values provided by the ABRF **(Fig. 6),** we could identify the probable cause of the discrepancy because of our stringent experimental design. It is that process and its attributes, rather than the submitted abundance ratios, which provide the main technical features of the data quality generated by the ProteoTope method.

The most probable source of this sample alteration is sample handling prior to labeling in our laboratory, or possibly during shipment. One obvious source of potential variability is the resolubilization of the desiccated pellet. There was no opportunity to optimize this process because of the imposed time limit, and the resolubilization of desiccated proteins is not standardized in our laboratory. We would normally recommend transport of proteins as frozen SDS solutions or tissue sections, although this is associated with higher costs. We were the only participant to resolubilize these desiccated proteins in boiling SDS buffer, suggesting that this approach may have been suboptimal for these samples, however further experiments would be necessary to draw a conclusion. The fact that at least one of the samples was apparently suboptimally resolubilized underlines that this was a real-life one-off experiment. This further emphasizes the requirement

for scrupulously standardized sample handling procedures when working with physico-chemically labile protein species. Nevertheless, the confidence with which we may draw these conclusions stems from our rigorous experimental design and the high quality quantitative data generated.

This introduces a further consideration of data quality assessment that merits brief discussion. In this study we employed the somewhat unusual number of 16 SDS-PAGE gels, generating 32 images, to compare two samples. The entire ProteoTope quantitative analysis consumed just 25% of each sample (nominally 20 μg = 2×2×5 μg), and therefore we could have generated 64 such differential 2D-PAGE gels using the same design with the nominally 80 μg protein in each sample. This high number of accurate measurements gave rise to extraordinarily precise and highly significant differential quantifications of the various abundance ratios in the samples we measured (after they had apparently been differentially solubilized). For instance, Ribonuclease A was a protein with a nominal 1:1 mixture ratio given by the ABRF. The ratios estimated for the four individual spots of this protein in **Fig. 5** ranged from 1.112 to 1.204, generating *P*-values (n = 16 per spot) between 0.042 to 1×10^{-5}. Once again, because of the meticulous experimental design, we can conclude that there was a slight difference (relative to BSA levels) in the abundance of this protein between the samples before the replicate aliquots were taken for iodination. A similar situation would apply for Horse Radish Peroxidase. Alternatively, there may have been a difference in BSA levels, against which signal intensities for both radio-isotopes were normalized. Consistent with the latter possibility, normalization of spot intensities to assumed 1:1 values of Peroxidase and Ribonuclease rather than 1:1 for BSA did give somewhat better approximation of abundance ratio estimations to those provided by the ABRF. In summary, although the extraordinarily stringent level of statistical certainty obtained here is seldom required, the availability of an analytical detection method with these technical parameters can be advantageous, especially when smaller numbers of replicates are performed on limited amounts of valuable material.

26. The weakest average protein spot intensity in this study (Spot BA_459 sample A) was 116 photo stimulated luminescence units (PSL) (11, 12). The highest was 94973 PSL (BA_2369), representing a dynamic range of 800-fold measured between protein signals in this experiment. The strongest signal was on gel 2 which had an intensity of 16800-fold above measurement background and occupied almost 60000 levels of the 16 bit data spectrum. The FLA3000 we used is a well characterized instrument whose technical specifications are available from the manufacturer (e.g. http://fujifilmlifescienceusa.com/assets/pdf/fla3000brochure.pdf).

Essentially, laser induced PSL events are recorded by a photomultiplier detector. Data are then written to a floating point matrix file which stores data logarithmically over the 65536 bits. The linear dynamic range of the Imaging Plate, although intrinsically vastly superior to alternative methods, is presently limited by the imaging device (data not shown). Briefly the Imaging Plate has at least 250-fold better dynamic range than is currently exploited by the FLA3000 imaging device.

Quantification of Proteins on Polyacrylamide Gels

Bryan John Smith

1. Introduction

Quantification of proteins is a common challenge. There are various methods described for estimation of the amount of protein present in a sample, for example, amino acid analysis and the bicinchoninic acid (BCA) method (*see* Chapters 83 and 3). Proteins may be quantified in sample solvent prior to electrophoresis and can provide an estimate of total amount of protein in a sample loaded onto a gel ***(1,2)***. These methods quantify total protein present but not of one protein in a mixture of several. For this, the mixture must be resolved. Liquid chromatography achieves this, and the various proteins may be quantified by their absorbancy at 220 nm or 280 nm. Microgram to submicrogram amounts of protein can be analyzed in this way, using microbore high-performance liquid chromatography (HPLC). A method has been published whereby theoretical extinction coefficients may be calculated for peptides, based on their sequence, though it is probably less suited to intact proteins because of the influence on UV aborption of longer sequence and structure. ***(3)***. Problems may occur if particular species chromatograph poorly (such as hydrophobic polypeptides on reverse-phase chromatography).

An alternative is polyacrylamide gel electrophoresis (as the mixture-resolving step) followed by protein staining and densitometry. Exceptions are small peptides that are not successfully resolved and stained in gels, and which are more suited to chromatography ***(3)***. Microgram to submicrogram amounts of protein (of more than a few kilodaltons in size) may be quantified in this way. Not every protein stain is best suited to quantification in gels, however. The popular noncolloidal Coomassie gel stains such as PAGE blue ‘83 are not suitable. As discussed by Neuhoff et al. ***(4)***, staining by Coomassie dye is difficult to control—it may not fully penetrate and stain dense bands of protein, it may demonstrate a metachromatic effect (whereby the protein–dye complex may

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

show any of a range of colors from blue through purple to red), and it may be variably or even completely decolorized by excessive destaining procedures (because the dye does not bind covalently). As a consequence, stoichiometric binding of Coomassie dye to protein is commonly not achieved. Sensitive silver stains are commonly used to detect rare proteins at levels at levels of the order of 0.05 ng/mm^2 in two-dimensional (2-D) gels, for example, but they, too, are not suitable for quantification. For various reasons, proteins vary widely in their stainability by silver—some do not stain at all, others may show a metachromatic effect. Use of silver staining for quantification is complicated by other factors, too—such as the difficulty in obtaining staining throughout the gel, not just at the surface. This subject is reviewed at greater length in **ref.** *5*, but in summary it may be said that while silver stain methods have great sensitivity, they are problematical for quantification purposes.

One quantitative staining method generates negatively stained bands ***(6)***. The technique generates a white background of precipitated zinc salt, against which clear bands of protein (where precipitation is inhibited). This may be viewed by dark field illumination. The gel may be scanned at this stage, the negative staining being approximately quantitative (for horse myoglobin) in a range from about 100 ng/mm^2 to 2 µg/mm^2 or more. Sensitivity may be improved by staining of the background by incubation with tolidine. The method was described for 12% and 15% T gels, but the degree of zinc salt precipitation and subsequent toning is dependent upon %T and at closer to 20%T the toning procedure may completely destain the gel, restricting the usefulness of the method.

A number of other quantitative staining methods have been discussed in the literature. Notably, Neuhoff et al. ***(4)*** have made a thorough study of various factors affecting protein staining by Coomassie Brilliant Blue G-250 (0.1% [w/v] Color Index number 42655 in 2% [w/v] phosphoric acid, 6% [w/v] ammonium sulfate). This colloidal stain does not stain the background in a gel and so washing can give crystal-clear backgrounds. A method derived from that of Reisner et al. ***(7)*** has proven useful for quantification of proteins on gels. The stain used is 0.4% (w/v) Brilliant Blue G250 in 3.5% (w/v) perchloric acid. This method is described below.

O'Keefe ***(8)*** described a method whereby cysteine residues are labeled with the thiol-specific reagent monobromobimane. On transillumination (at λ = 302 nm) labeled bands fluoresce. However, the method requires quantitative reaction of cysteines, which may be totally lacking in some polypeptides, and a nominal detection limit of 10 pmol of cysteine is claimed. Better luminescent stains have been developed by Molecular Probes—the Sypro family of dyes. The Sypro Ruby stain is possibly the most sensitive of these, approaching the sensitivity of silver stains. The method for use of this stain is given below.

2. Materials

2.1. Colloidal Coomassie Brilliant Blue G Method

1. A suitable scanning densitometer, for example, the Molecular Dynamics Personal Densitometer SI with Image Quant software or the Bio-Rad Fluor S MultiImager with Multi Analyst software. Such equipment can scan transparent objects such as wet gels, gels dried between transparent films, and photographic film, and digitize the image that may then be analyzed.
2. Protein stain: 0.4% (w/v) Coomassie Brilliant Blue G (C.I. 42655; Sigma, code B0770, 90% by elemental analysis) in 3.5% (w/v) perchloric acid (*see* **Note 1**). Stable for months at room temperature, in the dark. Beware the low pH of this stain. Use personal protective equipment (coat, gloves, safety glasses). Use fresh, undiluted stain, as supplied. For best results, do not re-use the stain.
3. Destaining solution: Distilled water.

2.2. Sypro Ruby Method

1. Equipment for scanning fluorescent bands on gels, for example, the Bio-Rad Fluor S MultiImager with Multi Analyst software, which can be used to photographically record or scan wet gels, allowing repeated scanning procedures (as staining or destaining proceeds). Simple viewing of stained bands may be done under a hand-held 300-nm UV lamp or on a transilluminator. Protect eyes with UV-opaque glasses. The Sypro dye may be excited at 280 or 450 nm and emits at 610 nm.
2. Protein stain: Sypro Ruby gel stain (Molecular Probes, product number S-12000 or S-12001) (*see* **Note 2**). This stain is stable at room temperature in the dark. Exact details of the stain are not revealed but according to the manufacturer, the stain contains neither hazardous nor flammable materials. Use fresh, undiluted stain only.
3. Destain: Background may be reduced by rinsing in water.
4. Clean dishes, free of dust that might contribute to background staining.

3. Method

3.1. Colloidal Coomassie Brilliant Blue G Method

1. At the end of electrophoresis, wash the gel for a few minutes with several changes of water (*see* **Note 3**), then immerse the gel (with gentle shaking) in the colloidal Coomassie Brilliant Blue G protein stain. This time varies with the gel type (e.g., 1.0–1.5 h for a 1–1.5 mm thick sodium dodecyl sulfate [SDS] polyacrylamide gel slab), but cannot really be overdone. Discard the stain after use, for its efficacy declines with use.
2. At the end of the staining period, decolorize the background by immersion in distilled water, with agitation, and a change of water whenever it becomes colored. Background destaining is fairly rapid, giving a clear background after a few hours (*see* **Notes 4** and **5**).

3. Measure the extent of blue dye bound by each band by scanning densitometry. Compare the dye bound by a sample with those for standard proteins run and stained in parallel with the sample, on the same gel (*see* **Notes 6–8** and **11–17**).

3.2. Sypro Ruby Method

1. At the end of electrophoresis, rinse the gel in water briefly, put it into a clean dish and then cover it with Sypro Ruby gel stain solution. Gently agitate until staining is completed, which may take up to 24 h or longer (*see* **Note 9**). Overstaining will not occur during prolonged stained. Do not let the stain dry up on the gel during long staining procedures. Discard the stain after use, for it becomes less efficacious with use. During the staining procedure the gel may be removed from the stain and inspected under UV light to monitor progress. If the staining is insufficient, the gel may be replaced in the stain for further incubation.
2. Destain the background by washing the gel in a few changes of water for 15–30 min.
3. Measure the extent of dye bound, that is, the luminescence, by each band by scanning. Compare the dye bound by a sample with that for standard proteins run and stained in parallel with the sample, on the same gel (*see* **Note 10**).

4. Notes

1. The Coomassie Brilliant Blue G stain mixture may be readily made from the components but a commercially-available alternative is the GelCode blue stain reagent from Pierce (product no. 24590 or 24592). Details of the stain components are not divulged, other than they also include Coomassie (G250), but the stain is used in the same way as described for the reagent prepared as described above. Pierce recommend that their GelCode stain is agitated before use, to disperse any dye aggregates that may have formed therein.
2. Molecular Probes do not reveal the components of their reagent. Although more sensitive than the blue stain, it does require UV irradiation for detection.
3. The water wash that precedes staining by Coomassie Brilliant Blue G is intended to wash away at least some SDS from the gel, and so speed up destaining of the background. However, it should be remembered that proteins are not fixed in the gel until in the acidic stain mixture and consequently some loss of small polypeptides may occur in the wash step. Delete the wash step if this is of concern, or employ a fixing step immediately after electrophoresis, for example, methanol/glacial acetic acid/water: 50:7:43, by volume for 15–30 min, followed by water washing to remove the solvent and acid.
4. Destaining of the background may be speeded up by frequent changes of the water, and further by inclusion in this wash of an agent that will absorb free dye. Various such agents are commercially available (e.g.,

Cozap, from Amika Corp.), but a cheap alternative is a plastic sponge of the sort used to plug flasks used for microbial culture. The agent absorbs the stain and is subsequently discarded. The background can be made clear by these means, and the stained bands remain stained while stored in water for weeks. They may be restained if necessary.

5. The Coomassie Brilliant Blue G-stained gel may be dried between transparent sheets of dialysis membrane or cellophane (available commercially, e.g., from Novex) for storage and later scanning. Beware that bubbles or marks in the membrane may add to the background noise upon scanning.
6. Heavily loaded samples show up during staining with Coomassie Brilliant Blue G, but during destaining the blue staining of the proteins becomes accentuated. Bands of just a few tens of ng are visible on a 1 mm-thick gel (i.e., the lower limit of detection is < 10 ng/mm^2). Variability may be experienced from gel to gel, however. For example, duplicate loadings of samples on separate gels, electrophoresed and stained in parallel, have differed in staining achieved by a factor of 1.5, for reasons unknown. Furthermore, different proteins bind the dye to different extents: horse myoglobin may be stained twice as heavily as is bovine serum albumin, although this, too, is somewhat variable. While this Coomassie Brilliant Blue G is a good general protein stain, It is advisable to treat sample proteins on a case by case basis.
7. It is a requirement of this method that dye is bound stoichiometrically to polypeptide over a useful wide range of sample size. The staining by Coomassie Brilliant Blue G may be quantitative, or nearly so, from about 10 to 20 ng/mm^2 up to large loadings of 1–5 µg/mm^2. Concentrated protein solutions may be diluted to fall within the useful range. A general point may be made, that whatever method is used for quantification, it should be checked with the protein of interest, to confirm that staining is linear (quantitative) over the range of sample size being used. The stoichiometry of dye binding is subject to some variation, such that standard curves may be either linear or slightly curved, but even the latter case is acceptable provided standards are run on the same gel as samples.
8. Because performance of the Coomassie Brilliant Blue G stain is variable it essential to run and stain standards and samples on the same gel, and to do so in duplicate.
9. The Sypro Ruby method allows for periodic observation and further staining if required. It can be the case that for small loadings, however, prolonged staining (24 h or more) may be required to obtain best sensitivity. The stained gel may be dried for storage but can then lose luminescence.
10. The Sypro Ruby method is subject to the same sort of variation as the Coomassie Brilliant Blue G method, from gel to gel with standard curves being linear or slightly curved. Generally the Sypro Ruby method is more

sensitive than the Coomassie Brilliant Blue G method, for instance about fivefold more so for bovine serum albumin. However, protein to protein variation may apparently be greater in the case of the Sypro Ruby stain. For instance, horse myoglobin binds about 10-fold less dye than bovine serum albumin does. Thus in one experiment, the minimum amount of bovine serum albumin detectable after Sypro Ruby staining was about 5 ng/mm^2 (about four- to fivefold more sensitive than samples stained in parallel by the Coomassie Brilliant Blue G method), whereas the minimum amount of horse myoglobin detectable was about 50 ng/mm^2 (similar to that detectable by the Coomassie Brilliant Blue G stain). It is therefore recommended that samples and standards are run and stained in parallel on the same gel, in duplicate.

11. Best quantification is achieved after having achieved good electrophoresis. Adapt the electrophoresis as necessary to achieve good resolution, lack of any band smearing or tailing, and lack of retention of sample at the top of the gel by aggregation. For stains where penetration of dense bands may be a problem, avoid dense bands by reducing the size of the loaded sample and/or electrophoresing the band further down the length of the gel (to disperse the band further) and/or use lower %T gel. Thin gels, of 1 mm thickness or less, allow easier penetration of dye throughout their thickness. Gradient gels have a gradient of pore size that may cause variation of band density and background staining. Use nongradient gels if this is a problem.
12. For absolute quantification of a band on a gel, accurate pipetting is required, as is a set of standard protein solutions that cover the concentration range expected of the experimental sample. Ideally, adjust the concentrations of the various standards and a sample so that the volume of each that is loaded onto the gel is the same and the need for pipet adjustment is minimized. Run and stain these standard solutions at the same time and if possible on the same gel, as the experimental sample in order to reduce possible variations in band resolution or staining, background destaining and so on. Ideally the standard protein should be the same as that to be quantified but if, as is commonly the case, this is impossible then another protein may be used (while recognizing that this protein may bind a different amount of dye from that by the experimental protein, so that the final estimate obtained may be in error). The standard protein should have similar electrophoretic mobility to the proteins of interest, so that any effect such as dye penetration, due to pore size, is similar. Make the standard protein solution by dissolving a relatively large and accurately weighed amount of dry protein in water or buffer, and dilute this solution as required. If possible, check the concentration of this standard solution by alternative means (say amino acid analysis). Standardize treatment of samples in preparation for electrophoresis—treating of sample

solutions prior to SDS-PAGE may cause sample concentration by evaporation of water for instance. To minimize this problem heat in small (0.5 mL) capped Eppendorf tubes, cool, and briefly centrifuge to take condensed water back down to the sample in the bottom of the tube.

13. When analyzing the results of scanning, construct a curve of absorbency vs protein concentration from standard samples and compare the experimental sample(s) with this. Construct a standard curve for each experiment.
14. If comparing the abundance of one protein species with others in the same sample, then standards are not required, provided that no species is so abundant that dye binding becomes saturated. Be aware that such relative estimates are approximate, as different proteins bind dye to different extents.
15. It is sometimes observed in electrophoresis that band shape and width are irregular—heavily loading a gel can generate a broad band that may interfere with the running of neighboring bands, for instance. It is necessary to include all of such a band for most accurate results.
16. Avoid damage to the gel—a crack can show artificially as an absorbing band (or peak) on the scan. Gels of low %T are difficult to handle without damage, but they may be made tougher (and smaller) by equilibration in aqueous ethanol, say, 40% (v/v) ethanol in water, 1 h or so. Too much ethanol may cause the gel to become opaque, but if this occurs merely rehydrate the gel in a lower % (v/v) ethanol solution. A gradient gel may assume a slightly trapezoid shape upon shrinkage in ethanol solutions—this makes scanning tracks down the length of the gel more difficult. When scanning, eliminate dust, trapped air bubbles, and liquid droplets, all of which contribute to noisy baseline.
17. Methods have been described for quantification of submicrogram amounts of proteins that have been transferred from gels to polyvinylidene difluoride or similar membrane (e.g., ***9***). A Sypro dye blot stain equivalent to the method described above for gels is available from Molecular Probes. Note, however, that transfer from gel to membrane need not (indeed, usually does not) proceed with 100% yield, so that results do not necessarily accurately reflect the content of the original sample.

Using SDS-PAGE and Scanning Laser Densitometry to Measure Yield and Degradation of Proteins

Aaron P. Miles and Allan Saul

1. Introduction

A variety of techniques are available for the quantification of proteins, their degradation products and other impurities. Densitometry is particularly useful due to its sensitivity, accuracy and versatility, and it can be applied to proteins in gels or on membranes and used with numerous detection methods. In addition to being accurate, sensitive and reproducible, the technique is cost-effective, simple, and does not require a high degree of specialized training, yet provides technical advantages over other available tools. For example, Vuletich and Osawa showed that densitometry following SDS-PAGE and electroblotting was 20-fold more sensitive than HPLC at detecting oxidatively modified myoglobin ***(1)***. In addition, Morçöl and Subramanian reported the development of a sensitive Ponseau-S-stained dot blot/densitometric protein assay that was less subject to interference by pH, detergent and other reagents than the commonly used Bradford protein assay ***(2)***. More recently, Zhu et al. and Miles et al. reported a quantitative densitometric method that measures host cell derived impurity levels on immunoblots of recombinant proteins expressed in *E. coli* ***(3, 4)***. This method was shown to be at least 20 times more sensitive than a commercially available ELISA kit designed to measure host cell impurity levels ***(3)***. Other groups have reported on the utility of gel or fluorograph densitometry, using multiple detection methods, in carbohydrate analysis ***(5)***, taxonomic and forensic applications ***(6)***, as a clinical diagnostic tool in Balkan nephropathy ***(7)*** and in the analysis of high density lipoproteins ***(8)***, as a means of quantifying relative levels of excretory-secretory polypeptides synthesized *in vitro* by *Schistosoma mansoni* daughter sporocysts ***(9)***, and for analyzing adsorption of proteins and an oligodeoxynucleotide in Alhydrogel®-based malaria vaccine candidates ***(10)***.

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

As a typical example we describe here the analysis of recombinant proteins by SDS-PAGE and scanning laser densitometry. This approach offers advantages over other techniques for two main reasons: 1) proteolytic degradation is common among these proteins, and this method is able to accurately quantify it in both minute and large amounts, and 2) the common constituents of fermentation and refolding tanks and purification processes do not cause interference, so it can be used at any stage throughout production and purification. Analysis of a recombinant malarial protein at two different stages of purity will be used to illustrate this method.

2. Materials

1. SDS-PAGE (sodium dodecyl sulfate-polyacrylamide gel electrophoresis) equipment.
2. Coomassie Blue staining solution: 40% methanol, 10% glacial acetic acid, two PhastGel Blue R tablets (Amersham Biosciences, Piscataway, NJ) per liter.
3. Coomassie Blue destaining solution: 5% methanol, 10% glacial acetic acid.
4. 0.45-micron filtration unit.
5. Concentrated, diafiltered test protein (Pvs25H) fermentation culture supernatant.
6. Purified test protein (Pvs25H) solution.
7. Personal Densitometer SI with ImageQuant software (Molecular Dynamics Inc., Sunnyvale, CA, ***[11]***).

3. Methods

The methods described below outline (1) the running of SDS-PAGE gels followed by visualization with Coomassie Blue, and (2) scanning and analyzing the gels using laser densitometry and ImageQuant software.

3.1. SDS-PAGE

1. Load the gel with samples as desired, and run according to the manufacturer's instructions.
2. Filter the staining solution using a 0.45 µm filtration unit (*see* **Note 1**).
3. Add staining solution to the gel, bring to a boil in a microwave oven, and agitate for 30 min (*see* **Notes 2** and **3**).
4. Pour off staining solution, add destaining solution, bring to a boil, and agitate for 15 min (*see* **Note 4**).
5. Change destaining solution, bring to a boil again, and continue agitation for 15 more min.
6. Change destaining solution once more, bring to a boil, and continue destaining until gel background is clear or almost clear, approximately 10 min. Take care not to overly destain the gel as minor protein bands can disappear (*see* **Note 5**).
7. Place the gel in water until scanned. **Fig. 1** shows a nonreduced 4–20% Tris-glycine SDS-PAGE gel that contains standards of purified Pvs25H (a recombinant form of

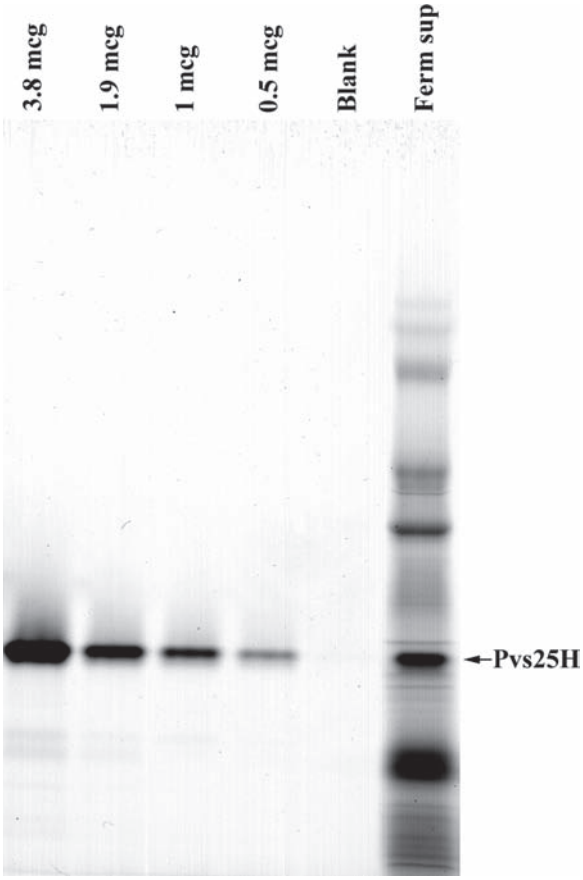

Fig. 1. SDS-PAGE of Pvs25H Fermentation Culture Supernatant with Purified Pvs25H Standards. Nonreduced 4–20% Tris-glycine SDS-PAGE Coomassie Blue-stained gel showing purified Pvs25H standards and concentrated, diafiltered fermentation culture supernatant. Purified Pvs25H was loaded in the indicated amounts for comparison to Pvs25H in the fermentation supernatant.

the 25 kDa ookinete suface protein from the malaria parasite *Plasmodium vivax*, ***[12]***) and a concentrated, diafiltered fermentation culture supernatant of the same protein. **Fig. 2** shows a reduced 15% acrylamide gel loaded with the same purified protein that was subjected to 37°C storage for up to 14 days to monitor stability (*see* **Note 6**). This protein is heavily disulfide bonded and must be reduced in order to visualize the degradation occurring over time. These gels will serve as examples of two applications of scanning laser densitometry: (1) monitoring low levels of degradation in a highly purified protein, and (2) quantifying yields of a protein recovered in a fermentation broth not yet subject to purification.

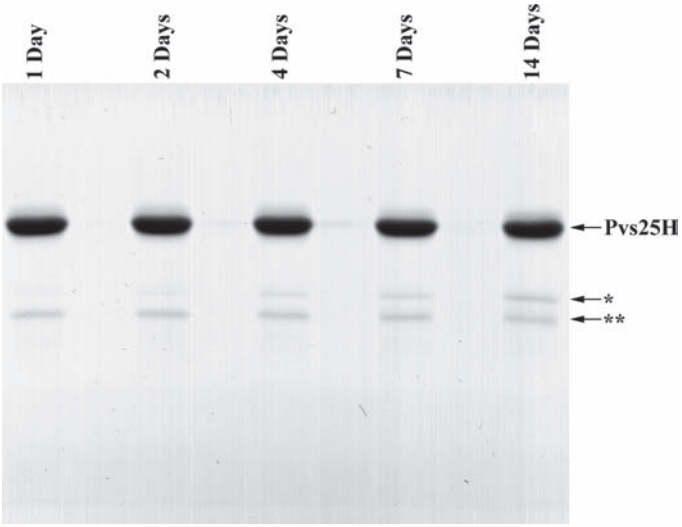

Fig. 2. SDS-PAGE of Purified Pvs25H Stored at 37°C. Reduced 15% SDS-PAGE Coomassie Blue-stained gel showing samples taken at the indicated time points during storage at 37°C. All protein loads are 2 µg, separated by blank lanes. *A minor band accumulating with time whose sequence corresponds to cleavage at a single site within Pvs25H. **A minor band (Pvs25H-derived) present in final purified Pvs25H, not increasing upon storage. This type of gel was chosen to better resolve Pvs25H, which migrates diffusely in a gradient gel (see **Fig. 1**).

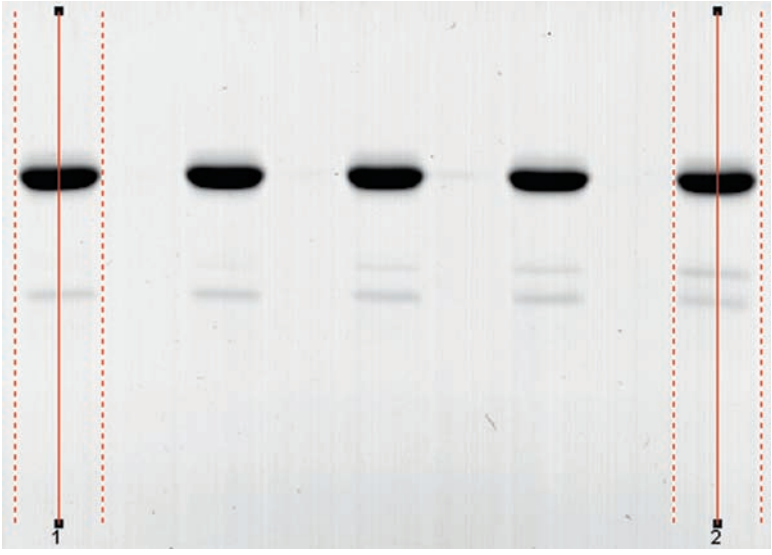

Fig. 3. Gel from Fig. 2 with Lines Drawn in ImageQuant for Analysis. Shown is the same gel as in **Fig. 2**, with lines drawn down two lanes using ImageQuant. These lines define the length and width of the areas being analyzed. Lengths and widths are adjusted to encompass all protein in each lane. These lines give rise to the line graphs shown in **Fig. 5**.

3.2. Laser Densitometry

1. Scan the gel according to manufacturer's instructions, ensuring that the lanes of the gel run straight from the top to the bottom of the scanning bed.
2. Draw an encompassing line for analysis down each lane of interest and widen the line appropriately. Include in the analyzed area of each lane enough length from top to bottom and enough width to envelope all visible protein bands. **Figs. 3** and **4** illustrate this, using the same gels as shown in **Figs. 2** and **1**, respectively.
3. Create a line graph for each line drawn. Examples are shown in **Fig. 5**, which shows representations (in optical density units) of purified Pvs25H stored for one (A) and 14 (B) days at 37°C, and **Fig. 6**, which shows Pvs25H in concentrated, diafiltered

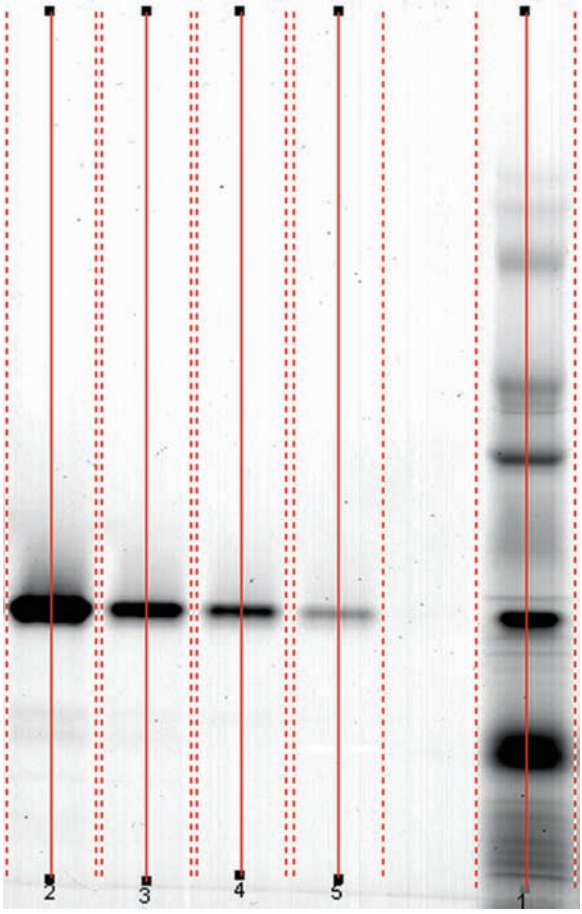

Fig. 4. Gel from Fig. 1 with Lines Drawn in ImageQuant for Analysis. Shown is the same gel as in **Fig. 1**, with lines drawn down each lane containing protein. The line drawn down the fermentation supernatant lane gives rise to the line graph shown in **Fig. 6**.

fermentation culture supernatant. Note in **Fig. 5B** the appearance of a minor degradation product over time (peak 2), and it's corresponding band in **Fig. 2**.

4. Adjust all relevant settings to give the most accurate representation of the baseline signal. Options for this within the ImageQuant software may include "automatic"

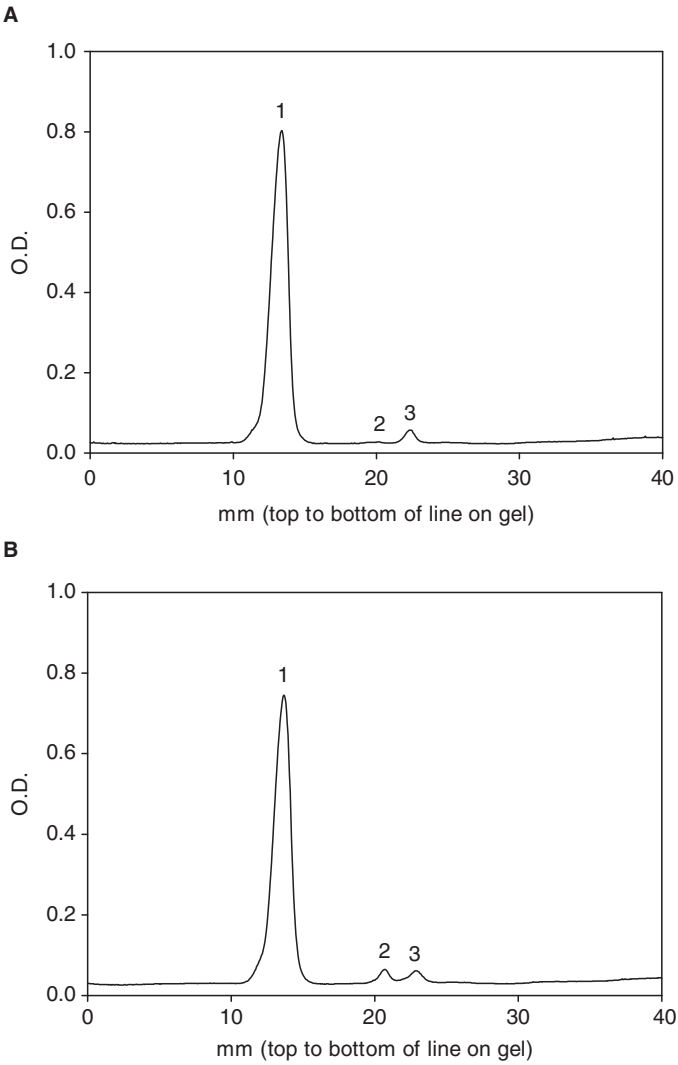

Fig. 5. Line Graphs of Pvs25H at 37°C, Days 1 and 14. The line graphs for the lines drawn in **Fig. 3** are shown, with (A) showing day 1 and (B) showing day 14. These are graphical representations of the optical density vs. millimeters measured by the scanner at each point from the top to the bottom of the drawn lines. In these cases, the baselines were detected by simply making minor adjustments to the peak detection parameters (baselines not shown). Note the increase in the area of peak 2, a minor degradation product, from day 1 to day 14.

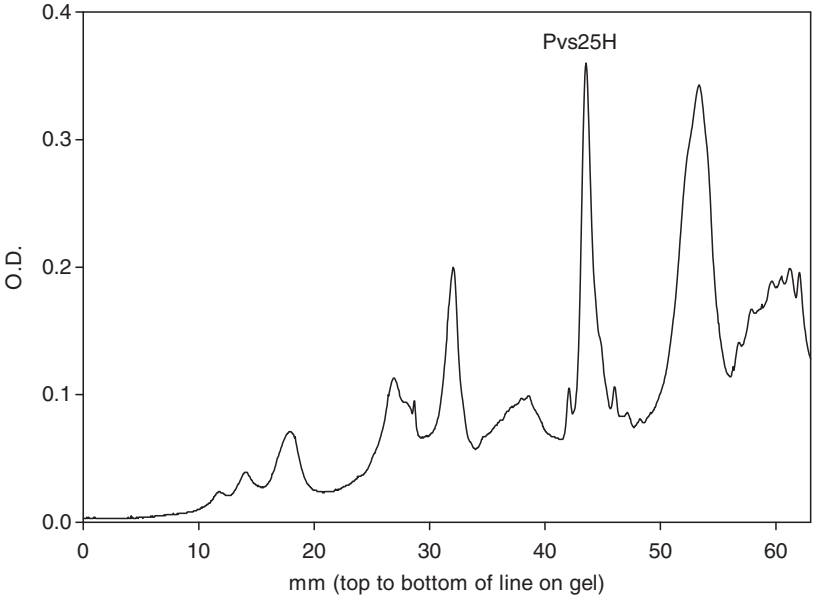

Fig. 6. Line Graph of Fermentation Culture Supernatant. The line graph for the line drawn in **Fig. 4** is shown. In this case, the baseline (not shown) was taken as the lowest point (point of lowest optical density [*see* **Note 9**]). The peak corresponding to Pvs25H is indicated. The line graphs for the standard lanes are not shown to avoid redundancy.

(the baseline is detected by the software based on manually adjusted settings to appropriately identify peaks), "lowest point" (the most transparent part of the lane is taken as the baseline), and point-by-point manipulation. There are other software programs available that allow more customized identification and tuning of the baseline and peaks (e.g., PeakFit). It is then usually necessary to redefine the peaks by hand, rather than letting the software do it, in order to fine tune where each peak begins and ends (*see* **Note 7**). Once the peaks are defined, they are integrated (i.e., the area under each peak is calculated by the software). In this way one quantifies the proportion of one or several peaks in relation to all others, and determines both the total protein in the lane and the percent of each protein of interest.

6. Using the areas generated from the integration of each Pvs25H standard peak, create a graph of area counts vs. known protein load using the appropriate software (e.g., Excel, SigmaPlot). Determine the linear range, fit a line for the data points of that range, and obtain an equation for the line. Using this method, the amount of Pvs25H in the fermentation supernatant lane of **Fig. 1** was found to be 1.49 µg. This corresponds to a total production of 500 mg from a 60 L fermentation (*see* **Note 8**). Likewise, the amount of full-length (nondegraded) purified Pvs25H was found to be decreasing with time, while a minor degradation product was increasing.

The purity of the main band dropped from 95.3% at day 1 to 94.5% by day 14. The degradation rate is thus found to be 0.06% per day at 37°C.

4. Notes

1. It is especially important when using this method to filter the Coomassie Blue stain prior to use. This eliminates large particles that otherwise stick to the gel and give rise to high background readings that interfere with quantification. Filtered stain leads to much cleaner, more transparent gels. To accelerate the filtering process and to help prevent clogging of the filter, use a conveniently sized filtration unit (e.g., 1 L) and pour the solution in slowly, allowing it to filter through, before pouring more. If too much solution is poured in all at once, large particles quickly block the filter. It is not necessary to use a 0.22 µm filter, which will become clogged more quickly anyway.
2. Microwaving allows staining and destaining to proceed much more quickly than at room temperature, with no loss in sensitivity.
3. Standard staining and destaining times must be adhered to, especially when gel-to-gel comparisons are to be made. Staining for less than 30 minutes can result in non-uniformity in the binding of the Coomassie Blue dye to the proteins, especially in bands containing large amounts of protein. This can in turn cause some underestimation in the analysis of those bands.
4. A sponge or paper towel can be added to soak up stain from the gel, but this is not necessary, especially when microwaving, as the gel will quickly destain.
5. It is unnecessary to destain the gel until the background is completely clear. A small amount of background stain will generally not be detected as a protein peak or peaks by the software, and will become part of the baseline. Higher concentrations of acrylamide in gradient gels require slightly more time to destain, but with more extended destaining times protein bands (especially low molecular weight bands) can disappear. This will affect quantification of yield and purity and should be avoided.
6. After purification of Pvs25H, it was determined that this protein is better resolved on a 15% SDS-PAGE gel than on a 4–20% gradient gel (compare **Fig. 1**, 3.8 µg lane, to **Fig. 2**, 1 Day lane). This serves to illustrate an important point to consider when performing densitometry: protein quantification is more difficult to perform when the protein runs as a diffuse band. Consequently, the error in this technique increases with poorer resolution. While a good estimate can still be achieved, peak identification can be problematic. If necessary, different gel types should be tested to find the one that best resolves each protein of interest.
7. One is often interested in the proportion of one peak (the protein of interest) in relation to all others. Defining the peaks by hand allows the peak of

interest to be isolated while, for instance, treating all other peaks as one. A percent yield is then easily calculated.

8. Scanning laser densitometry was found to be especially useful during the production of Pvs25H. This is because Pvs25H is produced as two populations of molecules that migrate well separated by SDS-PAGE (see large diffuse band beneath Pvs25H in **Fig. 1**). They do, however, co-purify during the Ni-NTA capture step. Traditional protein assays (e.g., BCA, Lowry, A_{280}) performed at this point would overestimate the yield of the target protein (labeled Pvs25H in **Fig. 1**), since these other methods are incapable of distinguishing between the two forms of Pvs25H that are produced. Densitometry makes this distinction, with the added benefit that no capture step is required before an estimate of yield is given.
9. When analyzing a sample that is not yet purified, determining the baseline is usually more difficult than when working with purified material. Each sample must be analyzed on a case-by-case basis as appropriate.

Acknowledgments

The authors wish to thank Anthony W. Stowers, Richard L. Shimp, Vu Nguyen, Jacqueline Glen, Brian Henderson, and Jin Wang for their contributions in producing and purifying the recombinant Pvs25H protein, and Holly McClellan for expert technical assistance.

Rapid and Sensitive Staining of Unfixed Proteins in Polyacrylamide Gels with Nile Red

Joan-Ramon Daban, Salvador Bartolomé, Antonio Bermúdez, and F. Javier Alba

1. Introduction

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) is one of the most powerful methods for protein analysis ***(1,2)***. However, the typical procedures for the detection of protein bands after SDS-PAGE, using the visible dye coomassie blue and silver staining, have several time-consuming steps and require the fixation of proteins in the gel. This chapter describes a rapid and very simple method for protein staining in SDS gels developed in our laboratory ***(3–5)***. The method is based on the fluorescent properties of the hydrophobic dye Nile red (9-diethylamino-5*H*-benzo[α]phenoxazine-5-one; *see* **Fig. 1**), and allows the detection of < 10 ng of unfixed protein per band about 5 min after the electrophoretic separation. Furthermore, it has been shown elsewhere ***(6,7)*** that, in contrast to the current staining methods, Nile red staining does not preclude the direct electroblotting of protein bands and does not interfere with further staining, immunodetection and sequencing (*see* Chapter 71).

Nile red was considered a fluorescent lipid probe, because this dye shows a high fluorescence and intense blue shifts in presence of neutral lipids and lipoproteins ***(8)***. We have shown that Nile red can also interact with SDS micelles and proteins complexed with SDS ***(3)***. Nile red is nearly insoluble in water, but is soluble and shows a high increase in the fluorescence intensity in nonpolar solvents and in presence of pure SDS micelles and SDS–protein complexes. In the absence of SDS, Nile red can interact with some proteins in solution but the observed fluorescence is extremely dependent on the hydrophobic characteristics of the proteins investigated ***(8,9)***. In contrast, Nile red has similar fluorescence properties in solutions containing different kinds of proteins associated with SDS, suggesting that this detergent induces the formation of structures having

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

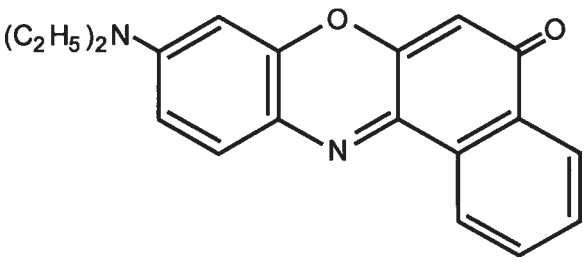

Fig. 1. Structure of the noncovalent hydrophobic dye Nile red.

equivalent hydrophobic properties independent of the different initial structures of native proteins ***(3)***. In agreement with this, X-ray scattering and cryoelectron microscopy results have shown that proteins having different properties adopt a uniform necklace-like structure when complexed with SDS ***(10)***. In these structures the polypeptide chain is mostly situated at the interface between the hydrocarbon core and the sulfate groups of the SDS micelles dispersed along the unfolded protein molecule.

The enhancement of Nile red fluorescence observed with different SDS–protein complexes occurs at SDS concentration lower than the critical micelle concentration of this detergent in the typical Tris–glycine buffer used in SDS-PAGE ***(3)***. Thus, for Nile red staining of SDS-polyacrylamide gels ***(4)***, electrophoresis is performed in the presence of 0.05% SDS instead of the typical SDS concentration (0.1%) used in current SDS-PAGE protocols. This concentration of SDS is high enough to maintain the stability of the SDS–protein complexes in the bands, but is lower than SDS critical micelle concentration and consequently precludes the formation of pure detergent micelles in the gel ***(4,5)***. The staining of these modified gels with Nile red produces very high fluorescence intensity in the SDS–protein bands and low background fluorescence (*see* **Fig. 2**). Furthermore, under these conditions (*see* details in **Subheading 3.**), most of the proteins separated in SDS gels show similar values of the fluorescence intensity per unit mass. A review about the physicochemical basis of Nile red staining has been published elsewhere ***(11)***.

2. Materials

All solutions should be prepared using electrophoresis-grade reagents and deionized water and stored at room temperature (exceptions are indicated). Wear gloves to handle all reagents and solutions and do not pipette by mouth. Collect and dispose all waste according to good laboratory practice and waste disposal regulations.

1. Nile red. Concentrated stock (0.4 mg/mL) in dimethyl sulfoxide (DMSO). This solution is stable for at least 3 months when stored at room temperature in a glass bottle wrapped in aluminum foil to prevent damage by light. **Handle this solution**

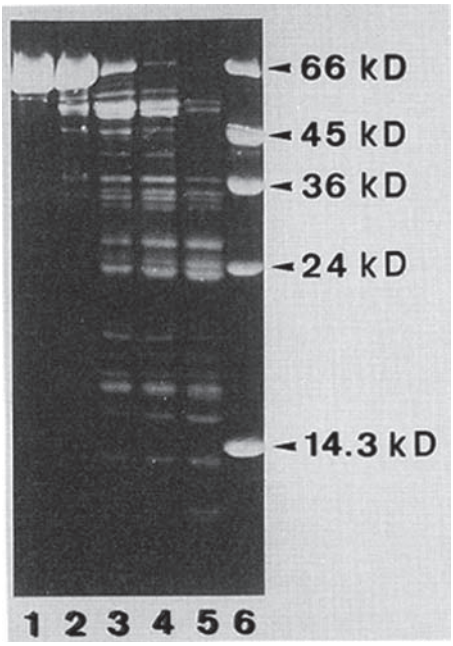

Fig. 2. Example of Nile red staining of different proteins and peptides in 0.05% SDS–15% polyacrylamide gels. The protein molecular weight markers (*lane 6*, from top to bottom: BSA, ovalbumin, glyceraldehyde-3-phosphate dehydrogenase, trypsinogen, and lysozyme), and BSA digested with increasing amounts of trypsin (*lanes 1–5*), were stained for 5 min with a solution of Nile red in water prepared by quick dilution of a stock solution of this dye in DMSO (*see* **Subheading 3.**).

with care, DMSO is flammable, and, in addition, this solvent may facilitate the passage of water-insoluble and potentially hazardous chemicals such Nile red through the skin. Nile red can be obtained from Sigma Chemical (St. Louis, MO).

2. The acrylamide stock solution and the resolving and stacking gel buffers are prepared as described in Chapter 21.
3. 2× Sample buffer: 4% (w/v) SDS, 20% (v/v) glycerol, 10% (v/v) 2-mercaptoethanol, 0.125 *M* Tris-HCl, pH 6.8; bromophenol blue (0.05% [w/v]) can be added as tracking dye.
4. 10× Electrophoresis buffer: 0. 5% (w/v) SDS, 0.25 *M* Tris, 1.92 *M* glycine, pH 8.3 (do not adjust the pH of this solution).
5. Plastic boxes for gel staining. Use opaque polypropylene containers (e.g., 21 × 20 × 7.5 and 12 × 7.5 × 7 cm for large [20 × 16 × 0.15 cm] and small [8 × 6 × 0.075 cm] gels, respectively) with a close-fitting lid to allow intense agitation without spilling the staining solution.
6. Orbital shaker for the agitation of the plastic boxes during gel staining.
7. Transilluminator equipped with midrange ultraviolet (UV) bulbs (~300 nm) to excite Nile red ***(3,4)***. A transilluminator with a cooling fan (e.g., Foto UV 300 [Fotodyne Inc., Harland, WI] or similar) is very convenient to prevent thermal

damage of the gel when long exposures are necessary (*see* **Subheading 3., step 11**). UV light is dangerous to skin and particularly to eyes. UV-blocking goggles and a full face shield, and protective gloves and clothing, should be worn when the stained gel is examined using the transilluminator. For the photography, we place the transilluminator with the gel and the photographic camera inside a home-made cabinet with opaque (UV-blocking) curtains to prevent operator exposure to UV light. Alternatively, the gel can be transilluminated inside a compact darkroom of a documentation system provided with a charge-coupled device (CCD) camera (e.g., Gel Doc 1000 from Bio-Rad Laboratories [Hercules, CA]). To avoid the problems associated with UV light, we have constructed a transilluminator that works in the visible region (~540 nm; green-light) and can also be used for the excitation of Nile red stained bands ***(12)***.

8. Photographic camera (e.g., Polaroid [Cambridge, MA] MP-4 camera) or a CCD camera.
9. Optical filters. With the Polaroid camera and UV transilluminator use the Wratten (Kodak [Rochester, NY]) filters number 9 (yellow) and 16 (orange) to eliminate the UV and visible light from the transilluminator. Place the two filters together in the filter holder of the camera so that filter 16 is on top of filter 9 (i.e., filter 16 should be facing towards the camera lens). Store the filters in the dark and protect them from heat, intense light sources and humidity. With the CCD camera and UV transilluminator we have used the filter 590DF100 (Bio-Rad). Wratten filter number 26 (red) is required for both Polaroid and CCD cameras when the bands are visualized with the green-light transilluminator.
10. Photographic films. The following Polaroid instant films can be used for the photography of the red bands (maximum emission at ~640 nm ***[3]***) seen after staining: 667 (ISO 3000, panchromatic, black-and-white positive film), 665 (ISO 80, panchromatic, black-and-white positive/negative film), and 669 (ISO 80, color, positive film). Store the films at 4°C.
11. Negative-clearing solution: 18% (w/v) sodium sulfite.
12. Wetting agent for Polaroid 665 negatives (Kodak Photo-Flo diluted at 1:600).
13. Different densitometers available commercially can be used for the densitometry of negative films. Alternatively, the images obtained with a CCD camera can be directly analyzed with the appropriate software (e.g., Molecular Analyst [Bio-Rad]).

3. Method

The method described in this part gives all the details for the staining SDS-polyacrylamide gels with Nile red. *See* **Note 1** for Nile red staining of gels without SDS. Unless otherwise indicated, all operations are performed at room temperature.

1. Typically we prepare 15% acrylamide–0.4% *bis*-acrylamide separating gel containing 0.05% SDS (*see* **Note 2**), 0.375 *M* Tris-HCl, pH 8.8. The stacking gel contains 6% acrylamide–0.16% *bis*-acrylamide, 0.05% SDS (*see* **Note 2**), 0.125 *M* Tris-HCl, pH 6.8
2. Dissolve the proteins in water, add one volume of the 2× sample buffer (**Subheading 2.3.,** *see* **Note 3**), and incubate the resulting samples in a boiling-water bath for

3 min. The samples are kept at room temperature before loading them into the gel (*see* **Note 4**).

3. Place the gel sandwiched between the glass plates in the electrophoresis apparatus, fill the electrode reservoirs with 1 × electrophoresis buffer (*see* **Note 2**), and rinse the wells of the gel with this buffer.
4. Load the protein samples (about 20 and 10 µL in large and small gels, respectively), carry out electrophoresis, and at the end of the run remove the gel sandwich from the electrophoresis apparatus and place it on a flat surface.
5. Wearing gloves, remove the upper glass plate (use a spatula) and excise the stacking gel and the bottom part of the separating gel (*see* **Note 5**).
6. Add quickly 2.5 mL of the concentrated Nile red (0.4 mg/mL) staining solution in DMSO to 500 mL of deionized water previously placed in a plastic box (*see* **Note 6**). These volumes are required for staining large gels; for small gels, use 0.25 mL of the concentrated Nile red solution in DMSO and 50 mL of water.
7. Immediately after the addition of concentrated solution of Nile red to water, agitate the resulting solution vigorously for 3 s (*see* **Note 6**).
8. Immerse the gel very quickly in the staining solution, put the lid on, and agitate vigorously (*see* **Note 6**) using an orbital shaker (at about 150 rpm) for 5 min (*see* **Note 7**).
9. Discard the staining solution and rinse the gel with deionized water (4×; about 10 s) to remove completely the excess Nile red precipitated during the staining of the gel (*see* **Note 8**).
10. Wearing gloves, remove the gel from the plastic box and place it on the UV or green-light transilluminator. Turn off the room lights, turn on the transilluminator and examine the protein bands, which fluoresces light red (*see* **Note 9**). Turn off the transilluminator immediately after the visualization of the bands (*see* **Note 10**).
11. Focus the camera (Polaroid or CCD) with the help of lateral illumination with a white lamp, place the optical filters described in **Subheading 2., item 9**, in front of the camera lens and, in the dark, turn on the transilluminator and photograph the gel (*see* **Note 10**). Finally, turn off the transilluminator.
12. Develop the different Polaroid films for the time indicated by the manufacturer (*see* **Note 11**). Spread the Polaroid print coater on the surface of the 665 positive immediately after development. (The positive prints of the 667 and 669 films do not require coating.) The 665 negatives can be stored temporary in water but, before definitive storage, immerse the negatives in 18% sodium sulfite and agitate gently for about 1 min, wash in running water for 5 min, dip in a solution of wetting agent (about 5 s), and finally dry in air (*see* **Note 12**).
13. Scan the photographic negatives to determine the intensity of the Nile red stained protein bands if a quantitative analysis is required. The quantitative analysis can also be performed directly from the image obtained with a CCD documentation system (*see* **Note 13**).

4. Notes

1. Isoelectric focusing gels do not contain SDS and should be treated with this detergent after the electrophoretic run to generate the hydrophobic SDS–protein complexes specifically stained by Nile red ***(6)***. In general, for systems

without SDS we recommend an extensive gel washing (20 min in the case of 0.75-mm thick isoelectric focusing gels) with 0.05% SDS, 0.025 *M* Tris, 0.192 *M* glycine, pH 8.3, after electrophoresis. The gel equilibrated in this buffer can be stained with Nile red following **steps 6–9** of **Subheading 3.**

2. To reduce the background fluorescence after the staining with Nile red it is necessary to preclude the formation of pure SDS micelles in the gel (*see* **Subheading 1.**). Thus, use 0.05% SDS to prepare both the separating and stacking gels and the electrophoresis buffer. This concentration is lower than the critical micelle concentration of this detergent (~0.1% ***[3]***), but is high enough to allow the formation of the normal SDS–protein complexes that are specifically stained by Nile red ***(4)***.
3. Use 2% SDS in the sample buffer to be sure that all protein samples are completely saturated with SDS. Lower concentrations of SDS in the sample buffer can produce only a partial saturation of proteins (in particular in highly concentrated samples), and consequently the electrophoretic bands could have anomalous electrophoretic mobilities. The excess SDS (uncomplexed by proteins) present in the sample buffer migrates faster than the proteins and form a broad band at the bottom of the gel (*see* **Note 5** and **ref.** *4*).
4. Storage of protein samples prepared as indicated in **Subheading 3.2.** at 4°C (or at lower temperatures) causes the precipitation of the SDS present in the solution. These samples should be incubated in a boiling-water bath to redissolve SDS before using them for electrophoresis.
5. The bottom part of the gel (i.e., from about 0.5 cm above the bromophenol blue band to the end) should be excised before the staining of the gel. Otherwise, after the addition of Nile red, the lower part of the gel produces a broad band with intense fluorescence. This band is presumably caused by the association of Nile red with the excess SDS used in the sample buffer (*see* **Note 3**). In the case of long runs, bromophenol blue and the excess SDS band diffuse into the buffer of the lower reservoir and it is not necessary to excise the gel bottom.
6. Nile red is very stable when dissolved in DMSO (*see* **Subheading 2.1.**), but this dye precipitates in aqueous solutions. Since the precipitation of Nile red in water is a rapid process and this dye is only active for the staining of SDS–protein bands before it is completely precipitated ***(4,5)***, to obtain satisfactory results, it is necessary: (a) to perform all the agitations indicated in these steps (in order to favor as much as possible the dispersion of the dye); (b) to work very rapidly in the **steps 6–9** of **Subheading 3.** Furthermore, to obtain a homogeneous staining the gel has to be completely covered with the staining solution.
7. The staining time is the same for large and small gels.
8. After the water rinsing indicated in the **step 9** of **Subheading 3.**, the staining process is completely finished and the gel can be photographed immedi-

ately. It is not necessary, however, to examine and photograph the gel just after staining. Nile red stained bands are stable and the gel can be kept in the plastic box immersed in water for 1–2 h before photography.

9. About 100 ng of protein per band can be seen by naked eye (when using the green-light transilluminator it is necessary to place a Wratten filter number 26 in front of the eyes to visualize the bands). Faint bands that are not visible by direct observation of the transilluminated gel can be clearly seen in the photographic image. Very faint bands (containing as little as 10 ng of protein) can be detected by long exposure using Polaroid film. Long integration times with a CCD camera allow the detection of 5 ng of protein per band (using both UV and green-light transilluminators). To obtain this high sensitivity it is necessary to have sharp bands; broad bands reduce considerably the sensitivity.
10. Nile red is sensitive to intense UV irradiation ***(3)***, but has a photochemical stability high enough to allow gel staining without being necessary to introduce complex precautions in the protocol (*see* **Subheading 3., steps 6–9**). For long-term storage, solutions containing this dye are kept in the dark. Transillumination of the gel for more than a few minutes produces a significant loss of fluorescence intensity. Thus, transillumination time must be reduced as much as possible both during visualization and photography. The relative short exposure times (2–12 s) required for the Polaroid film 667 and the CCD documentation system allow to make several photographs with different exposure times if necessary. With films (Polaroid 665 and 669) requiring longer exposures (4–5 min) only the first photograph from each gel shows the maximum intensity in the fluorescent bands.
11. The development time of Polaroid films is dependent on the film temperature. Store the films at 4°C (*see* **Subheading 2., item 10**), but allow them to equilibrate at room temperature before use.
12. The relatively large area (7.3 × 9.5 cm) of the Polaroid 665 negative is very convenient for further densitometric measurements (*see* **Note 13**). Furthermore, this negative can be used for making prints and digital images with an adequate level of contrast (*see*, e.g., the photograph presented in **Fig. 2**). The images obtained with the CCD documentation system can be stored in the computer and printed using different printers (inkjet printers with glossy paper yield photo quality images).
13. In quantitative analyses care has to be taken to ensure that the photographic film or the CCD documentation system have a linear response for the amounts of protein under study. Use different amounts (in the same range as the analyzed protein) of an internal standard to obtain an exposure time producing a linear response. Furthermore, the internal standard is necessary to normalize the results obtained with different gels, under different electrophoretic conditions and with different exposure and development times.

Nile red can be considered as a general stain for proteins separated in SDS gels ***(4)***. However, proteins with prosthetic groups such as catalase, and proteins having anomalous SDS binding properties such as histone H5, show atypical values of fluorescence intensity after staining with Nile red ***(4)***.

Zn^{2+}-Reverse Staining Technique

Carlos Fernandez-Patron

1. Introduction

With the advent of "proteomics," many previously unidentified proteins will be isolated in gels for subsequent structural and functional characterization. It is, therefore, important that methods are available for detecting these proteins with minimal risk of modification. This chapter describes a "reverse" staining technique that facilitates the sensitive detection of unmodified proteins ***(1–9).***

The Zn^{2+} reverse staining technique exploits the ability of biopolymers (in particular, proteins and protein-SDS complexes) to bind Zn^{2+} ***(9–11)*** and that of imidazole (ImH, $C_3N_3H_4$, *see* **Note 1**) to react with unbound Zn^{2+} to produce insoluble zinc imidazolate ($ZnIm_2$). Deposition of $ZnIm_2$ along the gel surface results in the formation of a deep white stained background, against which unstained biopolymer bands contrast (as biopolymer bands bind Zn^{2+}, they locally inhibit deposition of $ZnIm_2$ and are not stained; *see* **Notes 2** and **3**).

With regard to protein analysis, reverse staining is a very gentle method of detection that does not require strong acid solutions, organic dyes, chemical modifiers or protein sensitizers. Protein interactions with Zn^{2+}, established during the reverse staining step, are abrogated by metal chelation. As such, the risk of protein modification during reverse staining is minimal and reverse stained proteins can be efficiently eluted and used in biological and enzymatic assays *(see* **Note 4** and **refs. *7–9, 15***). Proteins can also be processed for microsequencing or mass spectrometric analysis at any time after detection *(see* **Note 5** and **refs. *5–9, 13, 14***).

Another benefit of the reverse staining technique is its high sensitivity of detection (~ 10 ng protein / band in SDS-PAGE gels), which is greater than that of the Coomassie blue stain (~100 ng protein / band) and approaches the

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

sensitivity of the silver stains (1–10 ng protein / band). Indeed, reverse staining often reveals many proteins that display low affinity for Coomassie blue and are thus not detected with this stain *(see* **Note 6** and **ref. *11***).

Other advantages of the reverse staining technique include the speed of procedure, as it consumes ~15 min, thus being significantly faster than the Coomassie blue (> 1 hr) and silver (> 2 hr) stains. The reverse stained gels can be kept in water for several hours to years without loss of image or sensitivity of detection. Similar to other stains, reverse stained patterns can be analyzed densitometrically, and a gel "toning" procedure has been recently developed to preserve the image upon gel drying ***(12).***

The Zn^{2+} reverse staining technique can be applied to detect virtually any gel-separated biopolymer that binds Zn^{2+} (i.e., proteins/peptides, glycolipids, oligonucleotides, and their multimolecular complexes) (**ref. *9*** and references therein*)*. Moreover, these biopolymers are detected regardless of the electrophoresis system used for their separation *(see* **Notes 7, 8,** and **9** and **ref. *9***), which was not possible with the previously developed metal salt stains ***(1–3)***. Therefore, Zn^{2+} reverse staining is a widely applicable detection method.

The SDS-PAGE method of protein electrophoresis is probably the most popular. Thus, the author chose to describe a standard reverse staining method that works very well with SDS-PAGE. The detection of proteins, peptides and their complexes with glycolipids in less commonly used gel electrophoresis systems is addressed as well (*see* **Notes 7** to **9**).

2. Materials

Reagent- and analytical-grade zinc sulfate, imidazole, acetic acid, sodium carbonate are obtained from Sigma (St. Louis, MO).

1. Equilibration solution (1x): 0.2 M imidazole, 0.1% (w/v) SDS (*see* **Note 1**).
2. Developer (1x): 0.3 M zinc sulfate.
3. Storage solution for reverse stained gels (1x): 0.5 % (w/v) sodium carbonate.

All solutions are prepared as 10 times concentrated stocks, stored at room temperature, and diluted (1:10) in distilled water, to yield the working concentration (1x), just before use.

3. Methods

3.1. Polyacrylamide gel electrophoresis

SDS-PAGE is conducted following the method of Laemmli ***(16)***. Native PAGE is conducted following the protocol of Laemmli, except that SDS is not included in the gel and electrophoresis solutions. Conventional agarose gel electrophoresis is conducted in 0.8% agarose gels and using Tris-acetate, pH 8.0; as gel and running buffer ***(17)***.

3.2. Standard Reverse Staining of SDS-PAGE and Native PAGE Gels

The following reverse staining method detects proteins in standard polyacrylamide gels (*see* **Note 2**, **Fig. 1**). All incubations are performed under continuous gentle agitation in a plastic or glass tray with a transparent bottom. The volume of the corresponding staining/storage solutions must be enough to cover the gel (typically 50 ml for 1 minigel (10 cm × 7 cm × 0.75 mm)).

1. Following electrophoresis, the gel is incubated for 15 min in the equilibration solution (*see* **Note 2**).
2. To develop the electropherogram, the imidazole solution is discarded and the gel soaked for 30–40 s in developer solution. **Caution!:** This step must not be extended longer than 45 s or band overstaining and loss of the image will occur. Overstaining is prevented by pouring off the developer solution and rinsing the gel 3–5 times (1 min) in excess water (*see* **Note 3**).

At this point, the reverse stained gel can be photographed **(Fig. 1).** Photographic recording is best conducted with the gel placed on a glass plate held a few centimeters above a black underground and under lateral illumination.

While SDS-PAGE is a popular, high-resolution method for separating complex protein mixtures, sometimes it is desired to avoid either protein denaturation or disruption of macromolecular complexes during electrophoresis. In this case, the proteins are separated in the absence of SDS (native PAGE or agarose gel electrophoresis). Therefore, it is desirable to avoid the use of SDS during the reverse

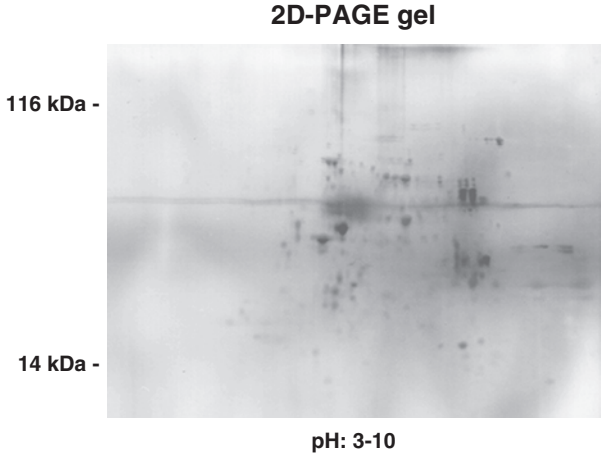

Fig. 1. Reverse staining of rat brain homogenate proteins (70 µg load) after 2D-PAGE. Proteins in a wide range of molecular weights and isoelectric points are detected as transparent spots. These spots contain protein-SDS complexes that bind Zn^{2+} and thereby inhibit the precipitation of $ZnIm_2$ locally.

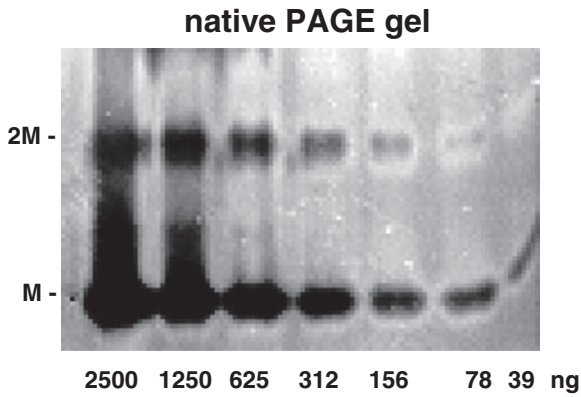

Fig. 2. Reverse staining of serial dilutions of human serum albumin (HSA) after native PAGE. HSA migrates yielding two main bands corresponding to its monomer (M) and its dimer (2M) and is detected under native conditions (no SDS) due to its natural ability to complex with Zn^{2+}.

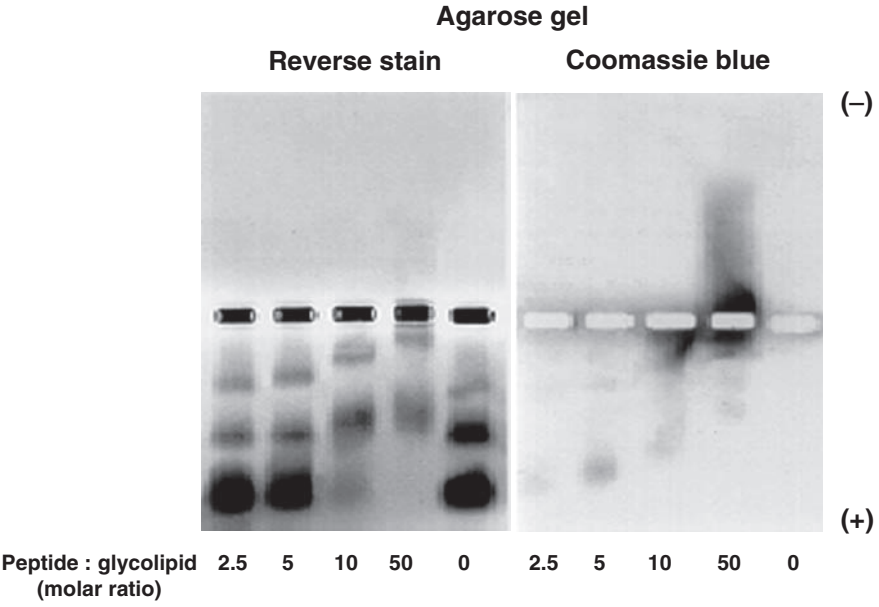

Fig. 3. Reverse staining of complexes between a synthetic cationic peptide with lipopolysaccharide binding properties and the glycolipid of a *N. meningitidis* strain. Formation of complexes was promoted by incubating (37°C) peptide and glycolipid for 30 min in 25 m*M* Tris-HCl, 0.1% Triton X-100, pH 8.0; at indicated peptide:glycolipid molar ratios. Reverse staining revealed bands of both: peptide.glycolipid complexes and uncomplexed glycolipid. Coomassie blue stained mainly the uncomplexed peptide migrating towards the negative (–) electrode. Coomassie blue failed to stain the glycolipid bands and stained peptide.glycolipid complexes very weakly.

staining step. Two procedures have been developed to resolve this problem (*see* **Notes 8** and **9**, **Figs. 2** and **3**).

4. Notes

1. Imidazole is a five-membered heterocyclic ring containing a tertiary ("pyridine") nitrogen at position 3, and a sondary ("pyrrole") nitrogen at position 1. It is a monoacidic base whose basic nature is due to the ability of pyridine nitrogen to accept a proton. The pyrrole nitrogen can lose the hydrogen atom producing imidazolate anion (Im^-), at high pH values (pK_a ~14.2). However, deprotonation of imidazole's pyrrolic nitrogen may also occur at lower pH values, upon complexation of Zn^{2+} at the pyridinium nitrogen *(***ref. *9*** and references therein*)*. As a result, $ZnIm_2$ can form and precipitate at pH > 6.2. Upon treatment of a polyacrylamide or agarose electrophoresis gel with salts of zinc(II) and imidazole, a complex system is generated. Complexity is due to the presence of amide groups in the polyacrylamide matrix and sulfate groups in the agarose gel as well as Tris, glycine and dodecylsulfate, hydroxyle and carbonate anions in the electrophoresis buffers. These groups can coordinate with Zn(II), act as counteranions in the complexes of zinc with imidazole, and lead to the formation of complex salts and hydroxides. Diffusion phenomena (reflected in the times required for optimal gel "equilibration" and "development" during reverse staining) also critically influence the reverse staining reactions between Zn^{2+} and imidazole (*see* **Notes 2** and **3**). Nevertheless, when the protocol described in this chapter is followed, $ZnIm_2$ is the major component of the precipitate that stains the gels treated with zinc sulfate and imidazole ***(9)***.
2. This reverse staining protocol is optimized for use with any standard PAGE system regardless of whether PAGE is the first (1D-PAGE) or the sond (2D-PAGE) dimension in the separation strategy. The equilibration step assures that proteins in the gel are all uniformly coated with SDS. Therefore, protein's ability to bind Zn^{2+} is modulated by the protein-SDS complex and limits of detection (10 ng protein / band) are similar for gels cast with and without SDS (i.e., SDS-PAGE and native PAGE, respectively). The larger the gel thickness or acrylamide concentration, the longer the equilibration step. A 15 min long equilibration is enough for gels with ≤ 15% acrylamide and ≤ 1 mm thickness. Preparative gels are often as thick as 3–5 mm; these gels should be equilibrated for 30–60 min. Insufficient equilibration may result in faint reverse stained patterns, which may fade upon prolonged storage.
3. Development time must be between 30 and 45 s as insufficient development results in pale background staining and over-development causes overstaining. An overstained gel can be re-stained. For this, the gel is treated with 10 mM EDTA or 100 m*M* glycine for 5–10 min to redissolve the

white $ZnIm_2$ precipitate that has deposited on the gel surface, rinsed in water (30 s) and, finally, soaked in the "storage" sodium carbonate solution. If the reverse stained pattern does not restore in ~5 min, the reverse staining procedure can be repeated as indicated in Methods. Usually, the reverse stained pattern will restore during the equilibration step due to the precipitation of traces of Zn^{2+} already present in the gel with the imidazole from the equilibration solution. If the above suggestions do not lead to a homogenous reverse stained pattern of suitable quality, the gel can be "positively" restained with Coomassie blue or silver ***(5).*** In this case, it is recommended that the reverse-stained gel be treated with EDTA (50 mM, pH 8.0; 30 min incubation) to free proteins of Zn^{2+}. Then, the gel can be processed with Coomassie blue or silver stains.

4. Protein elution from reverse stained gels can be performed following any conventional method such as electroelution or passive elution; however, a highly efficient procedure has been developed ***(7, 8).*** The reverse stained band of interest is excised, placed in a (1 ml) plastic vial and incubated with EDTA (50 m*M*, 2 × 5 min and 10 m*M*, 1 × 5 min) to chelate protein bound zinc ions. Supplementation of EDTA with non-ionic detergents is optional but convenient if protein is to be in-gel refolded; e.g., Triton X-100 was useful when refolding proteins that were to be bioassayed ***(9, 15).*** EDTA (or EDTA, detergent mixture) is replaced by an appropriate "assay" buffer (e.g., phosphate saline solution), in which the protein band is equilibrated. Finally, the band is homogenized and protein is eluted into an appropriate volume of the assay buffer ***(7, 8, 14).*** The slurry is centrifuged and the supernatant filtered to collect a clean, transparent solution of protein ready for subsequent analysis ***(7–9, 14, 15).***
5. An important application of reverse staining is in structural/functional proteomics ***(13, 14).*** Identification of proteins separated by electrophoresis is a prerequisite to the construction of protein databases in proteome projects. Matrix assisted laser desorption/ionization-mass spectrometry (MALDI-MS) has a sensitivity for peptide detection in the lower fmol range. In principle, this sensitivity should be sufficient for an analysis of small amounts of proteins in silver-stained gels. However, a variety of known factors (e.g., chemical sensitizers such as glutaraldehyde) and other unknown factors modify the silver-stained proteins, leading to low sequence coverage ***(13).*** Low-abundance proteins have been successfully identified after $ZnIm_2$-reverse-staining ***(13, 14).***
6. Reverse staining of gels that have been already stained with Coomassie blue reveals proteins undetected with Coomassie blue, thus improving detection. Double staining can enhance sensitivity of detection in silver-stained gels as well. Before subjecting a Coomassie (or silver)-stained

gel to double staining, the gel should be rinsed in water (2–3 × 10 min). This step assures a substantial removal of acetic acid from Coomassie and silver stains. Then, the gel is subjected to the standard reverse staining protocol. The resultant double stained patterns consist of the previously seen Coomassie blue (brown, in the case of silver)–stained bands and new unstained (reverse-stained) bands that contrast against the deep-white, $ZnIm_2$, stained background.

7. Reverse staining can be used in combination with other "specific" protein stains to indicate the presence of both protein and glycolipid. As with proteins, the biological properties of the presumed glycolipid bands are testable in a functional experiment following elution from the reverse stained gel ***(9, 18)***. After the electrophoresis step, the gel is rinsed for 30 min (2x, 15 min) in aqueous solution of methanol (40%, v/v). This step presumably removes excess SDS from glycolipid molecules that co-migrate with the proteins in SDS-PAGE, making the glycolipid adopt a conformation with high affinity for Zn^{2+}. Next, the gel is reverse stained (Methods). Similar to proteins, glycolipid bands show up transparent and unstained. Sensitivity of detection is ~10 ng glycolipid / band. If the same (or a parallel gel) is treated with Coomassie blue (silver) stain, that does not detect glycolipids; protein and glycolipid bands can be distinguished by their distinct staining and migration properties ***(9, 18)***. A replicate protein sample treated with proteinase K is a useful control, as this protease digests protein, but not glycolipid.
8. An alternative method of precipitating $ZnIm_2$ facilitates the reverse staining of native PAGE gels without the use of SDS ***(9)***. A *quick* and a *slow* reverse staining procedure were implemented ***(9)***. The *quick* version makes use of the characteristic neutral to basic pH of the gels immediately after electrophoresis. When the gel is incubated (3–6 min) in an slightly acidic solution containing zinc sulfate and imidazole (pre-mixed to yield the molar ratio Zn(II) : ImH = 15 m*M* : 30 m*M*, pH 5.0 – 5.5), the gel stains negatively as $ZnIm_2$ deposits along its surface. Blotchy deposits are prevented by intense agitation and resolubilized by lowering the pH of the zinc-imidazole solution; this also provides a basis for a *slow* version of this method. In the slow version (**Fig. 2**), the gel is incubated (10–20 min) in a solution of zinc sulfate (15 m*M*) and imidazole (30 m*M*) adjusted to pH 4.0. No precipitation occurs at this pH. The solution is poured off, the gel is rinsed with water (30 s); the electropherogram is developed by incubating the gel during ~5 min in 1% sodium carbonate. Sodium carbonate increases the pH first at the gel surface. Therefore, Zn^{2+} and imidazole, already present in the gel, react at the gel surface to form $ZnIm_2$. Again, protein bands are not stained as they complex with Zn^{2+} and locally prevent the precipitation of $ZnIm_2$.

9. Many proteins and peptides as well as glycolipids and their complexes with certain proteins/peptides separate well on agarose gels under non-denaturing conditions ***(9)***. To reverse stain an agarose gel ***(9)***; following electrophoresis, the gel is incubated for 25 – 30 min in a zinc sulfate-imidazole solution (Zn(II) : ImH = 15 mM: 30 mM, adjusted to pH 5.0 with glacial acetic acid). During this step, Zn^{2+} and imidazole diffuse into agarose matrix. The gel is then rinsed in water for 5–8 min to remove any excess of the staining reagents from the gel surface. The reverse stained electropherogram is developed by incubating the gel for 5–8 minutes in 1% Na_2CO_3 **(Fig. 3).** Of note, due to poorly understood factors, agarose gels are not as amenable to reverse staining as polyacrylamide gels. Patterns of positive and negative bands are often seen in agarose gels.

Acknowledgments

The author expresses his gratitude to his former colleagues, Drs. L. Castellanos-Serra and E. Hardy from the Centre for Genetic Engineering and Biotechnology (CIGB), Havana, Cuba for their contributions to the development of the reverse staining concept, and to the CIGB for early support. Currently, the author is a New Investigator of the Canadian Institutes of Health Research and the Heart and Stroke Foundation of Canada as well as funded by grants from Natural Sciences and Engineering Council and the Canadian Institutes of Health Research.

Protein Staining with Calconcarboxylic Acid in Polyacrylamide Gels

Wei-Tao Cong, Sun-Young Hwang, Li-Tai Jin, and Jung-Kap Choi

1. Introduction

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) has become a highly reliable separation technique for protein characterization. Broad application of electrophoresis techniques has required the development of detection methods that can be used to visualize the proteins separated on polyacrylamide gels. A few of these methods are Coomassie blue (CB) staining ***(1)***, silver staining ***(2)***, fluorescent staining ***(3–5)***, specific enzyme visualization ***(6)***, and radioactive detection ***(7)***.

CB staining is the most commonly used method owing to its proven reliability, simplicity, and economy (***8, 9***), but it lacks sensitivity compared with the silver-staining method. In addition, the staining/destaining process is time consuming ***(10)***. Silver staining is the most sensitive nonradioactive protein detection method currently available, and can detect as little as 10 fg of protein (***11, 12***). However, it has several drawbacks, such as high-background staining, multiple steps, high cost of reagent, and toxicity of formaldehyde ***(10)***.

In this chapter a protein staining method using calconcarboxylic acid (1-[2-hydroxy-4-sulfo-l-naphthylazo]-2-hydroxy-3-naphthoic acid) is described (*see* **Note 1**; **Fig. 1**; **ref.** ***13***). This method can be performed by both simultaneous and postelectrophoretic staining techniques. Simultaneous staining using 0.01% of NN in upper reservoir buffer eliminates the poststaining step, and thus enables detection of the proteins more rapidly and simply. In poststaining, proteins can be stained by a 30 min incubation of a gel in 40% methanol/7% acetic acid solution of 0.05% NN and destaining in 40% methanol/7% acetic acid for 40 min with agitation. NN staining can detect as little as 10 ng of bovine serum albumin (BSA) by poststaining and 25 ng by simultaneous staining, compared to 100 ng detectable by CB poststaining (*see* **Note 2**). These techniques produce

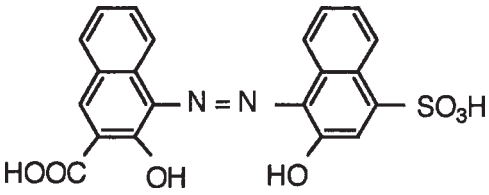

Fig. 1. Structure of NN.

protein-staining patterns identical to the ones obtained by the conventional CB staining and also work well in nondenaturing PAGE, like in SDS-PAGE. The bands stained with NN present purple color. In addition, NN staining gives better linearity than CB staining, although the slopes (band intensity/amount of protein) of it are somewhat lower (*see* **Table 1**, **Fig. 2**). It suggests that NN staining is more useful than CB staining for quantitative work of proteins.

2. Materials

1. All working solutions should be freshly prepared with distilled water and clean glassware or plastic ware. All steps were carried out at room temperature with shaking.
2. Destaining solution (1.0 L): Mix 530 mL distilled water with 400 mL methanol and 70 mL glacial acetic acid.
3. Simultaneous staining solution (1.0% [w/v] NN): Dissolve 1.0 g NN (pure *NN without K_2SO_4) in 100 mL reservoir buffer. Stir until fully dissolved at 50–60°C (stable for months at 4°C) (*see* **Note 3**).
4. Poststaining solution (0.05% [w/v] NN): Dissolve 0.05 g NN (pure *NN) in 100 mL destaining solution. Stir until dissolved thoroughly (store at room temperature).

3. Methods

3.1. Simultaneous Staining

The method is based on the procedure of Borejdo and Flynn ***(14)***, and is described for staining proteins in a 7.5% SDS-polyacrylamide gel.

1. Electrophorese the samples for 10 min to allow protein penetration into the upper gel phase.
2. Turn off the power, and then add 1% NN dissolved in reservoir buffer to the upper reservoir buffer to give a final concentration of 0.01–0.015% NN (*see* **Notes 3** and **4**).
3. Stir the reservoir buffer sufficiently to ensure homogeneity.
4. Resume electrophoresis.
5. Immediately after electrophoresis, remove the stained gel from the apparatus.
6. Destain the stained gels in 40% methanol/7% acetic acid for 30 min. To destain completely, change destaining solution several times and agitate (*see* **Notes 5–7**).

*NN diluted with 100- to 200-fold K_2SO_4 has been used as an indicator for the determination of calcium in the presence of magnesium with EDTA.

Table 1
Linearity of CB and NN Staining for Four Purified Proteins

	Slope[b]		*y*-intercept[b]		Correlation coefficient[b]	
Protein[a]	A	B	A	B	A	B
BSA	14.1	10.1	13.2	6.4	0.986	0.994
OVA	8.7	7.1	2.7	1.4	0.993	0.998
G-3-P DHase	8.0	5.8	5.3	2.2	0.997	0.999
CA	15.4	13.5	12.5	8.8	0.986	0.997

[a]Proteins were separated on 12.5% polyacrylamide gel, densities and band area were determined with computerized densitometer. Some of the data are illustrated in **Fig. 2**. The range of amount of proteins was 0.25–12.5 µg. The number of points measured was six (0.25, 0.5, 1.0, 2.5, 5.0, and 12.5 µg).
[b]Slopes, *y*-intercepts, and correlation coefficients were determined by linear regression analysis. A, CB staining; B, NN staining.

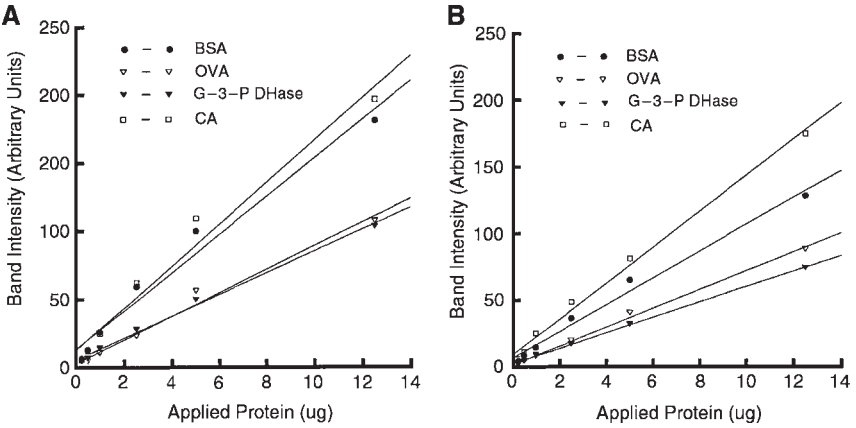

Fig. 2. Densitometric comparison of CB and NN staining. Proteins were separated on 12.5% gels. (A) poststaining with 0.1% CB; (B) simultaneous staining with 0.015% NN. Densitometric scanning was performed at 585 nm (CB) and 580 nm (NN). The curves are fitted by the method of least squares. Each point represents the mean of three determinations. BSA, bovine serum albumin; OVA, ovalbumin; G-3-P DHase, glyceraldehyde-3-phosphate dehydrogenase; CA, carbonic anhydrase

3.2. Postelectrophoretic Staining

1. Agitate the freshly run gel in 0.05% NN staining solution for 30 min.
2. Pour off the staining solution and rinse the gel with changes of destaining solution (two to three times). Staining solution can be reused several times.
3. Destain the stained gels in 40% methanol/7% acetic acid for 40 min with agitation (*see* **Notes 8** and **9**).

4. Notes

1. NN has several functional groups, such as hydroxyl, diazoic, carboxyl, and sulfonate groups (*see* **Fig. 1**). At acidic pH, NN probably forms electrostatic bonds with protonated amino groups, which are stabilized by hydrogen bonds and Van der Waals forces, as CB does ***(1)***.
2. The protocol for poststaining is the same as that for CB staining, except for staining/destaining times and dye used.
3. The preparation of staining solution requires stirring and warming at 50–60°C since NN is poorly soluble.
4. The simultaneous staining method allows one to control the intensity of stained bands reproducibly by adjusting the concentration of the dye in the upper reservoir. More than 0.02% NN in the upper reservoir buffer does not increase sensitivity but requires more destaining time.
5. Gel staining/destaining with NN is pH dependent. Intense staining occurs at pH 1.6–4.4, and weak staining with blue-purple color is observed at alkaline pH. In excessively strong acidic solution (pH<1.0), however, the staining effect is markedly decreased, because the solubility of the dye is decreased and, thus replacement between dye anions and acetate ions may be suppressed (*see* **Fig. 3**). In destaining solution, the stained band diffuses, and its intensity is decreased significantly at pH higher than 4.4. Destaining in this pH range is rather slow compared with that in strongly acidic conditions.
6. The rate of destaining speeds up with increasing methanol content; however, at high methanol content (>55%), gels are opaqued and shrunken. Addtionally, increasing the temperature of destaining solution is a great help in removing background (at 60–70°C, in 5 min), although sensitivity is a little reduced.

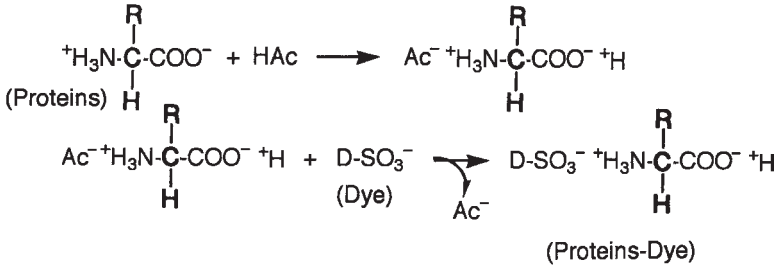

Fig. 3. Mechanism of protein–dye interaction in acidic solution.

7. Destaining can be completed within 30 min in 7.5% polyacrylamide gels, but destaining time should be increased for 10 and 12.5% gels (50–60 min).
8. Bands stained with NN are indefinitely stable when gels are stored in a refrigerator wrapped up in polyethylene film or dried on Whatmann No. 1 filter paper.
9. Throughout the staining/destaining processes, it is necessary to agitate the gel container using a shaker.

Detection of Proteins in Polyacrylamide Gels by Silver Staining

Michael J. Dunn

1. Introduction

The versatility and resolving capacity of polyacrylamide gel electrophoresis has resulted in this group of methods becoming the most popular for the analysis of patterns of protein expression in a wide variety of complex systems. These techniques are often used to characterise protein purity and to monitor the various steps in a protein purification process. Moreover, two-dimensional polyacrylamide gel electrophoresis (2-DE) remains the core technology of choice for separating complex protein mixtures in the majority of proteome projects ***(1).*** This is due to its ability to separate simultaneously thousands of proteins and to indicate post-translational modifications that result in alterations in protein pI or M_r. Additional advantages are the high-sensitivity visualization of the resulting 2-DE separations, compatibility with quantitative computer analysis to detect differentially regulated proteins ***(2),*** and the relative ease with which proteins from 2-DE gels can be identified and characterised by mass spectrometry (MS) ***(3).***

After 2-DE, the separated proteins must be visualised at high sensitivity, and the detection method should ideally combine the properties of an extended dynamic range, a linear staining response, reproducibility, and compatibility with post-electrophoretic protein identification procedures, especially those based on the use of MS. Unfortunately, no current staining method can fulfil all of these requirements.

Staining methods based on the use of the organic dye, Coomassie Brilliant Blue (CBB), have been used extensively for the detection of proteins on 2-DE gels, due to their low price, ease of use and compatibility with downstream

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

protein identification by MS. However, methods using CBB are limited by their lack of sensitivity (around 200–500 ng protein per spot), such that only a few hundred protein spots can usually be visualised on a 2-DE gel, even if milligram amounts of protein sample are loaded ***(4).*** The need to detect small amounts of protein within 2-DE gel spots has resulted in the development of a range of more sensitive detection methods ***(4).*** The first method that was able to meet this requirement and which is still used in many proteomic projects is silver staining.

The ability of silver to develop images was discovered in the mid-17th century and this property was exploited in the development of photography, followed by its use in histological procedures. Silver staining for the detection of proteins following gel electrophoresis was first reported in 1979 by Switzer et al ***(5),*** resulting in a major increase in the sensitivity of protein detection. More than 100 publications have subsequently appeared describing variations in silver staining methodology ***(4, 6).*** This group of procedures is generally accepted to be around 100 times more sensitive than methods using CBB R-250, being able to detect low ng amounts of protein per gel band or spot.

All silver staining procedures depend on the reduction of ionic silver to its metallic form, but the precise mechanism involved in the staining of proteins has not been fully established. It has been proposed that silver cations complex with protein amino groups, particularly the ε-amino group of lysine ***(7),*** and with sulphur residues of cysteine and methionine ***(8).*** However, Gersten and his colleagues have shown that "stainability" cannot be attributed entirely to specific amino acids and have suggested that some element of protein structure, higher than amino acid composition, is responsible for differential silver staining ***(9).***

Silver staining procedures can be grouped into two types of method depending on the chemical state of the silver ion when used for impregnating the gel. The first group is alkaline methods based on the use of an ammoniacal silver or diamine solution, prepared by adding silver nitrate to a sodium-ammonium hydroxide mixture. Copper can be included in these diamine procedures to give increased sensitivity, possibly by a mechanism similar to that of the Biuret reaction. The silver ions complexed to proteins within the gel are subsequently developed by reduction to metallic silver with formaldehyde in an acidified environment, usually using citric acid. In the second group of methods, silver nitrate in a weakly acidic (approximately pH 6) solution is used for gel impregnation. Development is subsequently achieved by the selective reduction of ionic silver to metallic silver by formaldehyde made alkaline with either sodium carbonate or NaOH. Any free silver nitrate must be washed out

of the gel prior to development, as precipitation of silver oxide will result in high background staining.

Silver stains are normally monochromatic, resulting in a dark brown image. However, if the development time is extended, dense protein zones become saturated and colour effects can be produced. Some staining methods have been designed to enhance these colour effects, which were claimed to be related to the nature of the polypeptides detected ***(10).*** However, it has now been established that the colours produced depend on: (a) the size of the silver particles, (b) the distribution of silver particles within the gel, and (c) the refractive index of the gel ***(11).***

Rabilloud has compared several staining methods based on both the silver diamine and silver nitrate types of procedure ***(12).*** The most rapid procedures were found to be generally less sensitive than the more time-consuming methods. Methods using glutaraldehyde pretreatment of the gel and silver diamine complex as the silvering agent were found to be the most sensitive. However, it should be noted that the glutaraldehyde and formaldehyde present in many silver staining procedures results in alkylation of α- and ε-amino groups of proteins, thereby interfering with their subsequent chemical characterisation by MS. To overcome this problem, silver staining protocols compatible with mass spectrometry in which glutaraldehyde is omitted have been developed ***(13, 14)*** but these suffer from a decrease in sensitivity of staining and a tendency to a higher background. This problem can be overcome using post-electrophoretic fluorescent staining techniques ***(4, 15).*** One the most commonly used stains of this type is SYPRO Ruby (*see* Chapter 50), which has a sensitivity approaching that of standard silver staining and is fully compatible with protein characterisation by MS ***(16).***

The method of silver staining we describe here is recommended for analytical applications and is based on that of Hochstrasser et al ***(17, 18),*** together with modifications and technical advice that will enable an experimenter to optimise results. An example of a one-dimensional SDS-PAGE separation of the total proteins of human heart proteins stained by this procedure is shown in **Fig. 1.** The power of 2-DE combined with sensitive detection by silver staining to display the complex protein profile of a whole tissue lysate is shown in **Fig. 2.**

2. Materials

1. All solutions should be freshly prepared, and overnight storage is not recommended. Solutions must be prepared using clean glassware and deionised, distilled water.
2. Gel fixation solution: Trichloroacetic acid (TCA) solution, 20% (w/v).
3. Sensitisation solution: 10% (w/v) glutaraldehyde solution.

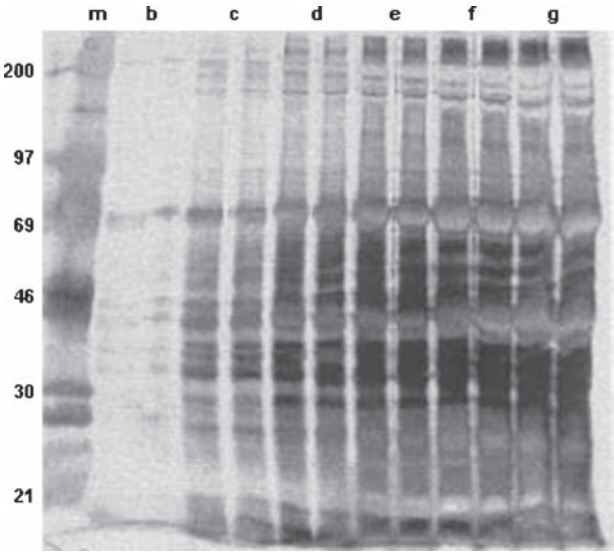

Fig. 1. One-dimensional 12%T SDS-PAGE separation of human heart proteins (lanes b-g) visualised by silver staining. Lane (m) contains the M_r marker proteins and the scale at the left indicates $M_r \times 10^{-3}$. The sample protein loadings were (b) 1 µg, (c) 5 µg, (d) 10 µg, (e) 25 µg, (f) 50 µg, (g) 100 µg.

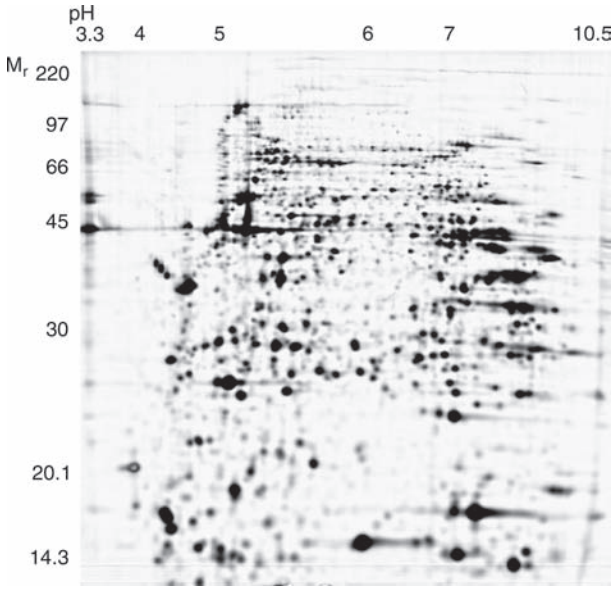

Fig. 2. 2-DE separation of human heart proteins visualised by silver staining. A loading of 100 µg protein was used. The first dimension was pH 3–10 NL IPG IEF and the second dimension was 12% T SDS-PAGE. The scale at the top indicates the non-linear pH gradient used in the first IPG 3–10 NL IEF dimension, while the scale at the left indicates $M_r \times 10^{-3}$.

4. Silver diamine solution: 21 mL of 0.36% (w/v) NaOH is added to 1.4 mL of 35% (w/v) ammonia and then 4 mL of 20% (w/v) silver nitrate is added drop-wise with stirring. When the mixture fails to clear with the formation of a brown precipitate, further addition of a minimum amount of ammonia results in the dissolution of the precipitate. The solution is made up to 100 mL with water. The silver diamine solution is unstable and should be used within 5 min.
5. Developing solution: 2.5 mL of 1% (w/v) citric acid, 0.26 mL of 36% (w/v) formaldehyde made up to 500 mL with water.
6. Stopping solution: 40% (v/v) ethanol, 10% (v/v) acetic acid in water.
7. Farmer's reducer: 0.3% (w/v) potassium ferricyanide, 0.6% (w/v) sodium thiosulphate, 0.1% (w/v) sodium carbonate.

3. Method

Note: *All incubations are carried out at room temperature with gentle agitation*

3.1. Fixation

1. After electrophoresis, fix the gel immediately (*see* **Note 1**) in 200 mL (*see* **Note 2**) of TCA (*see* **Note 3**) for a minimum of 1 h at room temperature. High-percentage polyacrylamide and thick gels require an increased period for fixation, and overnight soaking is recommended.
2. Place the gel in 200 mL of 40% (v/v) ethanol, 10% (v/v) acetic acid in water and soak for 2 × 30 min (*see* **Note 4**).
3. Wash the gel in excess water for 2 × 20 min, facilitating the rehydration of the gel and the removal of methanol. An indication of rehydration is the loss of the hydrophobic nature of the gel.

3.2. Sensitisation

1. Soak the gel in a 10% (w/v) glutaraldehyde solution for 30 min at room temperature (*see* **Note 5**).
2. Wash the gel in water for 3 × 20 min to remove excess glutaraldehyde.

3.3. Staining

1. Soak the gel in the silver diamine solution for 30 min. For thick gels (1.5 mm), it is necessary to use increased volumes so that the gels are totally immersed. Caution should be exercised in disposal of the ammoniacal silver reagent, since it decomposes on standing and may become explosive. The ammoniacal silver reagent should be treated with dilute hydrochloric acid (1 N) prior to disposal.
2. Wash the gel (3 × 5 min) in water.

3.4. Development

1. Place the gel in developing solution. Proteins are visualised as dark brown zones within 10 min (*see* **Note 6**), after which the background will gradually increase (*see* **Note 7**). It is important to note that the reaction displays inertia, and that

staining will continue for 2–4 min after removal of the gel from the developing solution. Staining times in excess of 20 min usually result in an unacceptable high background (*see* **Note 8**).

4. Terminate staining by immersing the gel in stopping solution.
5. Wash the stained gel in water prior to storage or drying.

3.5. Destaining

Partial destaining of gels using Farmer's reducing reagent is recommended for the controlled removal of background staining that obscures proper interpretation of the protein pattern.

1. Wash the stained gel in water for 5 min to remove the stop solution.
2. Place the gel in Farmer's reducer for a time dependent upon the intensity of the background.
3. Terminate destaining by returning the gel to the stop solution.

4. Notes

1. Gloves should be worn at all stages when handling gels, since silver staining will detect keratin proteins from the skin.
2. Volumes of the solutions used at all stages should be sufficient such that the gel is totally immersed. If the volume of solution is insufficient for total immersion, staining will be uneven and the gel surface can dry out.
3. A mixture of alcohol, acetic acid and water (9:9:2) is recommended for gel fixation in many published protocols, but TCA is a better general protein fixative and its use is compatible with silver staining provided that the gel is washed well after fixation to remove the acid.
4. In addition to removing TCA, the washing step also effectively removes reagents such as Tris, glycine and detergents (especially SDS) which can bind silver and result in increased background staining.
5. Treatment of the gel with reducing agents such as glutaraldehyde prior to silver impregnation results in an increase in staining sensitivity by increasing the speed of silver reduction on the proteins.
6. If image development is allowed to proceed for too long, dense protein zones will become saturated and negative staining will occur, leading to serious problems if quantitative analysis is attempted. In addition, certain proteins stain to give yellow or red zones regardless of protein concentration, and this effect has been linked to the post-translational modification of the proteins.
7. An inherent problem with the staining of gradient SDS-PAGE gels is uneven staining along the concentration gradient. The less concentrated polyacrylamide region develops background staining prior to the more concentrated region. A partial solution to this problem is to increase the time of staining in silver diamine (*see* **Subheading 3.3., step 1**).

8. Various chemicals used in one- and two-dimensional electrophoresis procedures can inhibit staining, whereas others impair resolution or produce artefacts. Acetic acid will inhibit staining and should be completely removed prior to the addition of silver diamine solution (**Subheading 3.3., step 1).** Glycerol, used to stabilise SDS gradient gels during casting, and urea, used as a denaturing agent in isoelectric focusing (IEF), are removed by water washes. Agarose, often used to embed rod IEF gels onto SDS-PAGE gels in 2-D PAGE procedures, contains peptides that are detected by silver staining as diffuse bands and give a strong background. Tris, glycine and detergents (especially SDS) present in electrophoresis buffers can complex with silver and must be washed out with water prior to staining. The use of 2-mercaptoethanol as a disulphide bond reducing agent should be avoided since it leads to the appearance of two artefactual bands at 50 and 67 kDa on the gel ***(19)***.
9. Radioactively labelled proteins can be detected by silver staining prior to autoradiography or fluorography for the majority of the commonly used isotopes (^{14}C, ^{35}S, ^{32}P, ^{125}I). In the case of ^{3}H, however, silver deposition will absorb most of the emitted radiation.

Background-Free Protein Detection in Polyacrylamide Gels and on Electroblots Using Transition Metal Chelate Stains

Wayne F. Patton

1. Introduction

Electrophoretically separated proteins may be visualized using organic dyes such as Ponceau Red, Amido Black, Fast Green, or most commonly Coomassie Brilliant Blue ***(1,2)***. Alternatively, sensitive detection methods have been devised using metal ions and colloids of gold, silver, copper, carbon, or iron ***(3–12)***. Metal chelates form a third class of stains, consisting of transition metal complexes that bind avidly to proteins resolved in polyacrylamide gels or immobilized on solid-phase membrane supports ***(13–27)***. In recent years, metal chelate stains have been designed and optimized specifically for compatibility with commonly used microchemical characterization procedures employed in proteomics. The metal chelate stains are simple to implement, and do not contain extraneous chemicals such as glutaraldehyde, formaldehyde, or Tween-20 that are well known to interfere with many downstream protein characterization procedures.

Metal chelates can be used to detect proteins on nitrocellulose, poly(vinylidene difluoride) (PVDF), and nylon membranes as well as in polyacrylamide and agarose gels. The metal complexes do not modify proteins, and are compatible with immunoblotting, lectin blotting, mass spectrometry, and Edman-based protein sequencing ***(13–17,22–27)***. Metal chelate stains are suitable for routine protein measurement in solid-phase assays owing to the quantitative stoichiometry of complex formation with proteins and peptides ***(15,16)***. Such solid phase protein assays are more sensitive and resistant to chemical interference than their solution-based counterparts ***(15)***.

A variety of metal ions and organic chelating agents may be combined to form metal chelate stains but only a few have been evaluated extensively for protein detection in electrophoresis. Ferrene S has been utilized for the specific detection of iron-containing proteins, such as cytochrome *c*, transferrin, ferritin, and lactoferrin in polyacrylamide gels ***(18)***. In this situation the metal complex only forms when the chelate interacts with the native metal ion bound within the protein itself. Copper phthalocyanine 4, 4' ,4", 4'" -tetrasulfonic acid has been shown to stain total protein in electrophoresis gels and on nitrocellulose membranes ***(19)***. In addition, we demonstrated the use of Ferrene S-ferrous, Ferrozine-ferrous, ferrocyanide-ferric, and Pyrogallol Red-molybdate complexes for colorimetric detection of electrophoretically separated proteins immobilized on membranes ***(13–16)***. In 1978, a pink bathophenanthroline disulfonate-ferrous complex was reported as a nonspecific protein stain for polyacrylamide gel electrophoresis ***(20)***. The stain is rather insensitive and was later modified by substituting [^{59}Fe] into the complex in order to detect proteins by autoradiography ***(21)***. Although increasing sensitivity substantially, the hazards associated with working with radioactivity and the burden of license application for an infrequently used radioisotope have precluded routine utilization of bathophenanthroline disulfonate-[^{59}Fe] as a general protein stain. Measuring light emission is intrinsically more sensitive than measuring light absorbance, as the later is limited by the molar extinction coefficient of the colored complex ***(28)***. Thus, luminescent protein detection systems utilizing chelates complexed to transition metal ions such as europium, or ruthenium should offer greater sensitivity than their colorimetric counterparts without the accompanying hazards associated with radioactivity. The organic component of the complex absorbs light and transfers the energy to the transition metal ion, which subsequently emits light at longer wavelength.

This is demonstrated by substituting europium into the bathophenanthroline–disulfonate complex ***(17)***. This luminescent reagent has been commercialized as SYPRO Rose protein blot stain (Molecular Probes, Eugene, OR). The bathophenanthroline disulfonate-europium complex can detect as little as 8 ng of protein immobilized on nitrocellulose or PVDF membranes. By comparison, the original bathophenanthroline disulfonate–ferrous complex is capable of detecting 600 ng of protein, while the modification employing [^{59}Fe] is capable of detecting 10–25 ng of protein ***(20,21)***. The luminescent stain is readily removed by incubating blots in mildly alkaline solution, is highly resistant to photobleaching and is compatible with popular downstream biochemical characterization procedures including immunoblotting, lectin blotting, and mass spectrometry ***(17)***. Disadvantages of the bathophenanthroline disulfonate–europium stain are that the dye can only be adequately visualized using 302 nm UV-B epi-illumination and the dye exhibits intense 430 nm (blue) fluorescence emission as well as the desired red emission maxima of 595 and 615 nm.

Subsequently, SYPRO Rose Plus protein blot stain, an improved europium-based metal chelate stain roughly 10 times brighter than the original bathophenanthroline disulfonate-europium stain, was introduced ***(25,26)***. The intense blue fluorescence from uncomplexed ligand, observed in the original stain, was eliminated by employing a thermodynamically more stable europium complex. Due to improved absorption properties, the stain could now be readily visualized with UV-A UV-B or UV-C epi-illumination. Just as with the bathophenanthroline disulfonate–europium stain, SYPRO Rose Plus stain is easily removed by increasing solution pH. The stain is fully compatible with biotin–streptavidin and immunoblotting detection technologies that use a wide variety of visualization strategies. Neither of the europium-based stains is compatible with laser-based gel scanners as they lack visible excitation peaks. SYPRO Ruby dye is a proprietary ruthenium-based metal chelate stain developed to address the limitations of the SYPRO Rose and SYPRO Rose Plus dyes. SYPRO Ruby protein blot stain visualizes electroblotted proteins on nitrocellulose and PVDF membranes with a detection sensitivity of 0.25–1 ng of protein/mm^2 in slot-blotting applications. Approximately 2–8 ng of protein can routinely be detected by electroblotting, which side-by-side comparisons demonstrate is as sensitive as colloidal gold stain ***(22)***. While colloidal gold staining requires 2–4 h, SYPRO Ruby dye staining is complete in 15 min. The linear dynamic range of SYPRO Ruby protein blot stain is vastly superior to colloidal gold stain, extending over a 1000-fold range. The dye can be excited using a standard 302 nm UV-B transilluminator or using imaging systems equipped with 450-, 473-, 488-, or even 532- nm lasers. Unlike colloidal gold stain, SYPRO Ruby stain does not interfere with mass spectrometry or immunodetection procedures ***(22)***.

SYPRO Ruby protein gel stain and SYPRO Ruby IEF protein gel stains allow one-step, low background staining of proteins in polyacrylamide or agarose gels without resorting to lengthy destaining steps (*see* **Fig. 1**). The linear dynamic range of these dyes extends over three orders of magnitude, thus surpassing silver and Coomassie Blue stains in performance. An evaluation of 11 protein standards ranging in isoelectric point from 3.5 to 9.3 indicates that SYPRO Ruby IEF gel stain is 3–30 times more sensitive than highly sensitive silver stains ***(24)***. Proteins that stain poorly with silver stain techniques are often readily detected by SYPRO Ruby dye ***(27)***. Similar to colloidal Coomassie Blue stain but unlike silver stain, SYPRO Ruby dye stains are end point stains. Thus, staining times are not critical and staining can be performed over night without gels overdeveloping.

A potential disadvantage to detection of proteins using luminescent compared to colorimetric metal chelate stains is the requirement for ancillary equipment such as a laser gel scanner, UV light box, bandpass filters, and photographic or charge-coupled device (CCD) camera. The tremendous improvement in detection sensitivity and linear dynamic range certainly justifies the investment in equipment. Procedures for the detection of electrophoretically

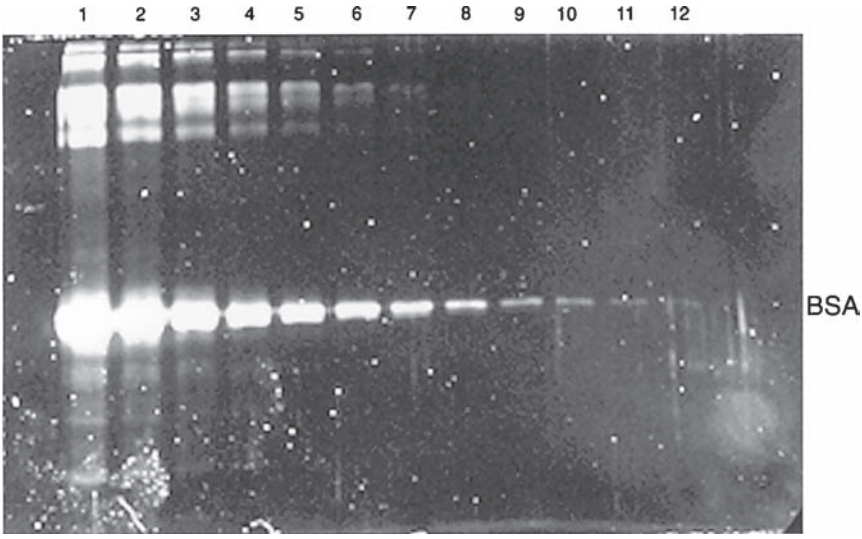

Fig. 1. Protein detection sensitivity in 1-D gels using SYPRO Ruby Protein gel stain: Twofold serial dilutions of solution-quantified bovine serum albumin (P-7656, Sigma Chemical, Saint Louis, MO) electrophoretically separated on 13% Duracryl SDS-polyacrylamide gels (Genomic Solutions, Ann Arbor, MI). After staining with SYPRO Ruby protein gel stain (Molecular Probes, Eugene, OR), gels were imaged using a Lumi-Imager-F1 scanner (Roche Biochemicals, Indianapolis, IN). The 302-nm UV-B transilluminator was used in conjunction with the system's 600-nm emission filter. As little as 250 pg of serum albumin is detectable, with a linearly increasing signal extending to 1000 ng.

separated proteins utilizing colorimetric and luminescent metal chelate stains are presented in this chapter. Methods for the elution of the metal chelate stains are also presented. The procedures are applicable for detection of proteins or peptides in polyacrylamide or agarose gels as well as on nitrocellulose, PVDF, or nylon membranes. Owing to the electrostatic mechanism of the protein visualization methods, metal chelate stains are unsuitable for detection of proteins and peptides immobilized on cationic membranes.

2. Materials

2.1. Colorimetric Detection of Electroblotted Proteins on Membranes

1. Block buffer: 0.1% polyvinylpyrrolidone-40 (PVP-40) in 2% glacial acetic acid.
2. Ferrozine–ferrous stain (stable for at least 6 mo at room temperature): 0.75 m*M* 3-(2-pyridyl)-5,6-*bis* (4-phenylsulfonic acid)-1,2,4-triazine disodium salt

(Ferrozine), 30 m*M* ferric chloride, 15 m*M* thioglycolic acid in 2% glacial acetic acid. Alternatively, commercially prepared stain solutions of Ferrozine–ferrous (Rev–Pro stain kit; Genomic Solutions, Ann Arbor, MI) or Pyrogallol Red-molybdenum (Microprotein-PR kit; Sigma Chemical Company, St. Louis, MO) can be used.
3. 2% Glacial acetic acid.
4. Ferrocyanide–ferric stain (stable for at least 6 mo at room temperature): 100 m*M* sodium acetate, pH 4.0; 100 m*M* potassium ferrocyanide, 60 m*M* ferric chloride.

2.2. Luminescent Detection of Electroblotted Proteins Using Bathophenanthroline Disulfonate-europium (SYPRO Rose Stain)

1. Formate buffer: 100 m*M* formic acid, pH 3.7, 100 m*M* sodium chloride.
2. Bathophenanthroline–europium blot stain (stable for at least 6 mo at room temperature): 1.5 m*M* bathophenanthroline disulfonic acid disodium salt, 0.5 m*M* europium chloride, and 0.2 m*M* EDTA (added from 1000× stock, pH 7.0).

2.3. Luminescent Detection of Electroblotted Proteins Using SYPRO Rose Plus Protein Blot Stain

1. SYPRO Rose Plus protein blot stain kit (Molecular Probes, Inc. cat. #S-12011) The kit contains the following components:
   SYPRO Rose Plus blot wash solution (component A), 200 mL
   SYPRO Rose Plus blot stain solution (component B), 200 mL
   SYPRO Rose Plus blot destain solution (component C), 200 mL

The kit contains sufficient material for staining 10–40 minigel electroblots or four large-format electroblots (20 × 20 cm). The SYPRO Rose Plus solutions may be reused up to four times with little loss in sensitivity.

2.4. Luminescent Detection of Electroblotted Proteins Using SYPRO Ruby Protein Blot Stain

1. SYPRO Ruby protein blot stain (Molecular Probes, Inc.) is provided in a unit size of 200 mL. The 200-mL volume is sufficient for staining 10–40 minigel electroblots or four large-format electroblots (20 × 20 cm). SYPRO Ruby protein blot stain may be reused up to four times with little loss in sensitivity.
2. 7% Acetic Acid, 10% methanol.

2.5. Luminescent Detection of Proteins in SDS-Polyacrylamide Gels Using SYPRO Ruby Protein Gel Stain

1. SYPRO Ruby protein gel stain (Molecular Probes, Inc.) is provided ready to use, in either 200 mL volume (will stain ~four minigels) or 1 L volume (~ 20 minigels or 2–3 large-format gels).
2. 7% Acetic Acid, 10% methanol.

2.6. Luminescent Detection of Proteins in Isoelectric Focusing (IEF) Gels Using SYPRO Ruby IEF Protein Gel Stain

1. SYPRO Ruby IEF protein gel stain (Molecular Probes, Inc.) is supplied as a 400-mL ready-to-use staining solution, sufficient to stain ~10 IEF minigels or two standard flatbed IEF gels. Use caution when handling the SYPRO Ruby IEF protein gel stain as it contains a strong acid that can cause burns.

2.7. The Elution of Metal Chelate Stains

1. 50 m*M* Tris-HCl, pH 8.8, 200 m*M* NaCl, 20 m*M* EDTA (for the Ferrozine–ferrous stain).
2. 200 m*M* Sodium carbonate, 100 m*M* EDTA, pH 9.6 (for the Ferrozine–ferrous stain enhanced with the ferrocyanide–ferric stain and for the bathophenanthroline–europium blot stain).
3. 200 m*M* Sodium carbonate; 100 m*M* EDTA, pH 9.6 in 30% methanol (for the bathophenanthroline-europium gel stain).
4. SYPRO Rose Plus blot destain solution (component C) (for the SYPRO Rose Plus protein blot stain.)

3. Methods

3.1. Colorimetric Detection of Electroblotted Proteins on Membranes

The colorimetric metal chelate stains allow rapid visualization of proteins on solid-phase supports with detection sensitivities that are comparable to Coomassie Brilliant Blue staining ***(13–16)***. Detection sensitivity of the Ferrozine–ferrous stain can be enhanced to a level comparable to silver staining by further incubating membranes in ferrocyanide-ferric stain ***(13,15)***. The colorimetric metal chelate stains are fully reversible and compatible with Edman-based protein sequencing, lectin blotting, mass spectrometry and immunoblotting ***(13–16)***.

1. After electroblotting, vacuum slot blotting, or dot blotting, membranes are completely immersed in block buffer for 10 min. Blocking and staining steps are performed on a rotary shaker (50 rpm).
2. Thoroughly immerse membranes in Ferrozine-ferrous stain for 10–15 min until purple bands or spots appear.
3. Unbound dye is removed by several brief rinses in 2% glacial acetic acid until the membrane background appears white. Shaking can be performed manually using wash volumes roughly 2× greater than in the blocking and staining steps.
4. If increased sensitivity is desired, the blot can be double stained by subsequently incubating in the ferrocyanide-ferric stain for 10–15 min (*see* **Notes 1–3**).
5. Unbound dye is removed by several brief washes in 100 m*M* sodium acetate, pH 4.0 (*see* **Note 4**). Shaking can be performed manually using wash volumes roughly 2× greater than in the blocking and staining steps.
6. Stained proteins are visualized by eye and quantified using a CCD camera (*see* **Note 5**).

3.2. Luminescent Detection of Electroblotted Proteins Using Bathophenanthroline Disulfonate-Europium (SYPRO Rose Stain)

Bathophenanthroline disulfonate–europium complex (SYPRO Rose protein blot stain) is a medium sensitivity metal chelate stain that offers the same advantages as colorimetric stains, but with the additional benefits of a 500-fold linear dynamic range and detection sensitivity of <15–30 ng of protein *(17)*. The stain can be visualized using 302 nm UV epi-illumination and emits at 590 and 615 nm. There is also a blue 450 nm emission, however, due to uncomplexed ligand. Bathophenanthroline disulfonate–europium complex is readily removed by incubation of blots in mildly alkaline solution.

1. Following electroblotting, vacuum slot blotting, or dot blotting, membranes are washed 2× for 30 min with formate buffer followed by 4× for 30 min with deionized water (*see* **Note 6**). All washing and staining steps are performed on a rotary shaker (50 rpm).
2. Membranes are completely immersed in the bathophenanthroline-europium blot stain for 15 min.
3. Unbound dye is removed by washing 4–6× for 1 min in deionized water (*see* **Note 7**).
4. Membranes are dried at room temperature or in a 37°C drying oven (for quicker results) following the washing steps (*see* **Note 8**).
5. Stained proteins are visualized by reflective UV illumination (*see* **Note 9**).

3.3. Luminescent Detection of Electroblotted Proteins Using SYPRO Rose Plus Protein Blot Stain

SYPRO Rose Plus protein blot stain is an improved europium-based complex with a narrow emission maximum centered at 615 nm. The blue fluorescence observed with SYPRO Rose dye has been eliminated with the new stain and SYPRO Rose Plus dye is readily excited using UV-A, UV-B, or UV-C epi-illumination. Transillumination is not recommended. Typically 2–8 ng of electroblotted protein may be detected using the stain. SYPRO Rose Plus protein blot stain is easily removed by incubation in a mildly alkaline solution. The stain can not be visualized using a laser-based gel scanner, but is fully compatible with mass spectrometry and immunoblotting technologies.

1. Following electroblotting, vacuum slot blotting, or dot blotting, membranes are completely immersed in SYPRO Rose Plus protein blot wash solution and incubated at room temperature for 15 min in a small, polypropylene staining dish. Perform all washing and staining steps with continuous, gentle agitation (ideally, on an orbital shaker at 50 rpm).
2. Repeat the wash step.
3. Incubate the membrane in four changes of deionized water for 10 min each.

4. Completely immerse the membrane in SYPRO Rose Plus protein blot stain reagent for 15 min.
5. Wash the membrane 4–6× for 1 min in deionized water, to remove excess dye from the membrane. Stained membranes should be monitored using UV epi-illumination periodically to determine whether background luminescence has been washed away (*see* **Note 10**).
6. Blots treated with the SYPRO Rose Plus blot stain are best preserved by allowing membranes to air dry. After staining, wet membranes should not be touched, since residue found on latex gloves may destroy the staining pattern. Use forceps to handle wet blots. Once dry, membranes can be handled freely.
7. Stained proteins are visualized by reflective UV illumination (*see* **Note 11**).

3.4. Luminescent Detection of Electroblotted Proteins Using SYPRO Ruby Protein Blot Stain

SYPRO Ruby protein blot stain is suitable for visualizing proteins on nitrocellulose or PVDF membranes using UV transillumination, UV epi-illumination, or laser excitation at 450–532 nm ***(22)***. Roughly 2–8 ng of protein can routinely be detected on electroblots and the linear dynamic range of detection is roughly 1000-fold. Unlike other sensitive detection technologies such as colloidal gold stain, SYPRO Ruby protein blot stain is fully compatible with mass spectrometry and Edman-based sequencing. The stain is fairly permanent, but is lost during protein blocking steps associated with Western blotting. Thus, the fluorescent pattern must be recorded and documented prior to immunodetection of a specific target on the blot.

3.4.1. Staining Proteins After Electroblotting to Nitrocellulose Membranes

1. Following electroblotting, vacuum slot blotting, or dot blotting to nitrocellulose, membranes are completely immersed in 7% acetic acid, 10% methanol and incubated at room temperature for 15 min in a small, polypropylene staining dish. Perform all washing and staining steps with continuous, gentle agitation (ideally, on an orbital shaker at 50 rpm).
2. Incubate the membrane in four changes of deionized water for 5 min each.
3. Completely immerse the membrane in SYPRO Ruby protein blot stain reagent for 15 min.
4. Wash the membrane 4–6× for 1 min in deionized water. This wash serves to remove excess dye from the membrane. Membranes stained with SYPRO Ruby protein blot stain should be monitored using UV epi-illumination periodically to determine if background luminescence has been washed away (*see* **Notes 12** and **13**).
5. Blots treated with the SYPRO Ruby protein blot stain can be preserved by allowing membranes to air-dry. After staining, wet membranes should not be touched, since residue found on latex gloves may destroy the staining pattern. Use forceps to handle wet blots. Once dry, membranes can be handled freely.

6. Stained proteins may be visualized by reflective or transmissive UV illumination or using a laser-based gel scanner (*see* **Notes 12** and **13**).

3.4.2. Staining Proteins After Electroblotting to PVDF Membranes

1. Following electroblotting, vacuum slot blotting, or dot blotting, to a sheet of PVDF membrane, allow the membrane to dry completely.
2. Float the membrane face down in 7% acetic acid, 10% methanol and incubate for 15 min. Perform all washing and staining steps with continuous, gentle agitation (e.g., on an orbital shaker at 50 rpm).
3. Incubate the membrane for 5 min each in four changes of deionized water.
4. Float the membrane face down in SYPRO Ruby protein blot stain reagent for 15 min.
5. Wash the membrane 2–3× for 1 min in deionized water. This wash serves to remove excess dye from the membrane. Membranes stained with SYPRO Ruby protein blot stain should be monitored using UV epi-illumination periodically to determine if background luminescence has been washed away (*see* **Notes 12** and **13**).
6. Blots treated with the SYPRO Ruby protein blot stain are best preserved by allowing the membranes to air-dry. After staining, wet membranes should not be touched, since residue found on latex gloves may destroy the staining pattern. Use forceps to handle wet blots. Once dry, the membranes can be handled freely.
7. Stained proteins may be visualized by reflective or transmissive UV illumination or using a laser-based gel scanner (*see* **Notes 12** and **13**).

3.5. Luminescent Detection of Proteins in Sodium Dodecyl Sulfate (SDS)-Polyacrylamide Gels Using SYPRO Ruby Protein Gel Stain

SYPRO Ruby protein gel stain is an ultrasensitive dye for detecting proteins separated by SDS-polyacrylamide or 2-D polyacrylamide gel electrophoresis (PAGE). The background fluorescence is low, the stain's linear dynamic range extends over three orders of magnitude, and shows low protein-to-protein variation. The stain is more sensitive than colloidal Coomassie Blue stain and equal in sensitivity to the best silver stains available. The stain is ready-to-use, and gels cannot over stain. Optimal staining requires about 3–4 h. Staining times are not critical, however, and staining can be performed overnight. SYPRO Ruby protein gel stain will not stain extraneous nucleic acids, and it is compatible with further downstream microchemical processing. The stain does not interfere with subsequent analysis of proteins by Edman-based sequencing or mass spectrometry. SYPRO Ruby protein gel stain can be used with many types of gels, including 2-D gels, Tris-glycine SDS gels, Tris-tricine precast SDS gels, and nondenaturing gels. SYPRO Ruby protein gel stain is also compatible with gels adhering to plastic backings, although the signal from the inherent blue fluorescence of the plastic must be removed with an appropriate emission

filter. The stain is suitable for peptide mass profiling using MALDI-TOF mass spectrometry ***(25–27).*** Stained gels can be visualized with a 302-nm UV transilluminator, various laser scanners, or other blue light-emitting sources. The dye maximally emits at about 610 nm.

1. Prepare and run SDS-polyacrylamide or 2-D polyacrylamide gels according to standard protocols. Perform staining with SYPRO Ruby protein gel stain using continuous, gentle agitation (e.g., on an orbital shaker at 50 rpm). For small gels, use circular staining dishes on orbital shakers if possible.
2. Clean and *thoroughly rinse* the staining dishes before use (*see* **Note 14**).
3. Fix the gel in 10% methanol and 7% acetic acid in a plastic dish for 30 min. This step improves the sensitivity of the stain in 2-D gels, but is optional for 1-D SDS-PAGE gels.
4. Pour the staining solution into a small, clean plastic dish. For one or two standard-size minigels, use ~50–100 mL of staining solution; for larger gels, use 500–750 mL (*see* **Note 15**).
5. Place the gel into fresh staining solution (*see* **Note 16**). Protect the gel and staining solution from light at all times by covering the container with a lid or with aluminum foil.
6. Gently agitate the gel in stain solution at room temperature. The staining times range from 90 min to 3 h, depending on the thickness and percentage of polyacrylamide in the gel. Specific staining can be seen in as little as 30 min. However, a minimum of 3 h of staining is required for the maximum sensitivity and linearity. For convenience, gels may be left in the dye solution overnight or longer without over staining.
7. After staining, rinse the gel in deionized water for 30–60 min to decrease background fluorescence. To further decrease background fluorescence the gel can be washed in a mixture of 10% methanol and 7% acetic acid for 30 min instead of water (*see* **Note 17**). This is especially recommended for 2-D gels. The gel may be monitored periodically using UV illumination to determine the level of background fluorescence (*see* **Note 18**).
8. To dry the stained gel for permanent storage, incubate the gel in a solution of 2% glycerol for 30 min. Dry the stained gel using a gel dryer by standard methods. Note that proteins present at very low levels may no longer be detectable after gel drying.
9. Stained proteins in wet or dried gels may be visualized by reflective or transmissive UV illumination or using a laser-based gel scanner (*see* **Note 18**).

3.6. Luminescent Detection of Proteins in Gels Using SYPRO Ruby IEF Protein Gel Stain

SYPRO Ruby IEF protein gel stain is a ready-to-use, ultrasensitive, luminescent protein stain created especially for the analysis of proteins in IEF gels. This fluorescent stain attains comparable sensitivity to that of the best silver-staining techniques. Staining protocols are simple, the stain is ready-to-use, and it cannot overstain. It will not stain extraneous nucleic acids and the stain detects

glycoproteins and other difficult-to-stain proteins. It does not interfere with subsequent analysis of proteins by Edman-based sequencing or mass spectrometry. SYPRO Ruby IEF protein gel stain is also compatible with agrose gels or polyacrylamide gels adhering to plastic backings.

1. Prepare and run IEF gels according to standard protocols. The staining technique is appropriate for carrier ampholyte isoelectric focusing or immobilized pH gradient (IPG) gels ***(24)***. Perform SYPRO Ruby IEF gel staining with continuous, gentle agitation (e.g., on an orbital shaker at 50 rpm). For small gels, use circular staining dishes on orbital shakers if possible.
2. Clean and *thoroughly rinse* the staining dishes before use. (*see* **Note 20**).
3. Incubate the gel in the undiluted stain overnight. (*see* **Note 19**). **Caution: SYPRO Ruby IEF protein gel stain contains a caustic acid. The stain should be handled with care, using protective clothing, eye protection, and gloves.**
4. Rinse the gel in four changes of deionized water over 2 h to decrease background fluorescence. The gel may be monitored periodically using UV transillumination (*see* **Note 21**) to determine the level of background fluorescence. For IEF gels with plastic backings, the gel separates from the backing during this water wash. It is important that the backing be removed from the gels as it has high inherent fluorescence.
5. To dry the stained gel for permanent storage, incubate the gel in a solution of 2% glycerol for 30 min. Dry the stained gel using a gel dryer by standard methods. Note that proteins present at very low levels may no longer be detectable after gel drying.
6. Stained proteins in wet or dried gels may be visualized by reflective or transmissive UV illumination or using a laser-based gel scanner (*see* **Note 21**).

3.7. Elution of Metal Chelate Stains

The Ferrozine-ferrous, Pyrogallol Red–molybdate, Ferrocyanide–ferric, colorimetric metal chelate stains as well as the luminescent bathophenanthroline disulfonate–europium and SYPRO Rose Plus protein blot stains are readily removed from electroblotted proteins by incubation in mildly alkaline solution. SYPRO Ruby protein blot stain is not readily reversible by similar methods, although it is slowly removed from proteins during blocking and incubation steps commonly used in immunoblotting procedures. The gel stains are also not readily destained.

The Ferrozine–ferrous stain can be eluted by immersing the blots in 50 m*M* Tris-HCl, pH 8.8, 200 m*M* NaCl, 20 m*M* EDTA for 15 min on a rotary shaker (50 rpm). Blots treated with the Ferrozine–ferrous stain followed by enhancement with the ferrocyanide–ferric stain require harsher elution conditions. This stain is eluted by incubation in 200 m*M* sodium carbonate, 100 m*M* EDTA, pH 9.6 for 10 min. As the bathophenanthroline-europium and SYPRO Rose Plus stains can be observed only upon UV illumination, they do not require elution

if subsequent colorimetric detection procedures are to be performed ***(29)***. If concerned about interference with subsequent procedures, however, the stains can be eluted from blots by incubation in 200 m*M* sodium carbonate, 100 m*M* EDTA, pH 9.6 or using SYPRO Rose Plus destain solution (component C). All the metal chelate stains mentioned above may be destained using the following protocol:

1. Incubate the membrane in appropriate destain reagent for 15 min with continuous gentle agitation.
2. Rinse twice for 1 min each in deionized water.

4. Notes

4.1. Colorimetric Detection of Proteins on Nitrocellulose, PVDF, or Nylon Membranes

1. Although enhancement of the Ferrozine–ferrous stain with ferrocyanide–ferric stain substantially increases detection sensitivity, the double stain is also more difficult to elute than the Ferrozine–ferrous stain alone (*see* **Subheading 3.7**, for methods of stain reversal).
2. The ferrocyanide-ferric stain may form a precipitate after long–term storage. The precipitate is easily resuspended by vigorous shaking or sonication.
3. If a dried nitrocellulose membrane is incubated in the ferrocyanide–ferric stain, a patchy background may result that is difficult to destain. Dry blots should be rehydrated briefly in deionized water prior to incubation in the ferrocyanide–ferric stain.
4. The number of washes necessary to remove background staining may vary slightly. The ferrocyanide–ferric stain may initially remain bound to the nitrocellulose membrane but the membrane background will become white with sufficient washing.
5. Membranes may be imaged transmissively or reflectively. Transmissive imaging is preferred over conventional reflective imaging as it improves signal detection while maintaining a white background. Furthermore, in some cases the protein sample penetrates through the membrane support to the reverse side (particularly with vacuum slot blotters). The metal chelate complexes stain proteins present throughout the thickness of the membrane and on both surfaces but reflective scanning only detects signal on the front surface, leading to a poorer linear dynamic range of quantitation. This problem is alleviated with transmissive scanning. Typically, a 45 W white light box is used in conjuction with a 450 ± 70 nm bandpass filter to enhance image contrast when imaging Ferrozine–ferrous or Pyrogallol Red-molybdenum stains. For blue stains such as Ferrozine-ferrous followed by the ferrocyanide-ferric stain, a 600 ± 70 nm bandpass filter may enhance the image contrast. Because the membrane support blocks a

substantial amount of transmitted light, care must be taken to completely mask the sample with black cardboard for transmissive imaging.

4.2. Luminescent Detection of Electroblotted Proteins Using Bathophenanthroline Disulfonate-Europium (SYPRO Rose Stain)

6. Since formate ions may chelate europium ions, the washes with deionized water are crucial for complete removal of the formate buffer. Otherwise, the staining solution may be inactivated. Care should be taken to aspirate off all the solution between washes.
7. Removal of unbound bathophenathroline-europium stain can not be visually monitored as with the colorimetric stains. We have found that washing 4× for 1 min is effective. However, the number and duration of washes may vary from case to case (depending on the size of the membrane and the volume of each wash). Therefore, optimal washing should be determined empirically for each application.
8. After staining, wet membranes should not be touched since residue found on latex laboratory gloves may destroy the stain. Once dry, membranes can be handled freely. Since water is known to quench europium luminescence, drying the membrane also serves to enhance the signal (about twofold).
9. Images are best obtained using a cooled CCD-camera by digitizing at about 1024 × 1024 picture elements (pixels) resolution with 12- or 16-bit gray scale levels assigned per pixel. To visualize the stain, the front face of membranes should be illuminated with the UV source: a hand-held, UV-B (302 nm) light, a UV light box placed on its side, or a top illuminating system such as the Bio-Rad Fluor-S imager. Direct transillumination through the blotting membrane yields unsatisfactory results. SYPRO Rose protein blot stain is best visualized using a 490-nm longpass filter such as a SYPRO protein gel photographic filter (Molecular Probes, Inc., cat. no. S-6656) or a 600-nm bandpass filter.

4.3. Luminescent Detection of Electroblotted Proteins Using SYPRO Rose Plus Protein Blot Stain

10. Removal of unbound bathophenathroline–europium stain cannot be visually monitored as with the colorimetric stains. We have found that washing 4× for 1 min is effective. However, the number and duration of washes may vary from case to case (depending on the size of the membrane and the volume of each wash). Therefore, optimal washing should be determined empirically for each application.
11. Proteins stained with SYPRO Rose Plus protein blot stain are readily visualized by eye using epi-illumination with a UV light source. Illuminate the

front face of the membranes using a hand-held, UV-B (302 nm) light source, a UV light box placed on its side, or a top illuminating system such as the Bio-Rad Fluor-S™ imager. For greatest sensitivity and accurate quantitation, photograph the blot using Polaroid photography with a 490-nm longpass filter such as the SYPRO protein gel photographic filter (Molecular Probes, Inc., cat. no. S-6656) or use a computerized CCD camera-based image analysis system equipped with a 600-nm bandpass filter. Direct transillumination through the blotting membrane yields unsatisfactory results.

4.4. Luminescent Detection of Electroblotted Proteins Using SYPRO Ruby Protein Blot Stain

12. Proteins stained with SYPRO Ruby protein blot stain are readily visualized by eye using epi-illumination with UV light source. Illuminate the front face of the membranes using a hand-held, UV-B (302 nm) light source, a UV light box placed on its side, or a top illuminating system. Alternatively, use direct transillumination through the blotting membrane. For greater sensitivity and accurate quantitation, photograph the blot using Polaroid® photography or a computerized CCD camera-based image analysis system equipped with a 490-nm longpass filter such as the SYPRO protein gel photographic filter (Molecular Probes, Inc., cat no. S-6656) or a 600-nm bandpass filter. Laser-based imaging systems can also be used.
13. Images are best obtained using a cooled CCD-camera by digitizing at about 1024 × 1024 picture elements (pixels) resolution with 12- or 16-bit gray scale levels assigned per pixel. To visualize the stain, the front face of membranes should be illuminated with the UV source: a hand-held, UV-B (302 nm) light, a UV light box placed on its side, or a top illuminating system such as the Bio-Rad Fluor-S imager. Satisfactory results are obtained from direct transillumination through the blotting membrane as well. SYPRO Ruby protein blot stain is best visualized using a 490-nm longpass filter such as a SYPRO protein gel photographic filter (Molecular Probes, Inc., cat. no. S-6656) or a 600 nm bandpass filter. Proteins stained with the dye can also be visualized using imaging systems equipped with 450-, 473-, 488-, or even 532-nm lasers.

4.5. Luminescent Detection of Proteins in SDS-Polyacrylamide Gels Using SYPRO Ruby Protein Gel Stain

14. Polypropylene dishes, such a Rubbermaid® Servin' Savers, are the optimal containers for staining because the high-density plastic adsorbs only a minimal amount of the dye. Clean and rinse the staining containers well before use, as detergent will interfere with staining. It is best to rinse the containers with ethanol before use. For small gels, circular staining dishes provide the

best fluid dynamics on orbital shakers, resulting in less dye aggregation and better staining. For large format 2-D gels, polyvinyl chloride photographic staining trays, such as Photoquip Cesco-Lite 8 in. × 10 in. photographic trays also work well. Glass dishes are not recommended.

15. Minimal staining volumes for typical gel sizes are as follows:
    50 mL, for 8 cm × 10 cm × 0.75 mm gels (minigels)
    330 mL, for 16 cm × 20 cm × 1 mm gels
    500 mL, for 20 cm × 20 cm × 1 mm gels
    or ~ 10 times the volume of the gel for other gel sizes
16. Use only fresh staining solution for optimal sensitivity. Longer staining times result in greater sensitivity. Using too little stain will lower the sensitivity.
17. Always store gels in the dark to prevent photobleaching. When gels are stored in the staining solution, the signal decreases somewhat after several days; however, depending on the amount of protein in bands of interest, gels may retain a usable signal for many weeks.
18. The stained gel is best viewed on a standard 302 nm UV or a blue-light transilluminator. Gels may also be visualized using various laser scanners: 473 nm (SHG) laser, 488 nm argon-ion laser, 532 nm (YAG) laser. Alternatively, use a xeon arc lamp, blue fluorescent light, or blue light-emitting diode (LED) source. Gels may be photographed by Polaroid or CCD camera. Use Polaroid 667 black-and-white print film and the SYPRO protein gel stain photographic filter (Molecular Probes, Inc., cat. no. S-6656). Exposure times vary with the intensity of the illumination source; for an f-stop of 4.5, roughly 1–3 s should be required.

4.6. Luminescent Detection of Proteins in IEF Gels Using SYPRO Ruby IEF Protein Gel Stain

19. Minimal staining volumes for typical gel sizes are as follows:
    50 mL, for 6 cm × 9 cm × 1 mm gels (minigels)
    150 mL, for 22 cm × 22 cm × 1 mm (Multiphor II format gels, Amersham-Pharmacia Biotech)
    Or approx 10 times the volume of the gel for other gel sizes.
20. Polypropylene dishes, such as Rubbermaid® Servin' Savers, are the optimal containers for staining because the high-density plastic adsorbs only a minimal amount of the dye. Clean and rinse the staining containers well before use as detergent will interfere with staining. It is best to rinse the containers with ethanol before use. For small gels, circular staining dishes provide the best fluid dynamics on orbital shakers, resulting in less dye aggregation and better staining. For large-format 2-D gels, polyvinyl chloride photographic staining trays, such as Photoquip Cesco-Lite 8 in. × 10 in. photographic trays also work well. Glass dishes are not recommended.

21. The stained gel is best viewed on a standard 302-nm UV or a blue-light transilluminator. Gels may also be visualized using various laser scanners: 473-nm (SHG) laser, 488 nm argon-ion laser, 532-nm (YAG) laser. Alternatively, use a xenon arc lamp, blue fluorescent light, or blue light-emitting diode (LED) source. Gels may be documented by conventional photography using the SYPRO protein gel stain photographic filter (Molecular Probes, Inc., cat. no. S-6656) or using a CCD camera equipped with 600-nm bandpass filter. Exposure times vary with the intensity of the illumination source; for an f-stop of 4.5, roughly 1–3 s should be required.

Detection of Proteins in Polyacrylamide Gels by Fluorescent Staining

Michael J. Dunn

1. Introduction

Techniques of polyacrylamide gel electrophoresis are often the method of choice for the analysis of patterns of protein expression in a wide variety of complex systems. In particular, two-dimensional polyacrylamide gel electrophoresis (2-DE) is the core technology for separating complex protein mixtures in the majority of proteome projects ***(1)***. This is due to its unrivalled power to separate simultaneously thousands of proteins and to indicate post-translational modifications that result in alteration in protein pI or M_r. Additional advantages are the high sensitivity with which the separated proteins can be visualised, the availability of sophisticated computer image analysis software for the qualitative and quantitative analysis of differential patterns of protein expression ***(2)***, and the relative ease with which proteins from 2-DE gels can be identified by mass spectrometry (MS) ***(3, 4)***.

The successful use of polyacrylamide gel electrophoresis as an analytical tool for investigating protein expression and as a micro-preparative procedure for protein identification and characterisation depends on the availability of detection methods that are both quantitative and sensitive. Coomassie Brilliant Blue R-250 (CBB R-250) has been used for many years as a general protein stain following gel electrophoresis. Its restricted dynamic range limits its suitability for accurate quantitative analysis, although it is compatible with most methods of chemical characterisation. However, CBB R-250 has a limited sensitivity of around 200–500 ng protein per spot ***(5)***. The development of colloidal CBB staining using CBB G-250 ***(6)*** provided a significant increase in sensitivity at around 10 ng protein. However, the trend towards the use of thinner gels and the need to detect small amount of protein within single bands or spots resolved by

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

one- or two-dimensional electrophoresis have necessitated the development of more sensitive detection methods ***(5).***

Silver staining for the detection of proteins following gel electrophoresis was first reported in 1979 by Switzer et al ***(7),*** resulting in a major increase in the sensitivity of protein detection. More than 100 publications have subsequently appeared describing variations in silver staining methodology **(5, 8).** This group of procedures is generally accepted to be around 100 times more sensitive than methods using CBB R-250, being able to detect low ng amounts of protein per gel band or spot. Although silver staining has become the most widely used technique for high sensitivity visualisation of gel separated proteins, its variable binding characteristics towards many proteins and its relatively restricted dynamic range limit the accuracy and reliability of quantitation. Moreover, saturated protein bands and spots tend to be negatively stained making their quantitation impossible. Standard methods of silver staining are also often not compatible with chemical characterisation by mass spectrometry as the glutaraldehyde and formaldehyde present results in alkylation of α- and ε-amino groups of proteins. To overcome this problem, silver staining protocols compatible with mass spectrometry in which glutaraldehyde is omitted have been developed ***(9, 10)*** but these suffer from a decrease in sensitivity of staining and a tendency to a higher background.

Many of the problems associated with silver staining can be overcome using detection methods based on the use of fluorescent compounds ***(5).*** This group of methods are highly sensitive and generally exhibit excellent linearity and a high dynamic range, making it possible to achieve good quantitative analysis particularly if a suitable imaging device is used. In addition, these methods should in general have good compatibility with protein identification by MS. Two approaches can be used, the first being to couple the proteins with a fluorescently labelled compound prior to electrophoresis. Examples of such compounds are dansyl chloride ***(11),*** fluorescamine (4-phenyl-[furan-2(3H),1-phthalan]-3,3 -dione) ***(12),*** o-phthaldialdehyde (OPA) (13), and MDPF (2-methoxy-2, 4-diphenyl-3(2H)-furanone) ***(14).*** The latter reagent has a reported sensitivity of 1 ng protein/band and is linear over the range 1–500 ng protein/band.

The main disadvantage of pre-electrophoretic staining procedures is that they can cause protein charge modifications, for example fluorescamine converts an amino group to a carboxyl group when it reacts with proteins. Such modifications usually do not compromise SDS-PAGE unless a large number of additional charged groups are introduced into the protein. However, they result in altered mobility during other forms of electrophoresis, resulting in altered separations by native PAGE, IEF and 2-DE. More recently, compounds that react with cysteine or lysine residues have been described and used successfully for 2-DE separations. The cysteine-reactive reagent monobromobimane ***(15)*** has been used to label proteins prior to analysis by 2-DE ***(16).*** Using a cooled CCD

camera to measure fluorescence, the limit of detection was found to be 1 pg protein/spot ***(17).***

In an alternative approach, a pre-electrophoretic fluorescent staining method based on the labelling of protein samples with *N*-hydroxy succinimidyl ester derivatives of fluorescent cyanine (Cy) dyes and known as two-dimensional difference gel electrophoresis (2-D DIGE) is currently being widely used ***(18, 19).*** This approach has the advantage that a pair of protein samples can be labelled separately with Cy3 and Cy5 derivatives. The two samples can be mixed and then separated together on the same 2-DE gel. The resulting 2-DE gel is then scanned to acquire the Cy3 and Cy5 images separately. Improved quantitative accuracy of comparison of multiple pairs of samples can be achieved using a pooled internal standard labelled with a third dye, Cy2 ***(20, 21).*** Recently saturation labeling with cysteine-reactive cyanine fluorescent dyes has been described ***(22).*** This technique provides increased sensitivity for expression profiling of scarce samples such as laser-microdissected clinical specimens ***(23).***

Another approach to overcoming the problems associated with charge modification during the IEF dimension is to label the proteins while present in the first dimension gel after IEF, prior to the second dimension separation by SDS-PAGE. Two fluorescent labels that have been used in this way are MDPF ***(24)*** and a fluorescent maleimide derivative ***(25).***

An alternative approach, which also overcomes the problem of protein charge modifications, is to label the proteins with fluorescent molecules such as 1-aniline-8-naphthalene sulphonate (ANS) ***(26)*** and OPA after the electrophoretic separation has been completed. However, these two methods suffer the disadvantage of relative insensitivity. Additional post-electrophoretic fluorescent staining reagents, such as SYPRO Orange and Red, have been described ***(5, 27, 28).*** These stains have a high sensitivity (4–10 ng protein/band) and excellent linearity with a high dynamic range. Using a fluorescent imaging device, the SYPRO dyes have been shown to be linear over three orders of magnitude in protein quantity ***(28).*** The other advantage of this method is that staining can be achieved in only 30 min, compared with staining with silver and CBB R-250 which can take from 2 hr to overnight. Gels can be stained without fixation so that they can be subjected to subsequent Western blotting procedures. However, staining with these reagents requires that the proteins are complexed with SDS, so that if the gels are fixed prior to staining or electrophoresis is carried out in the absence of this detergent, then the gels must be incubated in a solution of SDS prior to staining. Moreover, these dyes require 7% acetic acid and organic solvent in the staining solution, which can cause problems in electroblotting, electroeleution and measurement of enzyme activity. The dye SYPRO Tangerine was subsequently developed to overcome these shortcomings ***(29).***

Recently, epiconnone, a non-fluorescent azophilone that fluoresces when it binds to proteins, has been found to a useful fluorescent stain for gel separated proteins ***(30).*** It is marketed under the trade names Deep Purple (GE Healthcare) and Lava Purple (Fluorotechnics) and has been found to be very sensitive and linear over four orders of magnitude ***(31).***

SYPRO Ruby is a ruthenium-based metal chelate stain that binds to the basic amino acid residues in proteins ***(32, 33).*** The advantage of this dye over the other SYPRO stains is that the presence of SDS is not required for binding so that gels can be fixed in the normal way and then simply soaked in the SYPRO Ruby staining solution for a minimum of 3 hr. In addition, SYPRO Ruby has a sensitivity similar to the most sensitive silver stains ***(32, 34),*** and it has been reported that some proteins that stain poorly with silver techniques are readily detected by SYPRO Ruby ***(33).*** In addition, staining times are not critical and staining can be performed overnight without gels overdeveloping. Together with its very high dynamic range of over 1000-fold, these properties make SYPRO Ruby an excellent choice for quantitative applications. It also has been shown to be linear over three orders of magnitude and to have excellent compatibility with chemical characterisation methods ***(35, 36).*** The original formulation of SYPRO Ruby required specific fixation in 7% acetic acid and 10% methanol, while a more recent formulation of the stain is tolerant to a wide range of fixatives ***(37).*** An additional advantage of SYPRO Ruby is that it can be used for multiplexed staining in combination with florescence detection of glycoproteins with Pro-Q Emerald ***(38)*** and phosphoproteins with Pro-Q Diamond ***(39).*** A 2-DE gel separation of rat heart proteins visualised with SYPRO Ruby is shown in **Fig. 1.**

2. Materials

1. All solutions should be freshly prepared, and overnight storage is not recommended.
2. Fixation solution: 10% (v/v) methanol, 7% (v/v) acetic acid (*see* **Note 1**).
3. SYPRO Ruby staining solution (*see* **Note 2**).
4. Washing solution: 10% (v/v) methanol, 7% (v/v) acetic acid (*see* **Note 3**).

3. Method

Note: All incubations are carried out at room temperature with gentle agitation.

1. After electrophoresis, fix the gel immediately (*see* **Note 4**) in 500 mL (*see* **Note 5**) of fixation solution for a minimum of 1 h at room temperature *(see* **Note 6**).
2. Place the gel into 500 mL of SYPRO Ruby protein gel stain solution for a minimum of 3 h (*see* **Note 7**).
3. Incubate the gel in 500 mL of washing solution for 30 to 50 min to wash excess dye out of the polyacrylamide matrix (*see* **Note 8**).
4. Image the gel (*see* **Note 9**).

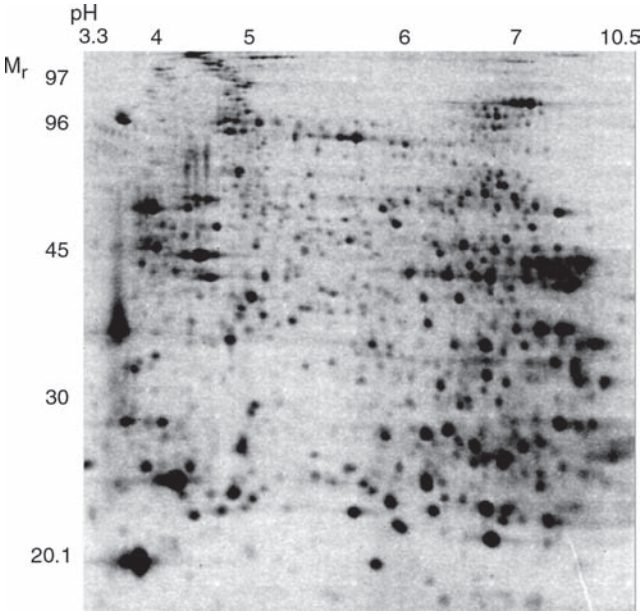

Fig. 1. A 2-DE separation of rat heart proteins visualised by SYPRO Ruby staining. Note that the fluorescent image is shown as an inverted image to show black spots on a white background for convenient viewing. The first dimension was pH 3–10 NL IPG IEF and the second dimension was 12% T SDS-PAGE. The scale at the top indicates the non-linear pH gradient used in the first IPG 3–10 NL IEF dimension, while the scale at the left indicates $M_r \times 10^{-3}$.

4. Notes

1. Methanol may be substituted with ethanol without loss of sensitivity, and a range of other fixatives can be used ***(36).***
2. SYPRO Ruby protein gel stain is only available as a pre-made solution from the manufacturers (Invitrogen, Molecular Probes, Paisley, UK).
3. Methanol may be replaced with ethanol in the washing solution.
4. Gloves should be worn at all stages when handling gels, particularly when they will be used for subsequent chemical characterisation, to prevent contamination with keratin proteins from the skin.
5. Volumes of the solutions used at all stages should be sufficient such that the gel is totally immersed. If the volume of solution is insufficient for total immersion, staining will be uneven and the gel surface can dry out. The volumes given here are suitable for a 24 × 20 cm 2-D gel.
6. High-percentage polyacrylamide and thick gels require an increased period for fixation, and overnight soaking is recommended.
7. The staining time is not critical and staining can be performed overnight without gels overdeveloping. In this case, the containers used for staining should be wrapped with aluminium foil to avoid light exposure.

8. Gels stained with SYPRO Ruby can be stored in the washing solution for a period of time (several days to a week) before image acquisition. In this case, the containers used for staining should be wrapped with aluminium foil to avoid light exposure.
9. SYPRO Ruby dye can be excited using a standard 300 nm UV transilluminator, so that gel images can be documented using any suitable camera system. However, for quantitative analysis the gel must be digitised using a suitable imaging system such as laser fluorimager (equipped with 450, 473, 488 or even 532 nm lasers) or a multi-wavelength CCD-based fluorimaging system ***(28).***

Detection of Glycoproteins in Gels and Blots

Nicolle H. Packer, Malcolm S. Ball, Peter L. Devine, and Wayne F. Patton

1. Introduction

As we become more aware of the significance of posttranslational modifications, such as glycosylation, in the production of recombinant proteins and in the proteomic studies of development and disease, techniques for the identification and characterization of the oligosaccharides attached to proteins need to be established.

After separation of the proteins by either one-diemensional-(1D)- or two-dimensional-(2D)-polyacrylamide gel electrophoresis (PAGE), the initial step is to identify which proteins are glycoproteins so that further characterization can proceed. Various methods have been developed since the early detection of glycoproteins on gels ***(1)*** and blots, with color, fluorescence, and lectin detection now carried out at the analytical level. The actual level of detection of course depends on the extent of glycosylation of the protein, as the reagents react only with the carbohydrate moiety. We have chosen to describe here the stains that we have found to be the most useful for visualizing glycoproteins, both on gels and blots, after separation by electrophoresis. It should be noted that all the staining procedures currently in use destroy the structure of the carbohydrate and thus prevent further analysis of the glycan component once the glycoprotein is visualized.

As an initial characterization step, once the glycoprotein of interest has been located, a protocol for analyzing the monosaccharide composition on replicate blots of these proteins is also described.

1. Periodic acid-Schiff staining is a generally useful technique for locating glycoproteins on gels and nitrocellulose blots, although the sensitivity may not be sufficient for many applications. Realistically, only 1–10 µg of a highly glycosylated protein

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

can be detected and the stain is most useful for mucins and proteoglycans. Periodic acid oxidizes vicinal diols of glycosyl residues to dialdehydes. The aldehydes are then allowed to react with fuchsin (Schiff's reagent) to form a Schiff base. Glycoproteins stain pink with fuchsin on a clear background.

2. Digoxigenin (DIG)–anti-digoxigenin, alkaline phosphate (AP) labeling is an extension of the periodic acid–Schiff method above although the sensitivity is much greater (realistically, depending on the degree of glycosylation, about 0.1 μg of glycoprotein). Glycoproteins can be detected on dot blots or after Western transfer to membranes such as nitrocellulose or polyvinylidene difluoride (PVDF). Vicinal (adjacent) hydroxyl groups in sugars of glycoconjugates are oxidized to aldehyde groups by mild periodate treatment. The spacer-linked steroid hapten digoxigenin (DIG) is then covalently attached to these aldehydes via a hydrazide group. DIG-labeled glycoconjugates are subsequently detected in an enzyme immunoassay using a DIG-specific antibody conjugated with AP. DIG glycan detection is known to label almost all known *N*- and *O*-linked glycans including GPI anchors.
3. Lectins are carbohydrate binding proteins which are particularly useful in glycoprotein and carbohydrate analysis as they can be conjugated to a variety of enzymes or haptens for use in sensitive detection systems. Their specificity can be used to probe for specific structures in the glycoconjugates. Lectins are usually classified on the basis of the monosaccharides with which they interact best, but it is important to note that complex glycoconjugates are generally found to be much better ligands. In addition, the position of a particular monosaccharide in a glycan chain (i.e., to what it is attached) will affect lectin binding, so results obtained in lectin binding studies should be treated with caution. For example, (a) the wheat germ agglutin (WGA) is inhibited most strongly by dimeric GlcNAc, but in glycoproteins this lectin also reacts very strongly with sialic acid and peptide-linked GalNAc; (b) the peanut agglutin binds to Gα1,3GalNAc but does not react when this structure is sialylated. The labeled lectin–carbohydrate conjugate can then be visualized by enzyme immunoassay in the same way as in (b).
4. Recently a new kit that uses a fluorescent hydrazide to react with the periodate-oxidized carbohydrate groups on glycoproteins has been released commercially. The fluorescent tag (Pro-Q™ Emerald 300) is excited by ultraviolet light and emits at a visible light (green) wavelength. The fluorescent signal allows an increased level of detection of the glycoproteins (down to 1 ng of protein) on both gels and PVDF blots, while allowing the subsequent visualization of the total proteins with another fluorescent stain emitting at a different wavelength.
5. The monosaccharide composition of a glycoprotein is a useful start to full characterization. This is obtained by hydrolysis of the separated glycoprotein spots that have been electroblotted to PVDF, followed by monosaccharide analysis using high pressure anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD) ***(2)***.

In all methods, it is useful to include a glycosylated protein such as transferrin or ovalbumin in the marker lane as a control.

2. Materials

2.1. Periodic Acid-Schiff Staining

1. Solution A: 1.0% (v/v) periodic acid in 3% acetic acid. Periodic acid is corrosive and volatile—**handle with caution**. Be aware of the concentration of periodic acid in the solution that is being diluted, as periodic acid is only about 50% out of the reagent bottle.
2. Solution B: 0.1% (w/v) Sodium metabisulfite in 10 m*M* HCl.
3. Schiff's reagent: A commercial reagent from Sigma Chemical Co. (St. Louis, MO, USA) may be used or better staining can often be achieved by making fresh reagent:
   a. Dissolve 1 g of basic fuchsin in 200 mL of boiling distilled water, stir for 5 min and cool to 50°C.
   b. Filter and add 20 mL of 1 *M* HCl to filtrate.
   c. Cool to 25°C, add 1 g of potassium metabisulfite, and leave to stand in the dark for 24 h.
   d. Add 2 g of activated charcoal, shake for 1 min, and filter. Store at room temperature in the dark.

   Schiff's reagent is corrosive and slightly toxic and a very dilute solution will stain anything with oxidized carbohydrates a pink-purple color **Note:** wear gloves and protective clothing when using this solution and washing it out of the gel/blot.
4. Solution C: 50% (v/v) Ethanol.
5. Solution D: 0.5% (w/v) Sodium metabisulfite in 10 m*M* HCl.
6. Solution E: 7.5% (v/v) Acetic acid–5% (v/v) methanol in distilled water.

Solutions A, B, and D should be made up freshly.

2.2. DIG–Anti-DIG AP Labeling

1. Buffer A (TBS): 50 m*M* Tris-HCl, pH 7.5, 150 m*M* NaCl.
2. Buffer B: 100 m*M* Sodium acetate, pH 5.5.
3. Buffer C: 100 m*M* Tris-HCl, 50 m*M* $MgCl_2$, 100 m*M* NaCl.
4. Buffer D: 250 m*M* Tris-HCl, pH 6.8, 8% (w/v) sodium dodecyl sulfate (SDS), 40% (v/v) glycerol, 20% (v/v) 2-mercaptoethanol, bromophenol blue as tracking dye.
5. Buffer E: 50 m*M* potassium phosphate, 150 m*M* NaCl, pH 6.5 (PBS).
6. Blocking reagent: A fraction of milk proteins that are low in glycoproteins. 0.5 g sample is dissolved in 100 mL of buffer A. The solution should be heated to 60°C with stirring; the solution will remain turbid. Allow the solution to cool before immersing the membrane.
7. DIG Glycan Detection Kit (Roche Diagnostics, Basel, Switzerland) containing:
   a. Solution 1: 10 m*M* sodium metaperiodate in buffer B.
   b. Solution 2: 3.3 mg/mL of sodium metabisulfite.
   c. DIG-succinyl-ε-amidocaploic acid hydrazide.
   d. Anti-DIG-AP: Polyclonal sheep anti-DIG Fab fragments, conjugated with AP (750 U/mL).
   e. Solution 3: 75 mg/mL 4-nitroblue tetrazolium chloride dissolved in 70% (v/v) dimethylformamide.

f. Solution 4: 50 mg/mL of 5-bromo-4-chloro-3-indolyl-phosphate dissolved in dimethyl-formamide.

Make sure that solutions 3 and 4 are still good, as after a few weeks the solutions may begin to precipitate thus reducing the staining efficiency. Store these solutions (3 and 4) in the dark.

2.3. DIG-Labeled Lectin Staining

1. 1% KOH.
2. Blocking reagent (Roche Diagnostics): A fraction of milk proteins that are low in glycoproteins. A 0.5 g sample is dissolved in 100 mL of TBS. The solution should be heated to 60°C with stirring; the solution will remain turbid. Allow the solution to cool before immersing the membrane. Other blockers such as skim milk powder, gelatin, or bovine serum albumin (BSA) may lead to high background.
3. TBS: 50 m*M* Tris-HCl, pH 7.5, 150 m*M* NaCl.
4. TBS-Tween: TBS + 0.05% Tween 20.
5. Divalent cation stock solution: 0.1 *M* $CaCl_2$, 0.1 *M* $MgCl_2$, 0.1 *M* $MnCl_2$.
6. DIG-labeled lectins (Roche Diagnostics): Sambucus sieboldiana agglutinin (SNA), Maackia amurensis agglutinin (MAA), Arachis hypogaea (peanut) agglutinin (PNA), and Datura stramonium agglutinin (DSA).
7. Part of DIG Glycan Detection Kit (Roche Diagnostics) comprising:
   a. Anti-DIG-AP: Polyclonal sheep anti-DIG Fab fragments, conjugated with AP (750 U/mL)
   b. Buffer C: Tris-100 m*M* HCl, 50 m*M* $MgCl_2$, 100 m*M* NaCl.
   c. Solution 3: 75 mg/mL of 4-nitrobluetetrazolium chloride dissolved in 70% (v/v) dimethylformamide.
   d. Solution 4: 50 mg/mL of 5-bromo-4-chloro-3-indolyl-phosphate dissolved in dimethylformamide.

   Store these solutions (3 and 4) in the dark.

2.4. Pro-Q Emerald 300 Dye Staining

1. Pro-Q Emerald 300 glycoprotein gel stain kit (Molecular Probes, OR, USA) containing:
   a. Pro-Q Emerald 300 reagent, 50× concentrate in dimethyl formamide (DMF) (component A), 5 mL.
   b. Pro-Q Emerald 300 dilution buffer (component B), 250 mL.
   c. Periodic acid (component C), 2.5 g.
   d. SYPRO Ruby protein gel stain (component D), 500 µL.
   e. SDS, component E), 500 µL of a 10% solution.
   f. CandyCane glycoprotein molecular weight standards (component F), 40 µL, sufficient volume for approx 20 gel lanes. Each protein is present at approx 0.5 mg/mL. The standards contain a mixture of glycosylated and nonglycosylated proteins, which, when separated by electrophoresis, provide alternating positive and negative controls.

2. Fix solution: Prepare a solution of 50% methanol and 50% dH_2O. One 8 × 10 gel will require approx 100 mL of fix solution.
3. Wash solution. Prepare a solution of 3% glacial acetic acid in dH_2O. One 8 × 10 gel will require about approx 250 mL of wash solution.
4. Oxidizing solution. Add 250 mL of 3% acetic acid to the bottle containing the periodic acid (component C) and mix until completely dissolved.
5. CandyCane molecular weight standards diluted in sample buffer. For a standard lane on a 8 cm × 10 cm gel, dilute 0.5 µL of the standards with 7.5 µL of sample buffer and vortex-mix. This will result in approx 250 ng of each protein per lane, a sufficient amount for detection of the glycoproteins by the Pro-Q Emerald 300 stain. For large 16 cm × 18 cm gels, double the amount of standard and buffer used.

2.5. HPAEC Analysis of Monosaccharide Composition

1. Methanol.
2. 0.1 *M* TFA.
3. 2 *M* TFA.
4. Standard sugars:
   a. 0.1 mmole/mL of lactobionic acid.
   b. 0.1 mmole/mL of 2-deoxyglucose.
   c. 0.1 mmole/mL of *N*-acetyl neuraminic acid and *N*-glycolyl neuraminic acid.
   d. 0.1 mmole/mL of mixture of fucose, 2-deoxyglucose, galactosamine, glucosamine, galactose, glucose and mannose.

   Sugars should be dried thoroughly over phosphorus pentoxide in a desiccator before weighing.
5. Metal-free HPLC System with DIONEX CarboPac PA1 PA10 column, 4 mm × 25 cm and pulsed amperometric detector (HPAEC-PAD).

3. Methods

3.1. Periodic Acid–Schiff Staining

This method is essentially as described in **ref. *3*** for glycoproteins transferred to nitrocellulose membranes. A modification of the method for PVDF membranes is described in **ref. *4***.

3.1.1. Gel Staining (see Note 1)

1. Soak the gel in solution C for 30 min (*see* Note 2).
2. Wash in distilled water for 10 min. All of the ethanol must be removed from the gel, so make sure that the gel is immersed in the water properly. If necessary wash a second time to ensure the removal of the ethanol.
3. Incubate in solution A for 30 min. **Beware of the fumes from the acid.** From this point onwards the gel should be placed in the fume hood.
4. Wash in distilled water for at least 6 × 5 min or 5 × 5 min and 1× overnight.
5. Wash in solution B for 2 × 10 min. At this stage make up 100 mL of solution B and perform 2 × 30 mL washes; save the final 40 mL for **step 7**.

6. Incubate in Schiff's reagent for 1 h in the dark. It is essential after adding the Schiff's reagent that the gel is kept in the dark, as any light will stop the color from developing.
7. Incubate in solution B for 1 h in the dark.
8. Wash several times in solution D for a total of at least 2 h and leave as long as overnight to ensure good color detection (*see* **Notes 3** and **4**).
9. Store the gel in solution E.

*3.1.2. Membrane Staining (see **Note 5**)*

1. Wash the membrane in distilled water for 5 min (*see* **Note 6**).
2. Incubate in solution A for 30 min.
3. Wash in distilled water for 2 × 5 min.
4. Wash in solution B for 2 × 5 min.
5. Incubate for 15 min in Schiff's reagent (*see* **Note 3**).
6. Wash in solution B for 2 × 5 min.
7. Air dry the membrane.

3.2. DIG–Anti-DIG AP Labeling (See Note 7)

This staining procedure can only be used on membranes; however, the proteins can be prelabeled in solution before electrophoresis, or labeled on the membrane after blotting (*see* **Notes 8** and **9**). In both cases the color development is the same. Nitrocellulose membranes can be used but some background staining can occur with postlabeling. In preference, the proteins should be blotted onto PVDF.

The reagents for this method are provided in the Roche Diagnostics DIG Glycan Detection Kit and the methods described are essentially taken from that kit.

A similar kit based on biotin/streptavidin binding instead of the DIG–Anti-DIG interaction is marketed by Bio-Rad as the Immun-Blot® Glycoprotein Detection Kit.

*3.2.1. Prelabeling (see **Note 8**)*

1. Dilute protein solution 1:1 to 20 µL with buffer B (*see* **Note 7**).
2. Add 10 µL of solution 1 and incubate for 20 min in the dark at room temperature.
3. Add 10 µL of solution 2 and leave for 5 min. The addition of the sodium bisulfite destroys the excess periodate.
4. Add 5 µL of DIG-succinyl-e-amidocaproic acid hydrazide, mix, and incubate at room temperature for 1 h. Sensitivity may be increased by increasing the incubation time to several hours.
5. Add 15 µL buffer D and heat the mixture to 100°C for 5 min to stop the labeling.
6. Separate the labeled glycoproteins by SDS-PAGE and blot to the membrane (*see* **Note 10**) which is now ready for the staining reaction (*see* **Subheading 3.2.3**).

3.2.2. Postlabeling (see **Note 9***)*

1. Wash the membrane for 10 min in 50 mL buffer E (PBS). (*see* **Note 11**).
2. Incubate the membrane in 20 mL of solution 1 for 20 min at room temperature. For low amounts of oligosaccharide it may be necessary to increase the amount of sodium metaperiodate in the solution. Increasing the concentration up to 200 m*M* increases the final staining.
3. Wash in buffer E, 3 × 10 min
4. Incubate the membrane in 5 mL of buffer B containing 1 mL of DIG-succinyl-ε-amidocaproic acid hydrazide for 1 h at room temperature. For low amounts of glycoproteins greater sensitivity can be obtained by increasing the concentration of DIG-succinyl-ε-amidocaproic acid hydrazide; however no further benefit is gained by raising the concentration greater than 3 mL in 5 mL (*see* **Note 12**).
5. Wash for 3 × 10 min in buffer A. TBS may now be used to wash the membrane as the DIG labeling has taken place.

3.2.3. DIG Staining Reaction

1. Incubate the membrane for at least 30 min in the blocking reagent (*see* **Note 10**). The membrane can be stored for several days at 4°C at this stage, and in fact a lower background staining can be achieved by allowing the filter membrane to wash in the solution at 4°C overnight (shaking is not necessary) and then for 30 min at room temperature with shaking.
2. Wash for 3 × 10 min in buffer A.
3. Incubate the membrane with 10 mL of buffer A containing 10 µL of anti-digoxigenin-AP at room temperature for 1 h. Sensitivity can be increased by increasing the amount of anti-DIG in the solution by a factor of 2 (although any more has no appreciable effect), or by increasing the incubation time to several hours.
4. Wash for 3 × 10 min with buffer A.
5. Immerse the membrane without shaking into 10 mL of buffer C containing 37.5 µL solution 4 and 50 µL solution 3 (mix just before use). If there is a large amount of sugar present in the bands the color reaction can take only a few minutes; however, if there is little material the reaction could take several hours or overnight. The reaction is best done in the dark, as light can cause nonspecific staining of the membrane. If solutions 3 and 4 are not fresh then the reaction can take several hours and cause a large amount of background staining. It is possible to speed up the reaction by doubling the amounts of solutions 3 and 4 added to buffer C.
6. Wash the membrane several times with Milli-Q water and allow to air dry. The membrane is best stored in foil to reduce fading of the bands once the reaction is stopped.

3.3. DIG - Labeled Lectin Staining

A wide range of lectins are commercially available as free lectin or conjugates of peroxidase, biotin, DIG, fluorescein isothiocyanate (FITC), alcohol dehydrogenase, colloidal gold, or on solid supports such as agarose. A list of commonly used commercially available lectins is shown in **Table 1**. Peroxidase

Table 1
Some Commonly Used Lectins[a]

Taxonomic name	Common name	Specificity[b,c]
Aleuria aurantia	AAA	α-(1,6)Fuc
Amanranthus caudatus	Amaranthin (ACA)	Galb-(1,3)GalNAc
Canavalia ensiformis	Jackbean concancavalin A	α-Man > α-Glc (Con A)
Datura stramonium	Jimson weed (DSA)	β-(1,4)GlcNAc Terminal GlcNAc
Maackia amurensis	MAA	α-(2,3)Neu-N-Ac
Phaseolis vulgaris	Red kidney bean (PHA-L)	complex *N*-linked
Arachis hypogaea	Peanut (PNA)	Gal (1,3)GalNAc
Ricinus communis	Castor bean	Terminal Gal (RCA120)
Sambucus sieboldiana	Elderberry (SNA)	α-(2,6)Neu-N-Ac
Triticum vulgaris	Wheat germ (WGA)	$(GlcNAc)_2$ > GlcNAc
Helix pomatia	Snail, edible (HPA)	Terminal GalNAc
Lens culinaris	Lentil	α-Man, α-Glc
Glycine max	Soybean (SBA)	GalNAc
Erythrina cristagalli	Coral tree (ECA)	Gal (1,4)GlcNAc

[a]Many lectins are available commercially as free (unlabeled); digoxigenin (DIG) labeled; biotinylated; peroxidase labelled; or conjugated to agarose beads from companies such as Roche Diagnostics, Sigma Chemical Company, and Amersham-Pharmacia.
[b]GalNAc, *N*-acetyl galactosamine; GlcNAc, *N*-acetylglucosamine; Gal, galactose; Glc, glucose; Man, mannose; Fuc, fucose; NeuNAc, *N*-acetylneuraminic acid (sialic acid).
[c]D-sugars are the preferred sugars.

or AP-labeled lectins can be detected directly. Alternatively, lectins can be detected using anti-DIG peroxidase (if DIG labeled) or streptavidin peroxidase (if biotin labeled), followed by an insoluble substrate. Sensitivity is generally increased with these indirect methods. The detection can be carried out with blots on nitrocellulose or PVDF (*see* **Note 13**).

1. Fix membrane for 5 min with 1% KOH. (*See* **Note 12**).
2. Rinse for 1 min with distilled water.
3. Block unbound sites with a 1-h incubation at room temperature with blocking reagent.
4. Rinse away blocking reagent with 3 × 1 min washes with TBS-Tween.
5. Add DIG-labeled lectins diluted in TBS-Tween containing 0.1 m*M* $CaCl_2$, 0.1 m*M* $MgCl_2$, 0.1 m*M* $MnCl_2$. Leave overnight at 4°C (*see* **Notes 14** and **15**).
6. Remove unbound lectin by washing with 6 × 5 min in TBS-Tween.
7. Incubate nitrocellulose with 10 µL of anti-DIG AP diluted in 10 µL of TBS for 1 h at room temperature.
8. Repeat washing **step 6**.

9. Immerse the membrane without shaking into 10 µL of buffer C containing 37.5 µL of solution 4 and 50 µL of solution 3 (mix just before use).
10. Stop reaction when gray to black spots are seen (few minutes to overnight) by rinsing with water.

3.4. Pro-Q Emerald 300 Dye Staining

Pro-Q™ Emerald 300 Glycoprotein Gel Stain Kit (Molecular Probes, OR) provides a method for differentially staining glycosylated and nonglycosylated proteins in the same gel. The technique combines the green fluorescent Pro-Q™ Emerald 300 glycoprotein stain with the red fluorescent SYPRO Ruby total protein gel stain. A related product, Pro-Q™ Emerald 300 Glycoprotein Blot Stain Kit, allows similar capabilities for proteins electroblotted to PVDF membranes.

Using this stain allows detection of <1 ng of glycoprotein/band, depending on the nature and the degree of glycosylation, making it 500-fold more sensitive than the standard periodic acid–Schiff base method using acidic fuchsin dye. The green fluorescent signal from Pro-Q Emerald 300 stain can be visualized with 300 nm UV illumination.

1. Separate proteins by standard SDS-PAGE. Typically, the sample is diluted to about 10–100 µg/mL with sample buffer and 5–10 µL of diluted sample is added per lane for 8 cm × 10 cm gels. Large, 16 cm × 18 cm gels require twice as much material.
2. After electrophoresis, fix the gel by immersing it in 75–100 mL of fix solution and incubating at room temperature with gentle agitation (e.g., on an orbital shaker at 50 rpm) for 45 min.
3. Wash the gel by incubating it in 50 mL of wash solution with gentle agitation for 10 min. Repeat this step once.
4. Incubate the gel in 25 mL of oxidizing solution with gentle agitation for 30 min.
5. Wash the gel in 50 mL of wash solution with gentle agitation for 5–10 min. Repeat this step twice more.
6. Prepare fresh Pro-Q Emerald 300 Staining Solution by diluting the Pro-Q Emerald 300 reagent (component A) 50-fold into Pro-Q Emerald 300 dilution buffer (component B). For example, dilute 500 µL of Pro-Q Emerald 300 reagent into 25 mL of dilution buffer to make enough staining solution for one 8 × 10 cm gel.
7. Incubate the gel in the dark in 25 mL of Pro-Q Emerald 300 Staining Solution while gently agitating for 90–120 min. The signal can be seen after about 20 min and maximum sensitivity is reached at about 120 min. Staining overnight is not recommended.
8. Wash the gel with 50 mL of wash solution at room temperature for 15 min. Repeat this wash once for a total of two washes. Do not leave the gel in wash solution for more than 2 h, as the staining signal will start to decrease.
9. Visualize the stain using a standard UV transilluminator (*see* **Notes 16–20**).
10. To counter-stain nonglycosylated proteins in the sample, completely thaw the 10% SDS solution (component F), vortex-mixing to completely dissolve the SDS.

11. Dilute the 10% SDS solution 2000-fold into the SYPRO Ruby protein gel stain to make a final concentration of 0.005% SDS.
12. Proceed with staining as outlined in Chapter 49 in this volume describing the SYPRO Ruby protein gel staining procedure (*see* **Note 21**).

3.5. HPAEC Analysis of Monosaccharide Composition (See Note 22)

This technique requires about 100 pmol (5 µg) of glycosylated protein.

1. Excise spots that have been visualized by coomassie blue or amido black on PVDF membranes and place into screw-capped Eppendorf tubes (*see* **Note 23**).
2. Wet membrane with methanol. If the membrane is not properly wetted it will float and the hydrolysis will not be complete.

3.5.1. Analysis of Sialic Acids

1. Add 100 µL 0.1 *M* TFA to the wetted membrane. Mix and close the tube.
2. Incubate in heating block at 80°C for 40 min.
3. Remove membrane from tube and wash with 50 µL of water.
4. Dry combined solutions in a Speed Vac concentrator.
5. Resuspend in 25 µL and add 0.5 nmol lactobionic acid as internal standard for quantitation. Analyze by HPAEC-PAD using a linear gradient of 0–200 m*M* NaAcetate in 250 m*M* NaOH for 30 min (*see* **Notes 24–26**).
6. Compare retention time with standard of 1 nmol *N*-acetyl and *N*-glycolylneuraminic acids.

3.5.2. Analysis of Neutral Monosaccharides

1. Add 100 µL of 2 *M* TFA to the desialylated membrane spots (*see* **Note 27**). Mix and close tube (*see* **Note 24**). Re-wet membrane with methanol before addition of acid if dried out.
2. Incubate in a boiling water bath for 4 h.
3. Remove membrane from tube and wash with 50 µL of water. Keep membrane for subsequent amino acid analysis if required.
4. Dry combined solutions in a Speed Vac concentrator.
5. Resuspend in 25 µl of water and add 0.25 nmol of 2-deoxyglucose as internal standard for quantitation. Analyze by HPAEC-PAD eluted isocratically with 12 m*M* NaOH for 30 min (*see* **Notes 24–26**).
6. Compare with a standard mixture containing fucose, 2-deoxyglucose, galactosamine, glucosamine, galactose, glucose, and mannose (5 µl of 1 m*M* solution) (*see* **Note 28**). This is the order of elution of the monosaccharides from the CarboPac column.

4. Notes

4.1. Periodic Acid/Schiff Staining

1. This method can be used on PAGE gels, agarose, or polyacrylamide–agarose composite gels. The procedure should be carried out on an orbital shaker or rocker (an orbital shaker may cause background swirls on some

gels). High background staining can occur when staining some batches of agarose or composite gels.
2. All steps in this procedure should be performed with shaking and should be carried out in a fume hood.
3. A negative result often means that insufficient protein is present or that the protein has little glycosylation
4. Be aware that highly glycosylated proteins do not transfer well to nitrocellulose membranes, and failure to detect may be due to inefficient transfer to the membrane. It is sometimes useful to carry out the stain on the gel after transfer, to test for remaining glycoprotein.
5. PAS staining after transfer of glycoproteins to membranes eliminates the need for extensive fixation steps, as well as shortening the time needed for washing steps, without loss of staining intensity. Results are easier to visualize and are easier to store. Before Western transfer, it is suggested to gently rock the gel for 30–60 min in transfer buffer so as to remove SDS, which can lead to higher backgrounds during membrane staining.
6. Periodic acid–Schiff staining on nitrocellulose membranes increases sensitivity slightly and reduces washing times considerably compared with gel staining.

4.2. DIG–Anti-DIG AP Labeling

7. All steps in the procedure except for color development should be done on a shaker or rocker. Swirling background staining may occur when using a orbital shaker.
8. Prelabeling gives a higher sensitivity than postlabeling, requires less DIG (1 µl per labeling), and can be used with <0.25% SDS, Nonidet P-40 (NP-40), Triton X-100, but not with octylglucoside. Prelabeling results in broader bands than post-labeling and may result in a change of p*I* of the proteins in the first dimension. Pre-labeling is negatively influenced by mercaptoethanol, dithiothreitol (DTT), glycerol and Tris.
9. The postlabeling procedure is used for proteins that have already been separated by gel electrophoresis and immobilized on blots. It is important to use PBS (buffer E) instead of TBS (buffer A) in the initial stages as Tris inhibits the DIG labeling process.
10. Nitrocellulose and PVDF membranes can be used. Nylon membranes result in high background.
11. For mucins and other heavily glycosylated proteins it may be necessary to fix the bands to the membrane before labeling by washing in 1% KOH for 5 min. If this procedure is done, increase the initial washes to 3 × 10 min in buffer B.
12. Postlabeling results in sharper bands than prelabeling but has a lower sensitivity and requires more DIG (5 µL per gel).

4.3. DIG-Labeled Lectin Staining

13. The binding of some lectins will be increased by desialylation while the binding of others will be decreased.
14. Suggested dilutions of the DIG labeled lectins: SNA—1:1000, MAA—1:500, DSA—1:1000, PNA—1:100.
15. The divalent ions are necessary for optimal lectin reactivity. The stock solution should be diluted to give a final concentration of 1 m*M* of each ion.

4.4. Pro-Q Emerald 300 Dye Staining

16. The Pro-Q Emerald 300 stain has an excitation maximum at approx 280 nm and an emission maximum near 530 nm. Stained glycoproteins can be visualized using a 300 nm UV transilluminator. *The use of a photographic camera or charge coupled device (CCD) camera and the appropriate filters is essential to obtain the greatest sensitivity*.
17. It is important to clean the surface of the transilluminator after each use with deionized water and a soft cloth (such as cheesecloth). Otherwise, fluorescent dyes can accumulate on the glass surface and cause a high background fluorescence.
18. Use a 300 nm transilluminator with six 15 W watt bulbs. Excitation with different light sources may not give the same sensitivity.
19. Using a Polaroid® camera and Polaroid 667 black-and-white print film, the highest sensitivity is achieved with a 490 nm longpass filter, such as the SYPRO protein gel stain photographic filter (S-6656), available from Molecular Probes. Gels are typically photographed using an f-stop of 4.5 for 2–4 s, using multiple 1-s exposures.
20. Using a CCD camera, images are best obtained by digitizing at about 1024 × 1024 pixels resolution with 12–, 14– or 16– bit gray scale levels per pixel. A 520 nm long pass filter is suitable for visualizing the stain. A CCD camera-based image analysis system can gather quantitative information that will allow comparison of fluorescence intensities between different bands or spots. Using such a system, the Pro-Q Emerald stain has a linear dynamic range over three orders of magnitude. The polyester backing on some premade gels is highly fluorescent. For maximum sensitivity using a UV transilluminator, these gels should be placed polyacrylamide side down and an emission filter used to screen out the blue fluorescence of the plastic.
21. The green-fluorescent Pro-Q Emerald 300 staining should be viewed and documented before staining total proteins with SYPRO Ruby protein gel stain. Pro-Q Emerald dye signal will fade somewhat after SYPRO Ruby dye staining.

4.5. HPAEC Analysis of Monosaccharide Composition

22. Data on the composition of both the acidic sialic acids and the hexoses and amino sugars can be obtained sequentially from a single spot. After the

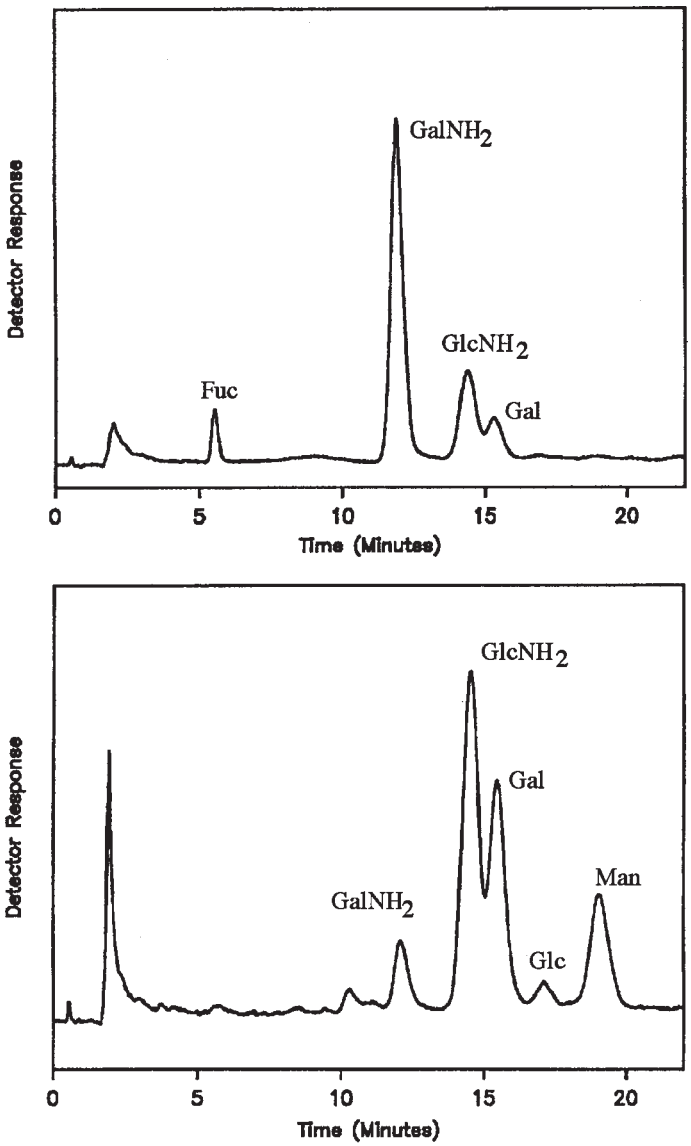

Fig. 1. Monosaccharide composition of glycoprotein hydrolysates. *(Upper)*, Bovine submaxillary mucin; *(lower)*, fetuin. Separation by HPAEC-PAD.

4 *M* TFA hydrolysis, amino acid analysis (6 *M* HCl, 1 h, 155°C) can be performed subsequently on the same spot for identification of the protein.

23. It is important for monosaccharide analysis that the tubes be kept clean in a cellulose-free environment (i.e., no paper, cotton wool, or dust!) because of the common glucose contamination from the hydrolysis of cellulose

and other ubiquitous polysaccharides. For the same reason a blank of all reagents should be run to establish background contamination levels.

24. The HPLC system must be totally metal free because of the caustic reagents. All solvents must be made free of carbon dioxide by boiling of the MilliQ water used. The water is cooled under argon and the solutions kept under helium to reduce the precipitation of sodium carbonate from the sodium hydroxide solutions and the resultant effect on the anion-exchange chromatography.
25. The DIONEX CarboPac PA10 column gives better separation of the monosaccharides than the CarboPac PA1 but the latter may still be used effectively and can be used for both monosaccharide and oligosaccharide analysis.
26. The columns must be washed with strong alkali (0.4 *M* NaOH) for 10 min and re-equilibrated between injections.
27. If more accurate quantitation of the amino sugars is required, stronger hydrolysis using 4 *M* HCl for 4 h at 100°C can be carried out instead of the milder 4 *M* TFA hydrolysis. Subsequent amino acid analysis cannot be performed in this case.
28. Glucose will almost always be present as a contaminant and so is exceptionally difficult to quantitate if it is a constituent. Examples of the monosaccharide composition of typical *N*-linked sugars (fetuin) and *O*-linked sugars (mucin) are shown in **Fig. 1**.

Acknowledgments

I thank Margaret Lawson for her invaluable technical assistance. I also thank the NHMRC (Grant No. 950475) for their support for this work.

Staining of Glycoproteins/Proteoglycans on SDS-Gels

Holger J. Møller and Jørgen H. Poulsen

1. Introduction

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) is a commonly employed technique for separation of proteins according to size. Among other applications, it is used for identification and characterization of proteins on the basis of molecular weight determinations. In this chapter, staining methods will be described that permit detection of highly glycosylated proteins on SDS gels at levels of a few nanograms.

Proteins with limited glycosylation are most often stained with Coomassie brilliant blue or, if high sensitivity is needed, with a silver-stain ***(1)***. These stains, however, are far less sensitive when used for detecetion of highly glycosylated proteoglycans (protein-glycosaminoglycans) or glycoproteins (protein-oligosaccharides), leading to weak staining or even failure of detection. This is presumably the result of steric interference by the carbohydrates with the binding of silver ions.

Proteoglycans are traditionally stained with cationic dyes, such as alcian blue or toluidine blue ***(2)***, that bind to the negatively charged glycosaminoglycan side chains, whereas more neutral glycoproteins can be detected by some variation of the Schiff base reaction involving initial oxidation of carbohydrates by periodic acid and subsequent staining with Schiff's reagent (PAS) ***(3)***, alcian blue ***(4)***, or a hydrazine derivate ***(5)***. A protocol for PAS staining of small SDS gels is described in **ref. *6***. However, these methods, although useful in many instances, are characterized by low sensitivity, generally requiring microgram amounts of protein for detection. At the same time, they are carbohydrate specific, which means that nonglycosylated proteins are not stained.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

The two methods described here are based on silver enhancement of traditional staining methods for proteoglycan and glycoprotein *(7–12)*, which result in a two-fold increase in sensitivity as compared with alcian blue or PAS alone. In both methods, alcian blue is used as the primary staining agent, binding either directly to the proteoglycans (**Subheading 3.1.**) or to oxidized glycoproteins (**Subheading 3.2.**), subsequently enhanced by a neutral silver-staining protocol.

The methods also stain highly negatively charged phosphoproteins (e.g., osteopontin and bone sialoprotein, rich in phosphate and acidic amino acids) that stain weakly with ordinary methods *(13)*. Furthermore, both glycosylated and nonglycosylated proteins are stained. Nonglycolylated proteins, however, stain weaker, and it is possible to exclude the staining of nonglycosylated proteins (*see* **Note 1** and **ref.** *14*).

A protocol for staining by the cationic dye "Stains-All" instead of alcian blue, combined with silver is described in **ref.** *13*. This method seems to more uniformly stain both nonglycosylated and negatively charged proteins

The high sensitivity of the methods make them very suitable for detection of proteoglycan/glycoprotein in dilute mixed samples, and for characterization of small amounts of purified materials, e.g., by determination of molecular weight before and after deglycosylation *(15–17)*. In this connection, it is important to note that, owing to heterogenity of carbohydrate substitution, highly glycosylated proteins usually move as diffuse bands or broader smears, so that unambiguous determination of molecular weight is not always possible.

For more specific purposes, other detection systems are usually employed. Sensitive detection of glycoproteins can be achieved with lectins or specific antibodies, most often after blotting onto a membrane *(18, 19)*. Proteoglycans can similarly be identified by antibodies directed toward the core protein or glycosaminoglycan structures *(20, 21)*, and glycosaminoglycans can be characterized by mass spectrometry *(22)*.

The methods described here are optimized for the small, supported gels used in the PhastSystem (Pharmacia, Uppsala, Sweden), which can be programmed for automatic staining resulting in fast and reproducible results. If other systems (larger gels) are used, generally longer time is needed in each step (*see* **Note 2**).

2. Materials

2.1. Staining of Proteoglycans

All chemicals used should be of analytical grade, and water should be of high purity.

1. Washing solution I: 25% ethanol (v/v), 10% acetic acid (v/v) in water.
2. Washing solution II: 10% ethanol (v/v), 5% acetic acid (v/v) in water.
3. Staining solution: 0.125% alcian blue (w/v) in washing solution I. Stir extensively and filtrate before use.

4. Stopping solution: 10% acetic acid (v/v), 10% glycerol (v/v) in water.
5. Developer stock: 2.5% (w/v) sodium carbonate in water.
6. Sensitizing solution: 5% (v/v) glutardialdehyde in water. (Prepare fresh when required.)
7. Silvering solution: 0.4% (w/v) silver nitrate in water. (Prepare fresh when required).
8. Developer: Add formaldehyde to the developer stock to a final concentration of 0.013% (v/v). e.g., add 35 µL of a 37% formaldehyde solution to 100 ml of developer stock, and stir for a few seconds. (Prepare fresh just before use).

2.2. Staining of Glycoproteins

1. Prepare all solutions described in **Subheading 2.1.**
2. Fixing solution: 10% (v/v) trichloroacetic acid in water.
3. Washing solution III: 5% (v/v) acetic acid in water.
4. Oxidizing solution: 1% (w/v) periodic acid in water.
5. Reducing solution: 0.5% (w/v) potassium metabisulfite in water.

3. Methods

3.1. Alcian Blue/Silver Staining of Proteoglycans (see Note 2)

This method stains proteoglycans, glycosaminoglycans, phosphoproteins, non-glycosylated proteins, and some glycoproteins with a high content of negatively charged groups. The method can be varied for specific staining of proteoglycan/glycosaminoglycan (*see* **Note 1**).

1. Immediately after electrophoresis, transfer the gel to the development chamber/staining tray (*see* **Note 3**), and wash the gel three times in washing solution I for 5, 10, and 15 min at 50°C (*see* **Note 4**).
2. Add the staining solution and stain the gel for 15 minutes at 50°C.
3. Wash the gel three times in washing solution I for 1, 4, and 5 min and subsequently twice in washing solution II for 2 and 4 min at 50°C (*see* **Note 5**).
4. Add the sensitizing solution for 6 min at 50°C (*see* **Note 6**).
5. Wash the gel twice in washing solution II for 3 and 5 min, and subsequently in water twice for 2 min at 50°C.
6. Submerge the gel in the silvering solution for 6.5 minutes at 40°C.
7. Wash the gel twice in water for 30 s at 30°C (see **Note 7**).
8. Develop the gel with the freshly prepared developer at room temperature for an initial period of 30 s and subsequently for 4–8 min, depending on the desired sensitivity, background staining, and specificity (*see* **Note 1**).
9. Stop the development and preserve the gel by adding the stopping solution for 5 min (*see* **Note 8**).

3.2. Periodic Acid Oxidation and Subsequent Alcian Blue/Silver Staining of Glycoproteins

Some glycoproteins stain weakly with alcian blue/silver alone, probably owing to the low content of negatively charged groups for binding of alcian blue. This is overcome by initial oxidation of carbohydrates by periodic acid.

1. After electrophoresis, transfer the gel to the development chamber/Petri dish, and add the fixing solution for 10 min at 30°C (*see* **Note 9**).
2. Wash the gel twice for 2 min in washing solution III and submerge the gel in the oxidizing solution for 20 min at 30°C.
3. Wash the gel twice for 2 min in washing solution III and subsequently in water twice for 2 min before adding the reducing solution for 12 min at 30°C.
4. Wash the gel with water twice for 2 min and subsequently with washing solution I twice for 2 min at 50°C.
5. Continue with **steps 2–9** of **Subheading 3.1** exactly as described.

4. Notes

1. The development time can be varied according to the desired sensitivity and background staining. Even if an automatic staining chamber is used, these steps can be performed advantagously in staining trays/Petri dishes. In the first development step, a dark precipitate is created and the gel is transfered to a fresh developing solution. After 1–3 minutes proteoglycans will appear, whereas nonglycosylated proteins appear after 4–8 minutes. The gel can be photographed sequentially on a light box during the development step for identification of proteoglycans. As a control, a gel can be stained for proteins with ordinary silver (**Subheading 3.1., steps 3–9**), in which proteoglycans will not stain.
2. The methods are optimized for the PhastSystem, which uses small, supported gels that are stained in an automatic development chamber. If larger gels are stained in staining trays at room temperature, longer incubation times are needed. For unsupported 1-mm thick gels, good results are obtained by increasing the washing with washing solution I in **steps 1** and **3** (**Subheading 3.1**) to a total of 2.5 and 1.5 hours, respectively, with four changes of the solution, and furthermore doubling the incubation times in all other steps.
3. Handle gels with gloves or forcepts, since fingerprints stain. The staining methods are highly sensitive, and it is essential that the equipment (development chamber/staining trays) is scrupulously clean and that high-quality water is used. Use a separate tray for the staining solution. Gels should be agitated during all staining, and washing procedures.
4. This rather extensive washing procedure is necessary to remove the SDS from the gel, which otherwise precipitates alcian blue, resulting in excessively high background. If gels are run in native PAGE, one short washing step is sufficient.
5. Alcian blue is irreversibly fixed in the gel by the subsequent silver staining and results in a greenish-black background if the stain is not washed out by dilute acetic acid. Only a weak bluish nuance in the background should remain.
6. Glutaraldehyde is injurious to health. If not carried out in a closed chamber, a fume cupboard should be used.

7. This step is important for washing out excess silver ions without losing silver bound to alcian blue/proteoglycan for autocatalytic reduction in the development step. Too little washing leads to formation of metallic silver in the background, whereas too intense washing leads to decreased sensitivity.
8. The image is stable, but over time, increased background staining will develop, especially from light exposure.
9. In this staining procedure, acetic acid/ethanol solutions are not always efficient for fixation of the proteins in the gel, whereas trichloroacetic acid works well.

Detection of Proteins and Sialoglycoproteins in Polyacrylamide Gels Using Eosin Y Stain

Fan Lin and Gary E. Wise

1. Introduction

A rapid, sensitive, and reliable staining technique is essential in detection of proteins in polyacrylamide gels. Coomassie brilliant blue R-250 (CBB) is the stain that meets these criteria except for sensitivity; i.e., CBB staining requires relatively large amounts of proteins. It has been reported that the sensitivity for CBB stain in polyacrylamide gels is 0.1–0.5 µg/protein band ***(1)***. This problem of relatively low staining sensitivity is often circumvented by employing silver staining techniques ***(2–5)***. However, it is difficult to transfer silver stained proteins to transfer membranes unless they either are negatively stained by silver ***(6)*** or the positively silver-stained proteins are treated with 2X SDS sample buffer prior to transfer ***(7)***. In addition, sialoglycoproteins cannot be detected by CBB and thus have to be visualized by other stains, such as the periodic acid-Schiff (PAS) reagent ***(8)***, silver stains ***(9)***, or silver/Coomassie blue R-250 double staining technique ***(10)***.

To circumvent the deficiencies of the above staining techniques, we have developed an eosin Y staining technique ***(11)***. This staining method allows one to detect proteins more rapidly than most CBB and silver staining methods. It detects a variety of proteins in amounts as little as 10 ng in polyacrylamide gels, including membrane sialoglycoproteins, and has the added advantage of the antigenicity of the stained proteins being retained. The precise mechanism by which eosin Y stains both proteins and sialoglycoproteins is not fully understood.

However, in the staining protocol described here, the fixing and developing solution of 10% acetic acid/40% methanol (pH 2.5) is strongly acidic. Under such conditions, eosin Y might be converted into its precursor form of the dihydrofluoran. Thus, a protein might be stained by means of both hydrophobic

interaction between aromatic rings of eosin Y and hydrophobic sites of the protein and by hydrogen bonding between hydroxyl groups of eosin Y and the backbone of a protein. Here we describe this detailed staining protocol and technical advice in order to enable others to obtain optimal staining results.

2. Materials

1. Eosin Y staining solution: A stock solution of 10% eosin Y (w/v) is prepared. This solution is stable at room temperature for at least 6 mo. Each 100 mL of staining solution contains 10 mL of 10% eosin Y solution, 40 mL of 100% methanol, 49.5 mL distilled deionized water, and 0.4–0.5 mL of full strength glacial acetic acid. The staining solution is made and filtered prior to use.
2. Gel fixation solution: 10% glacial acetic acid/40% methanol.
3. Gel developing solution: distilled-deionized water, 10% glacial acetic acid/40% methanol.
4. A black plastic board and a transilluminated fluorescent white light box.

3. Methods

3.1. Staining of Various Protein in SDS-PAGE

1. Immediately following electrophoresis, the SDS-polyacrylamide gel containing given proteins is fixed in 5 gel volumes of 10% glacial acetic acid/40% methanol for 10 min at room temperature with shaking and then rinsed with distilled water twice.
2. The gel is immersed with 200 mL (5–6 gel volumes) of the 1% eosin Y staining solution for 15 min at room temperature with shaking.
3. The gel is transferred to a clean glass container, quickly rinsed with distilled water and then washed with distilled water for 3 min (*see* **Note 2**).
4. The stained bands of the gel are developed by placing the gel in 10% acetic acid/40 methanol for about 15 s (*see* **Note 3**).
5. The development is stopped by immersing the gel in distilled water.
6. The gel can be kept in distilled water for at least 1 mo without fading.
7. The stained gel can be viewed either by using transilluminated fluorescent white light or by placing the gel on a black plastic board with top light illumination.

3.2. Staining of Membrane Sialoglycoproteins in SDS-PAGE

1. Immediately following electrophoresis, the SDS-polyacrylamide gel is placed in 200 mL (5–6 gel volumes) eosin Y staining solution for 45 min at room temperature with shaking.
2. The gel is quickly rinsed with distilled water and then washed with distilled water for 3 changes of 5 min each. Protein bands are visualized at the end of washing step (*see* **Note 4**).
3. The gel is then developed in 10% acetic acid/40% methanol for about 2 min.
4. The development of staining is terminated by washing the gel in distilled water twice.
5. The gel can be kept in distilled water for at least 1 mo without fading.

6. The stained gel can be viewed either by using transilluminated fluorescent white light or by placing the gel on a black plastic board with table top light illumination.

4. Notes

1. The 1% eosin Y staining solution needs to be made fresh and filtered prior to use. Eosin Y should be soluble in both water and methanol. Acetic acid must be added last. The final concentration of acetic acid in this staining solution is critical for staining background and sensitivity. The acetic acid should be added to solution with stirring. After adding acetic acid, the staining solution should appear to be cloudy but should not precipitate. If any precipitation occurs, it indicates that the acetic acid concentration is too high.
2. In **step 3** of staining various proteins, some orange precipitation may cover a SDS-gel surface. One may gently clean up the precipitation by wiping off the gel surface with a latex glove or by using Kimwipe tissue, which will reduce the background and improve the staining sensitivity.
3. An appropriate development time will ensure yellow–orange staining bands. Prolonging development in 10% acetic acid/40% methanol often results in yellow–orange bands becoming brown bands which, in turn, will decrease the staining sensitivity.
4. It should be noted that at the end of the washing step, the proteins should appear to be yellow-orange and the sialoglycoproteins appear to be light yellow. If the protein bands are still not visualized at this point, one may prolong the washing step for another 5–10 min.
5. The eosin Y stained gel can be stored in distilled water for at least 1 mo without fading. It is not recommended to dry and store the stained gels because the intensity and resolution of protein bands are greatly decreased.
6. The eosin Y stained proteins in SDS-gels can be transferred to immobilon-P membrane without additional treatment. The antigenicity of a given protein is usually not affected by the eosin Y stain ***(11)***.

A Modified Pro-Q Diamond Staining Protocol for Phosphoprotein Detection in Polyacrylamide Gels

Ganesh Kumar Agrawal and Jay J. Thelen

1. Introduction

Protein phosphorylation is one of the most common and arguably best studied post-translational modifications. Virtually all key cellular processes are regulated via reversible protein phosphorylation ***(1, 2)***. Identification of candidate regulatory protein kinases, their substrates, and the phosphorylation site are the key steps toward understanding the regulation of cellular processes and their complex network. This challenging area is known as phosphoproteomics ***(3, 4)***. One of the major advances in this area is the introduction of Pro-Q Diamond phosphoprotein stain (Pro-Q DPS)—a fluorescence-linked assay—to detect phosphoproteins at levels as low as 1 ng on a single polyacrylamide gel ***(5, 6)***. The characteristic features of Pro-Q DPS are: (i) binds directly and specifically to the phosphate moiety of phosphoproteins regardless of which amino acid residue is phosphorylated, (ii) is fully compatible with other stains and mass spectrometry, and (iii) has high sensitivity and linearity, ranging from 1 ng to 1 µg, allowing quantitative analysis of phosphoproteins at the global level. Though these properties are indeed desirable to conduct large-scale phosphoproteomics analysis, Pro-Q DPS is not economically attractive. Most importantly, it also lacks a fully optimized protocol to reproduce results from laboratory to laboratory.

To address these concerns, we recently introduced an alternative staining protocol for Pro-Q DPS ***(7)*** modified from previous publications ***(5, 6)*** and recommended manufacturer's protocols (Molecular Probes). In this chapter, we focus on describing the complete protocol of the modified Pro-Q DPS ***(7)***. Two of the major modifications include a three-fold dilution of Pro-Q DPS (directly by diluting the stock) and the use of three-fold less volume of the diluted staining solution than the manufacturer's recommended volume for one large-format

From: *The Protein Protocols Handbook, Third Edition*

Table 1
A Modified Pro-Q DPS Protocol for Phosphoprotein Detection in Polyacrylamide Gels

Step	Solution	Amount Mini (Large) Gel	Time (min)	Dark Incubation	Re-use of Solution
1	Fixation	100 mL (250 mL)	2 × 30	Not Required	Yes
2	Washing	100 mL (250 mL)	2 × 15	Not Required	No
3	Staining	65 mL (150 mL)	120	Required	Yes
4	Destaining	100 mL (250 mL)	4 × 30	Required	Yes
5	Washing	100 mL (250 mL)	2 × 5	Required	No

two-dimensional (2-D) gel (*see* **Table 1**). Therefore, this practical change in staining solution alone reduces the overall cost by nine-fold for performing a large-scale phosphoproteomics analysis. Moreover, the required volume of other solutions, such as fixation and destaining, is half of that recommended by manufacturer. The optimized conditions of this modified protocol are summarized for both mini (size 8 cm × 8 cm × 1 mm) and large (size 26 cm × 20 cm × 1 mm) gels in **Table 1**. Application of this simple, economical protocol to large scale identification and quantification of phosphoproteins expressed in developing rapeseed ***(8)*** has further demonstrated its suitability and reproducibility for conducting large-scale phosphoproteomics.

2. Materials

1. miniVE vertical electrophoresis unit (GE Healthcare, Piscataway, NJ).
2. Ettan DALTtwelve separation unit (GE Healthcare, Piscataway, NJ).
3. Mini-gel staining tray, size 13.75 cm × 13.75 cm × 5.25 cm (GLAD WARE, Oakland, CA) (*see* **Notes 1** and **2**).
4. Large-gel staining tray, size 26 cm × 20 cm × 10 cm (Daigger, Vernon Hills, IL; catalog number EFRCP 124PCLE) (*see* **Notes 1** and **2**).
5. SDS (sodium dodecyl sulfate) loading buffer: 5% (v/v) glycerol, 60 m*M* SDS, 100 m*M* DTT, 0.03 m*M* bromphenol blue, 60 m*M* Tris-HCl, pH 6.8 in deionized water.
6. Orbital shaker (GeneMate, OS350, ISC Bioexpress, Kaysville, UT).
7. Pro-Q DPS (Invitrogen, Carlsbad, CA; product number P33301). Store at 4°C (*see* **Note 3**).
8. PeppermintStick phosphoprotein molecular weight standards (Invitrogen, Carlsbad, CA; product numbers P33350). Store in aliquots at −20°C (*see* **Note 4**).
9. Methanol (Fisher Scientific, Houston, TX).
10. Acetic acid (Fisher Scientific, Houston, TX).
11. Acetonitrile (Fisher Scientific, Houston, TX).
12. Powder-free nitrile gloves (Fisher Scientific, Houston, TX).
13. Fixation solution: 50% methanol (v/v), 10% acetic acid (v/v) in deionized water. (*see* **Note 5**).

14. Washing solution: deionized water (18.2 MΩ conductivity).
15. Staining solution: three-fold diluted Pro-Q DPS (v/v) in deionized water.
16. Destaining solution: 50 m*M* sodium acetate-acetic acid, pH 4.0, 20% acetonitrile (v/v) in deionized water. To prepare one liter of destaining solution, combine 50 mL of 1000 mM sodium acetate, pH 4.0, 750 mL of deionized water, and 200 mL of acetonitrile (*see* **Note 6**).
17. Fluorescence image capture device: FLA 5000 laser scanner (Fuji Medical Systems, Stamford, CT).
18. Image quantification software: Image Gauge Analysis software (Fuji, Stamford, CT).
19. ImageMaster 2D Platinum software version 5 (GE Healthcare, Piscataway, NJ).

3. Methods

Since this chapter is specifically focused on describing the complete protocol of the modified Pro-Q DPS, details on mini- and large-gel preparation and extraction conditions for phosphoprotein analyses are not mentioned here. Any method can be used to make the desired SDS polyacrylamide gel (SDS-PAG) and to separate the proteins. We used the Laemmli ***(9)*** method for the development of this modified Pro-Q DPS protocol. After protein separation, the gel is stained using the modified Pro-Q DPS protocol. **Table 1** summarizes all steps including the required volumes of solutions for mini- and large-size gels, total incubation times and conditions, and whether solutions can be reused. Gels should be imaged immediately after Pro-Q DPS staining.

3.1. One- and Two-Dimensional Gels

1. Prepare 12% SDS-PAG of size 8 cm × 8 cm × 1 mm, termed mini- or 1-D gel (*see* **Note 7**).
2. Prepare 12% SDS-PAG of size 26 cm × 20 cm × 1 mm, termed large- or 2-D gel (*see* **Note 7**).
3. Separate proteins on gel, beside a lane containing PeppermintStick phosphoprotein molecular weight standards, at the desired voltage and time period (*see* **Note 4**).

3.2. Staining the Gel

1. Immerse the gel in fixation solution (100 mL for mini gel and 250 mL for large gel). Incubate at room temperature (RT) with constant shaking on an orbital shaker at a speed of 35 rpm for 30 min. Decant fix solution and repeat (*see* **Notes 2** and **8–12**).
2. Immerse the gel in washing solution (100 mL for mini gel and 250 mL for large gel) for 15 min. Decant wash solution and repeat (*see* **Notes 8, 9,** and **13**).
3. Incubate the gel in staining solution (65 mL for mini gel and 150 mL for large gel) in the dark for 2 h (*see* **Notes 8, 9, 14,** and **15**).
4. Immerse the gel in destaining solution (100 mL for mini gel and 250 mL for large gel) and incubate in the dark for 30 min. Decant destain solution and repeat this step three more times. The total required destaining time is 2 h (*see* **Notes 8, 9, 11,** and **16**).
5. Wash the gel with deionized water (100 mL for mini gel and 250 mL for large gel) in the dark for 5 min. Decant deionized water and repeat (*see* **Notes 8, 9,** and **17**).

3.3. Gel Scanning and Analysis

1. Scan the gel using a laser imager with 532-nm excitation and 580-nm bandpass emission filter (Fujifilm FLA 5000). Collect and analyze data as 100-µm resolution, 16-bit TIFF files (Image Gauge Analysis software, Fuji, Stamford, CT) (*see* **Notes 18** and **19**).
2. Use Image Gauge Analysis software (Fuji, Stamford, CT) and ImageMaster 2D Platinum software version 5 (GE Healthcare, Piscataway, NJ) to display and analyze data. (*see* **Notes 20** and **21**).

4. Notes

1. These trays are reusable and should be thoroughly cleaned with detergent, rinsed with deionized water, and then finally rinsed with 70% (v/v) ethanol prior to use.
2. Select appropriate tray for mini and large gels. For example, we routinely use a tray size of 13.75 cm × 13.75 cm × 5.25 cm and 26 cm × 20 cm × 10 cm for mini (8 cm × 8 cm × 1 mm)- and large (26 cm × 20 cm × 1 mm)-size gels, respectively. Volumes of solutions required to immerse the mini- and large- size gels are provided in **Table 1**.
3. Pro-Q DPS is light-sensitive and should be protected from light at all times. It is stable for six months even if it is stored at RT. In our experience, storage of Pro-Q DPS at 4°C prolongs its stability by at least two-fold. After this storage period, we found that the stability of stain drops sharply resulting in the loss of specificity. Therefore, it is recommended that the Pro-Q DPS activity should be checked on small size gel using PeppermintStick phosphoprotein molecular weight standards (or any protein standard containing ovalbumin and casein) before performing large-scale experiments. Additionally, we recommend all analytical gels should contain a molecular marker containing positive and negative phosphoprotein controls.
4. PeppermintStick phosphoprotein molecular weight standards carry two phosphorylated (ovalbumin and bovine β–casein of 45.0 and 23.6 kDa, respectively) and four non-phosphorylated (β-galactosidase, bovine serum albumin, avidin, and lysozyme of 116.25, 66.2, 18.0, and 14.4 kDa, respectively) standards. Such protein markers are important to include in any Pro-Q DPS-based experiments to exclude false positive identification by normalizing the detected phosphoprotein bands or spots against positive and negative phosphoprotein markers. It should be noted that any protein standard with ovalbumin and/or casein can be used for this purpose.
5. Unless stated otherwise, all solutions should be freshly prepared in deionized water (18.2 MΩ conductivity) before use.
6. It is recommended to prepare a stock solution of 50 m*M* sodium acetate, pH 4.0. Use acetic acid to adjust the pH to 4.0. Store at RT.

7. We used 4% T, 2.6% C stacking gels, pH 6.8, and 12% T, 2.6% C separating gels, pH 8.8. The % T is the total monomer concentration expressed in grams/100 mL, and % C is the percentage of cross-linker. The stacking and separating gel buffer concentrations were 125 m*M* Tris-HCl, pH 6.8, and 375 m*M* Tris-HCl, pH 8.8, respectively. Gels can be stored at 4–8°C for a week if wrapped to prevent dehydration. The reservoir buffer concentration was 25 m*M* Tris, 192 m*M* glycine, pH 8.3. All gel and reservoir buffers carried SDS to a final concentration of 0.1% (w/v). For mini (1-D)-gel electrophoresis, proteins were heat denatured for 5 min at 75°C in SDS loading buffer and cooled to RT before loading to wells. The electrophoresis units used for mini (1-D) and large (2-D) gels were miniVE vertical electrophoresis unit and Ettan DALTtwelve separation unit (GE Healthcare, Piscataway, NJ, USA), respectively.
8. Unless stated otherwise, all steps during this modified Pro-Q DPS procedure should be performed at RT with constant shaking on an orbital shaker at a speed of 35 rpm.
9. To decant the solution, it is important to wear powder-free nitrile gloves. Hold the tray with one hand and use the other to hold the gel in the tray. Tilt the tray to decant most of the solution. Be careful not to press the gel hard, otherwise gel may break or have finger impression.
10. This fixation step is important for fixation of proteins in the gel and at the same time to remove SDS from the gel matrix. It should be noted that the signal intensity and linear dynamic range decrease dramatically if the gel is not incubated with fixation solution for required period of time. We also recommend washing the gel twice with deionized water at RT for 10 min each prior to the fixation step (i.e. **Step 1** of **Subheading 3.2**). This is particularly important for a large-format 2-D gel, as it helps in washing out the SDS from the gel surface and to some extent from the gel matrix.
11. The one-time used fixation solution can be reused at least once more without compromising the signal intensity and linear dynamic range. Agrawal and Thelen *(7)* defined the reuse of solution "as a solution that has been used one-time and reserved for subsequent experiments."
12. If one wants to process the gel the next day, the fixation step is a good step to **stop** the protocol. In this situation, the gel can be left in the fresh fix solution overnight with constant shaking. However, we recommend completing the entire staining procedure including gel imaging the same day. This is because, we have experienced that overnight fixation of the gel requires longer washing time (may need additional wash) than mentioned in the **Table 1** (*see* **Step 2** of **Subheading 3.2**). Moreover, proper care is necessary to prevent the gel from folding-over after adding the washing solution. If this becomes problematic, one way to prevent gel

folding is to increase the volume of washing solution and the shaking speed. We found that gel folding causes uneven removal of methanol and acetic acid from the gel matrix (*see* **Note 13**) and as a consequence uneven detection of phosphoproteins having varying degree of signal intensity with Pro-Q DPS.

13. Removal of all methanol and acetic acid from the gel is critical. Residual methanol or acetic acid appears to quench Pro-Q DPS signal and reduce sensitivity ***(5, 6; Agrawal and Thelen, unpublished data)***. Residual methanol or acetic acid can also cause higher gel background (***Agrawal and Thelen, unpublished data***).
14. To create dark conditions for staining, we have used cardboard boxes (light-proof) or black plastic garbage bags to completely cover the gel tray. Minimize exposure to light during solution changes.
15. Staining solution can be reused only for qualitative detection of phosphoproteins. Linear quantitative range of Pro-Q DPS is lower with reused stain ***(7)***.
16. The destaining step reduces the gel background and also the non-specific signal. It should be noted that gels thicker than 1 mm may take longer than the recommended 2 h destaining time.
17. Keep the gel in deionized water at RT after washing step until imaging of the gel is finished.
18. We use an FLA 5000 laser scanner as fluorescence image capture device for imaging Pro-Q DPS stained gels. However, any flatbed fluorescent imager can be used for image capture. Pro-Q DPS has 555/580 nm excitation/emission maxima. Therefore, stained gels can be best imaged using excitation lasers or LEDs with a range of 532–560 nm coupled with a 580 nm longpass or a 600 nm bandpass emission filter.
19. After gel imaging, the gel can be directly stained with a total-protein stain, such as colloidal Coomassie Brilliant Blue, silver stain, or SYPRO Ruby protein gel stain. This should be performed immediately after gel imaging. The total-protein stain provides a landmark for excising the phosphoproteins for their identification by mass spectrometry and helps in determining the relative phosphorylation state of a given protein.
20. With these software programs, fluorescent protein signals in 1-D gel are displayed as dark bands or in 2-D gel dark spots.
21. Any 1-D or 2-D gel image analysis software can be used for band and spot quantification, respectively.

Acknowledgment

Electroelution of Proteins from Polyacrylamide Gels

Paul Jenö and Martin Horst

1. Introduction

Understanding the function of proteins requires determination of their structures. Advances in chemical technology make it possible to obtain a picture of global protein expression in model organisms such as the yeast *Saccharomyces cerevisiae*. Instrumental to these breakthroughs was the development of high-resolution two-dimensional gel electrophoresis and mass spectrometric means for rapid detection and analysis of peptides and proteins. While sequence information on single spots separated by two-dimensional electrophoresis can be quickly obtained by today's technology, structural characterization of proteins expressed in low abundance is still a difficult task. For example, in our attempts to isolate components of the import machinery of yeast mitochondria, some proteins turned out to be expressed at extremely low levels, and it soon became evident that conventional purification techniques were impractical to obtain these proteins in amounts sufficient for structural analysis. Furthermore, some proteins of the mitochondrial import machinery were rapidly degraded by proteases, and they could be obtained intact only by first denaturing mitochondria with trichloro-acetic acid and then solubilizing them in boiling sample buffer for sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) ***(1)***. This in turn made the separation of several milligrams of denatured proteins necessary, which was best achieved by preparative SDS-PAGE followed by electroelution of individual proteins.

Proteins isolated by electroelution usually contain large amounts of salts and SDS, which interfere with enzymatic digestion or Amino-D (N)-terminal sequencing. A number of methods are available to remove SDS from proteins, including precipitation of the detergent by organic solvents ***(2,3)***, and solvent extraction with ***(4)*** or without ion-pairing reagents ***(5)***. However, they all

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

suffer from the disadvantage that once the detergent is removed, many proteins become virtually insoluble in buffers lacking SDS. Alternatively, chromatographic methods can be used to remove SDS from proteins. Simpson et al. ***(6)*** described desalting of electroeluates based on the finding that certain reverse-phase matrices retain proteins at high organic modifier concentrations, whereas small molecular weight compounds are not. This allows bulk separation of salts, SDS, and Coomassie Blue staining components from protein material. Based on a different stationary phase, a similar approach was developed ***(7)*** to separate protein from contaminants originating from the electroelution process. In this method, electroeluted proteins are applied to a poly (2-hydroxyethyl) aspartamide-coated silica, which provides a polar medium for binding of proteins when equilibrated at high organic solvent concentration ***(8)***. Bound proteins are then eluted with a decreasing gradient of organic modifier, allowing recovery of protein free of SDS and buffer salts. Although the methodology is similar to the one described by Simpson et al. ***(6)***, proteins tend to adsorb to the poly (hydroxyethyl) aspartamide matrix at lower *n*-propanol concentrations than to reverse-phase matrices, therefore minimizing the danger of irreversible protein precipitation on the stationary phase.

In this chapter, we describe an electroelution procedure that has worked well with proteins in the molecular weight range of 20–100 kDa isolated from yeast mitochondrial membranes. In addition, a method is described which allows the desalting of these proteins into volatile buffer systems by hydrophilic-interaction chromatography.

2. Materials

1. Electrophoresis apparatus: Preparative electrophoresis is carried out on 16 × 10 cm separating and 16 × 2 cm stacking gels of 1.5 mm thickness with the buffer system described by Laemmli ***(9)***. For sample application, a preparative sample comb of 2 cm depth and 14 cm width is used. Up to 2.5 mg total protein is applied onto one preparative slab gel. Samples are electrophoresed at 15 V for 14 h. Chemicals used for electrophoresis (acrylamide, *N*,*N* -methylene *bis*-acrylamide, ammonium persulfate, *N*,*N*,*N′*,*N′* -tetramethyl-enediamine, SDS, and Coomassie Blue R250) are electrophoresis-grade and are purchased from Bio-Rad (Hercules, CA). Methanol and acetic acid used for staining are *pro analysis* (p.a.) grade from Merck (Darmstadt, Germany). Unless stated, all other chemicals used are of the highest grade available.
2. Staining solution: 0.125% (w/v) Coomassie Brilliant Blue R250, 50% (v/v) methanol, 10% acetic acid. Filter the staining solution over 320-µm filters (Schleicher and Schuell, Dassel, Germany) before use.
3. Destaining solution: 50% methanol, 10% acetic acid.
4. Electroelution apparatus: BIOTRAP from Schleicher and Schuell (Dassel, Germany, "Elutrap" trademark in the US and Canada).
5. BT1 and BT2 membranes for electroelution (Schleicher and Schuell).

6. Electroelution buffer: 25 m*M* Tris, 192 m*M* glycine, 0.1% SDS. This buffer is prepared with NANOpure water from a water purification system (Barnstead, Dubuque, IA, USA) and electrophoresis-grade SDS (Bio-Rad).
7. Electrodialysis buffer: 15 m*M* NH_4HCO_3, 0.025% SDS. Prepare the buffer with NANOpure water and electrophoresis-grade SDS (Bio-Rad).
8. High-pressure liquid chromatography (HPLC) equipment: we are using a Hewlett Packard HP1090M (Palo Alto, CA) liquid chromatograph connected to a diode array UV detector (Hewlett Packard, Palo Alto, CA) for operating columns of 4.6 × 200 mm or 2.1 mm diameter.
9. Poly (hydroxyethyl) aspartamide (PHA) columns: 5 µm particle size, 20 nm pore size, 4. × 200 mm or 2.1 × 200 mm (PolyLC, Columbia, MD).
10. Solvents for hydrophilic interaction chromatography: solvent A: 100% *n*-propanol (HPLC grade, Merck), 50 m*M* formic acid (Merck, analytical grade); solvent B: 50 m*M* formic acid in water (NANOpure).

3. Method

1. After electrophoresis, stain the gel for 15 min with Coomassie Blue. To prevent irreversible fixation of the protein, destaining is observed on a light box. As soon as the protein of interest becomes visible, the band is cut out with a razor blade. The gel piece is washed once with 10-mL of 1 *M* Tris-HCl, pH 8.0 for 5 min, followed by three 10-mL washes with water for 5 min each. Cut the gel piece with a razor blade into small cubes. Equilibrate them in 10-mL of electroelution buffer for 10 min with occasional shaking. In the meantime, assemble the electroelution apparatus.
2. The electroelution device is a block of polycarbonate (160 × 30 × 30 mm) that has an open channel along its axis (**Fig. 1**). An elution chamber that holds the polyacrylamide pieces is formed with trap inserts between points C and F of the body. During the elution process, the protein is trapped into a chamber formed between points F and G (**Fig. 1**). The device works with two types of membranes having different ion permeabilities: the BT1 membrane retains all charged macromolecules larger than 5 kDa, whereas buffer ions can freely permeate under the influence of an electric field. The macroporous BT2 membrane acts as a barrier that prevents particulate matter from entering the trap. It also keeps the buffer from flowing into the trap when the electric field is switched off, preventing dilution of the protein in the trap.

   Slide BT1 membranes between the clamping plates and the trap inserts at positions A and G of the BIOTRAP apparatus (**Fig. 1**). Since the BT1 membrane is an asymmetric membrane with two different surfaces, make sure that they are mounted in the proper orientation. The BT1 membrane is delivered moist and should not dry out. Buffer should be added within 5 min after insertion of the membranes. Insert a BT2 membrane at points C and F. If necessary, smaller elution chambers can be formed by inserting the BT2 membrane at positions D or E. Tighten the pressure screws to hold the membranes in place. Transfer the gel pieces with a spatula into the elution chamber formed between the two BT2 membranes inserted at positions C and F. Carefully overlay the gel pieces with electroelution buffer until the

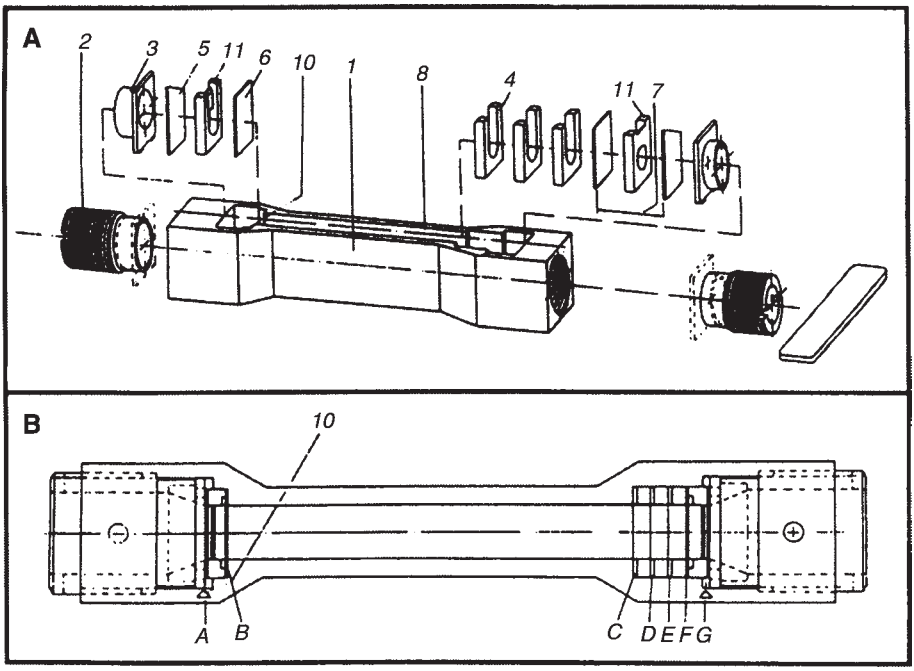

Fig. 1. Side **(A)** and top **(B)** view of the electroelution device. The apparatus is assembled by inserting a BT1 membrane at points A and G. The trap that collects the protein during the elution process is formed between points F and G. The chamber that holds the gel pieces is formed by inserting a BT2 membrane at point C. Smaller elution chambers can be made by inserting the BT2 at point D or E. The trap inserts and membranes are fixed by clamping plates, which press the trap inserts against the cell body. *1*, Cell body; *2*, pressure screw; *3*, clamping plate; *4*, trap inserts; *5*, membrane BT1; *6*, membrane BT2; *7*, trap chamber; *8*, elution chamber; *10*, mark for correct orientation of membrane BT1; *11*, trap insert for membranes BT1 (modified with permission from Schleicher and Schuell).

level of the liquid is approx 5 mm above the gel pieces. After some minutes, the trap is filled with buffer by seeping through membrane BT2. Make sure enough liquid is in the elution chamber so that the gel pieces remain completely immersed. Place the electroelution device into a horizontal electrophoresis chamber with the + mark directed toward the anode of the electrophoresis chamber. The dimensions of the horizontal electrophoresis tank are as follows: 30 cm length, 20 cm width, and 7 cm depth. The T-shaped table for agarose gels is 3 cm from the bottom. Add enough electroelution buffer to the electrophoresis chamber to fill half of the BIOTRAP (approx 3 L). Electroelute the protein for 18 h at 100 V (the current will be in the range of 70–90 mA). The volume into which the eluted protein is recovered depends on the buffer level inside the BIOTRAP and ranges from 200–800 µL.

3. Replace the electroelution buffer with 3 L of electrodialysis buffer and electrodialyze the sample for 6 h at 40 V against 15 m*M* NH_4HCO_3, 0.025% SDS.
4. Remove the eluted protein from the trap. Be careful not to perforate the BT1 membrane with the pipet tip! Rinse the trap twice with 100 µL of fresh electrodialysis buffer. Combine the dialysate and the washes. The solution is dried in a Speed Vac concentrator and stored at –20°C.
5. For desalting of the electroeluted protein, equilibrate the PHA column with solvent A (65% *n*-propanol, 50 m*M* formic acid). Electroeluates containing > 5 µg of protein are desalted on 4.6 mm internal diameter columns, which are operated at a flow rate of 0.5 mL/min. Less than 5 µg protein are chromatographed on 2.1 mm internal diameter columns at 75 µL/min. The effluent is monitored at 280 nm.
6. Dissolve the dried protein in a small volume of water (50–100 µL). The dried SDS efficiently solubilizes the protein. *n*-propanol is added to 65% final concentration. The sample is then applied in 50-µL aliquots onto the PHA column. After each injection, a number of UV-absorbing peaks, caused by Coomassie blue components, elute from the column. It is important that these components are completely washed out before the next aliquot is injected. With this procedure, the protein is efficiently concentrated on the column inlet. After the entire sample has been applied, the gradient is initiated, which is developed in 10 min from 65% *n*-propanol/50 m*M* formic acid to 50 m*M* formic acid. The protein elutes at the end of the gradient and is now devoid of any salt or SDS (**Fig. 2**).

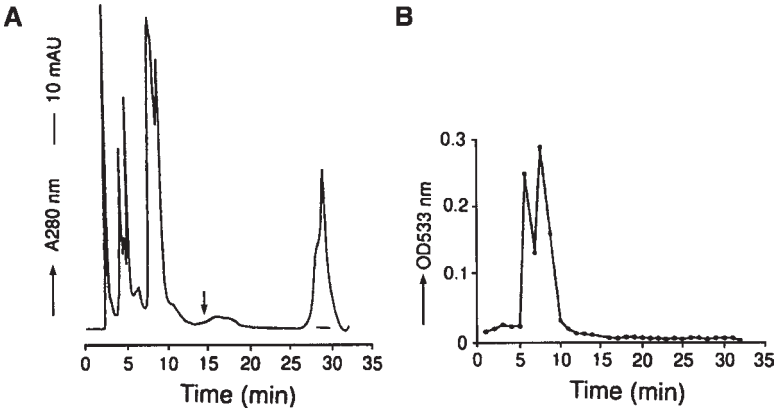

Fig. 2. Removal of SDS from an electroeluate. **(A)** 20 µg of a 45-kDa mitochondrial outer membrane protein in 50 µL was injected onto a PHA column (4.6 × 200 mm) that had been equilibrated in 70% *n*-propanol–50 m*M* formic acid. After the baseline had stabilized, the gradient was initiated (marked with an arrow). Bound protein was eluted with a linear 10-min gradient from 70% *n*-propanol–50 m*M* formic acid to 50 m*M* formic acid at a flow rate of 0.5 mL/min. The protein eluted between 27 and 30 min. **(B)** Fractions of 500 µL were collected and tested with Fuchsin red for the presence of SDS. (Modified with permission from **ref.** *7*).

7. The protein is now ready for further protein structural characterization. It can be directly subjected to automated Edman degradation. For enzymatic fragmentation, residual *n*-propanol has to be removed in the Speed Vac prior to adding the protease.

4. Notes

1. To locate the protein of interest in the gel, a staining method has to be chosen so that maximal sensitivity with minimal fixation is obtained. A number of methods exist to visualize proteins in the polyacrylamide matrix, such as formation of insoluble protein–SDS complexes with potassium ***(10)***, or precipitation of SDS by 4 *M* sodium acetate ***(11)***. We found staining of complex protein patterns with these methods difficult, as they tend to produce diffuse bands. Staining the gel for 15 min with Coomassie Blue is sufficient to visualize also faint bands without fixing the protein irreversibly. To minimize fixation of proteins, destaining is carried out on a light box, so that the band of interest can be sliced out of the gel as soon as it becomes visible.
2. The electroelution apparatus routinely used in our laboratory was originally described by Jacobs and Clad ***(12)*** and is commercially available from Schleicher and Schuell. We found this type of apparatus very reliable for routine use. The volume of the elution chamber can be adjusted depending on the volume of the gel pieces used. The volume can be increased or decreased by varying the position of the BT2 membranes between positions C and F (*see* **Fig. 1**). By forming the smallest possible elution chamber, one can process Coomassie Blue-stained bands from a single one-dimensional analytical PAGE. With the larger elution chamber, up to five preparative gels can be processed at a time. However, other suitably constructed devices will give identical results.
3. So far we have eluted proteins between 20 and 100 kDa with protein amounts ranging from 10 to 50 µg per band. After elution and dialysis, proteins are typically recovered in volumes of between 300 and 800 µL. However, elution of <10 µg of protein becomes difficult owing to the large volume of the trap, nonspecific adsorption of proteins to the BT1 membrane, or microleaks in the trap. In such cases, we prefer to run several preparative gels in parallel and pool multiple protein slices until the required amount of protein for electroelution is obtained. For low amounts of protein, several commercially available devices can be used which elute proteins into smaller volumes than the BIOTRAP apparatus.
4. Electroelution of proteins into ammonium hydrogen carbonate would be preferable, since NH_4HCO_3 can be removed by lyophilization. However, owing to the low buffering capacity of NH_4HCO_3, the pH of the buffer

drops after 4 h, rendering electroelution of high molecular weight proteins difficult due to their slow elution from the gel pieces. Therefore, it is preferable to electroelute proteins into Tris–glycine–SDS followed by electrodialysis into NH_4HCO_3-containing buffers.

5. When using 0.1% SDS in the electroelution buffer, the micelles formed in front of the BT1 membrane lead to massive accumulation of SDS in the trap. The detergent and low molecular weight contaminants can be easily removed by hydrophilic interaction chromatography with simultaneous desalting of the protein into a volatile buffer ***(7)***. Alternatively, the procedure devised by Simpson et al. ***(6)*** can be used to desalt the electroeluted protein.
6. Hydrophilic interaction chromatography of proteins requires careful control of the solvent composition. To test column performance, we use a test mixture consisting of cytochrome *c*, ovalbumin, and bovine serum albumin. Use of this test mixture allows finding the minimal *n*-propanol concentration at which the electroeluted protein binds to the stationary phase without the risk of precipitation by the organic solvent. Protein binding usually occurs at *n*-propanol concentrations between 60% and 65%. When performing electroelution with Tris–glycine buffers, direct application of the electroeluate is not possible due to precipitation of buffer salts above 50% *n*-propanol concentration. In such cases, buffer exchange into 0.1 *M* NH_4HCO_3, 0.01% SDS is carried out by electrodialysis in the electroelution apparatus. Ammonium bicarbonate can be removed by Speed Vac drying. The residual SDS facilitates solubilization of the dried protein with water. No salt precipitation is observed when adding *n*-propanol to 65% final concentration

   The solvent system used to elute bound proteins contains 50 m*M* formic acid. Unfortunately, this precludes detection of proteins at wavelengths below 250 nm. Since most proteins contain tyrosine and tryptophane residues, detection of eluting proteins is done at 280 nm. For proteins lacking tyrosines or tryptophanes, 0.05% trifluoroacetic acid (TFA) can be used instead of formic acid. However, exposure of the stationary phase to TFA should be kept to an absolute minimum, since TFA greatly reduces the lifetime of the column.

   Efficient removal of small molecular weight contaminants such as SDS and Coomassie Blue requires small injection volumes of the electroeluted protein. When using 4.6 mm i.d. columns, 50 µL injections were found to be optimal; for 2.1 mm i.d. columns, the injection volume is reduced to 20 µL. Larger volumes are concentrated on the column inlet with multiple injections. In such cases, the column should be allowed to reequilibrate between individual injections, otherwise loss of protein in the breakthrough volume occurs.

   Electroeluted proteins chromatographed by hydrophilic interaction often display unsymmetrical peaks. This may indicate the presence of several

different proteins in the eluate, which are partially resolved by the stationary phase, or heterogeneity of a single protein, which became modified during electrophoresis. Since the main purpose is to free the electroeluted protein from SDS and Coomassie Blue, we tend to elute the protein into one single peak by running very steep gradients, rather than trying to separate the eluting material into single components. This can be subsequently achieved by two-dimensional gel electrophoresis, or by reverse-phase chromatography after removal of residual *n*-propanol.

Autoradiography and Fluorography of Acrylamide Gels

Antonella Circolo and Sunita Gulati

1. Introduction

Autoradiography detects the distribution of radioactivity on gels or filters by producing permanent images on photographic film. It is frequently used in a variety of experimental techniques ranging from Southern and Northern blot analysis ***(1)***, to visualization of radioactive proteins separated in a sodium dodecyl sulfate (SDS)-Polyacrylamide gels ***(2)***, to detection of nuclear factors bound to a labeled DNA probe in gel shift analysis ***(3)***, and to localization of DNA bands in sequencing gels ***(4)***.

Autoradiographic images are formed when particles emitted by radioactive isotopes encounter the emulsion of an X-ray film and cause emission of electrons from silver halide crystals that, in turn, react with positively charged silver ions, resulting in the precipitation of silver atoms and the formation of an image ***(5)***.

^{35}S and ^{32}P isotopes are the most commonly used isotopes for autoradiography. ^{35}S is a β-emitter of relatively low energy (0.167 MeV). Thus ^{35}S particles penetrate a film to a depth of 0.22 mm, generally sufficient to interact with the emulsion in the film, as long as care is taken to assure that the film and the source of radioactivity are in direct contact, and that no barriers are posed between the film and the gel. In addition, gels must be completely dry before autoradiography. ^{32}P is a β-emitter with an energy of 1.71 MeV. Therefore, its particles penetrate water or other materials to a depth of 6 mm, passing completely through a film. In this case, gels or filters do not need to be dry, since water will not block particles of this energy and may be covered with a clear plastic wrap before autoradiography. The efficiency of ^{32}P-emitted β-particles is enhanced when an intensifying screen is placed behind the X-ray film, because radioactive particles that pass through the film cause the screen to emit photons that

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

sensitize the film emulsion. The use of intensifying screens results in a fivefold increased enhancement of the autoradiographic image when the exposure is performed at low temperature (−70°C). In general, calcium tungstate screens are the most suitable because they emit blue light to which X-ray films are very sensitive ***(6)***.

Radiation of sufficiently high energy (e.g., ^{32}P and ^{35}S) can be detected by simple autoradiography, but low energy emissions may not penetrate the coating of the film, and the most sensitive fluorography procedure is used in these cases. In fluorography, the use of fluorescent chemicals increases about 10-fold the sensitivity of detection of weak β-emitters (^{35}S and ^{14}C), and permits detection of radioactivity from ^{3}H, virtually undetectable with simple autoradiography. Gels are impregnated with scintillant or fluors, which come in direct contact with the low-energy particles emitted by ^{35}S, ^{14}C, and ^{3}H. In response to radiation, fluors emit photons that react with the silver halide crystals in the emulsion of the film. Because the wavelength of the emitted photons depends on the fluorescent chemical and not on the radioactive emission of the isotope, the same type of film can be used to detect radioactivity from isotopes of varying energies ***(7)***.

In this chapter, we describe the most common techniques of autoradiography and fluorography, and a double silver-staining method for acrylamide gels that approaches the sensitivity of autoradiography and that may be used for those experiments in which radiolabeling of proteins is not easily obtained (*see* **Note 1**). Autoradiography of wet and dry gels is described in **Subheading 3.1.**, and protocols for fluorography and methods for quantification of radioactive proteins in polyacrylamide gels are given in **Subheading 3.2.** Double silver staining is described in **Subheading 3.3.**

2. Materials

2.1. Autoradiography

1. X-ray film (Kodak XR [Rochester, NY], Fuji RX [Pittsburgh, PA], Amersham [Arlington Heights, IL], or equivalent).
2. Plastic wrap (e.g., Saran Wrap).
3. 3 MM Whatman paper.
4. SDS-PAGE fixing solution: 46% (v/v) methanol, 46% (v/v) water, 8% (v/v) acetic acid glacial. Store in an air-tight container. It is stable for months at room temperature.

2.2. Fluorography

1. X-ray blue-sensitive film (Kodak XAR-5, Amersham, or equivalent).
2. Plastic wrap.
3. 3 MM Whatman paper.
4. SDS-PAGE fixing solution (as in **Subheading 2.1.**).

5. Coomassie blue staining solution: 0.125% Coomassie brilliant blue R250 in SDS-PAGE fixing solution. Stir overnight to dissolve, filter through a Whatman paper, and store at room temperature protected from light. It is stable for several weeks. For longer storage, dissolve the Coomassie blue in 46% water and 46% methanol only, and add 8% acetic acid glacial just before use.
6. Commercially available autoradiography enhancers (acidic acid-based: En^{3}Hance from Dupont [Mount Prospect, IL], water-soluble: Fluoro-Hance from RPI [Dupont NEN, Boston, MA], or equivalent).
7. Hydrogen peroxide (15% solution).
8. Scintillation fluid.

2.3. Double Silver Staining

1. Silver stain kit (Bio-Rad, Hercules, CA).
2. Methanol, ethanol, acetic acid glacial.
3. Solution A: Sodium thiosulfate 436 g/L.
4. Solution B: Sodium chloride 37 g, cupric sulfate 37 g, ammonium hydroxide 850 mL to 1 L of dd H_2O. Store these solutions at room temperature.

3. Methods

3.1. Autoradiography

3.1.1. Wet Gels

When radioactive proteins have to be recovered from the gel, the gel should not be fixed and dried before autoradiography. However, only high-energy isotopes (^{32}P or ^{125}I) should be used.

1. At the end of the electrophoresis, turn off the power supply and disassemble the gel apparatus. With a plastic spatula, pry apart the glass plates, cut one corner of the gel for orientation, carefully remove the gel, place it over two pieces of Whatman paper, and cover with a plastic wrap, avoiding the formation of bubbles or folds.
2. In a dark room, place the gel in direct contact with the X-ray film, and place an intensifying screen over the film. Expose for the appropriate length of time at room temperature or freeze at −70°C.
3. Develop the film using an automatic X-ray processor or a commercially available developer as following: immerse the gel for 5 min in the X-ray developer, rinse in water for 30 s, transfer into the fixer for 5 min, rinse in running water for 10–15 min, and let dry. All the solutions should be at 18–20°C.

If the exposure of the gel is made at −70°C, allow the cassette to warm to room temperature and wipe off any condensation before opening. Alternatively, develop the film immediately as soon as the cassette is removed from the freezer, before condensation forms. If an additional exposure is needed, allow the cassette to dry completely before reusing.

Cardboard exposure holders may work better with wet gel, since metal cassettes may compress the gel too tightly. When an intensifying screen is used, the film should be exposed at −70°C. The screen enhances the detection of radioactivity up to 10-fold, but may decrease the resolution.

3.1.2. Dry Gels

Gels containing urea should always be fixed to remove urea crystals. When high resolution is required, gels should always be dried before exposure to film. Gels should also be dried when ^{35}S or other low-energy β-emitters are used as radioactive tracers. For improved sensitivity and resolution, gels containing ^{32}P should also be fixed and dried before autoradiography.

1. At the end of the electrophoresis, turn off the power supply, disassemble the gel apparatus, and carefully pry open the two glass plates with a plastic spatula. (To assure that the gel will adhere to one glass plate only, one of the glass plates should be treated with silicon before casting the gel.)
2. Cut one corner of the gel for orientation, place the gel with the supporting glass plate into a shallow tray containing a volume of fixing solution sufficient to cover the gels, and fix for 30 min (the time necessary for fixation varies according to the thickness of the gel, but longer times do not have deleterious effects).
3. After fixation, carefully remove the plate from the tray, taking care not to float away the gel, or with a pipet connected to a vacuum pump, remove the solution from the tray and carefully from the glass plate. Place a wet piece of Whatman paper over the gel, being careful to avoid formation of bubbles and folding of the gel. Blot dry the Whatman paper with dry paper towels, applying gentle pressure.
4. Flip over the plate and maintain it exactly over the tray of a gel dryer. Carefully begin to detach the gel from one corner of the glass plate. The gel will remain adherent to the Whatman paper and will detach easily from the plate. Carefully cover the gel with plastic wrap, avoiding folding, and then dry the gel in a slab gel vacuum dryer for 1 h at 80°C (*see* **Notes 2–6**).
5. When the gel is dry, remove the plastic wrap and expose to X-ray film. After an appropriate length of time, develop the film as described in **Subheading 3.1.1., step 3**.

To increase the resolution of the radiogaphy, gels in which several bands of similar molecular mass are visualized, should be exposed at room temperature, without an intensifying screen. The use of a screen will result in increased intensity of the radioactive signal, but in decreased sharpness of the image. SDS-PAGE or other gels in which fewer bands need to be resolved may be exposed with an intensifying screen.

3.2. Fluorography

Gels containing weak β-emitters (^{35}S, ^{14}C, and ^{3}H) should be fixed, impregnated with autoradiography enhancers, and dried to reduce the film exposure

time necessary for visualization of radioactive bands. SDS-PAGE should also be stained if nonradio-labeled mol-wt markers are used and for quantitative experiments (e.g., immunoprecipitation, detection of cell-free translated products, and so forth) where the radioactivity contained in specific proteins is to be measured in bands cut out from the gel ***(8,9)***.

1. Turn off the power supply, remove the gel from the mold, cut a corner for orientation, and place the gel on a tray containing Coomassie blue-staining solution (the volume of the solution should always be adequate to cover the gel, so that it can float freely). Incubate for 45 min at room temperature with gentle shaking.
2. Remove the staining solution, and replace with SDS-PAGE fixing solution (the staining solution can be filtered through filter paper and reused as long as the radioactivity on it remains low, or until the color changes from blue to purple).
3. Incubate overnight at room temperature with gentle shaking, and replace the fixing solution at least once to accelerate the destaining. Gels should be destained until the mol-wt markers are clearly visible and the background is clear (*see* **Note 7**).
4. Discard the fixing solution in accordance with radioactive liquid waste disposal procedures, and add the autoradiography enhancer.
5. If the enhancer used is based on acetic acid (e.g., En^{3}Hance from Dupont or its equivalent), the gel can be soaked in the enhancer without rinsing, and **steps 6–8** should be followed (*see* **Note 2**).
6. Allow the gel to impregnate with enhancer for 1 h with gentle shaking. Initially, a white precipitate may form on the surface of the gel, but it will disappear within the first 15 min of impregnation. Following impregnation, discard the used enhancer solution (do not mix with waste containing NaOH, $NaHCO_3$, and so forth). Add cold tap water to the gel to precipitate the fluorescent material and incubate the gel in water for 30 min. At this stage, the gel should appear uniformly opaque.
7. After the precipitation step, carefully place the gel over two pieces of wet filter paper, cover with plastic wrap, and dry under heat (60–70°C) and vacuum for 1–2 h on a slab gel dryer.
8. Remove the plastic wrap, tape the gel on a rigid support, and place it against a suitable blue-sensitive X-ray film, with an intensifying screen. Expose at −70°C for an appropriate length of time. Do not store the gel at room temperature for >48 h before exposure, since evaporation of the fluors may occur, resulting in reduced sensitivity. For a longer period of storage prior to exposure, freeze the gel at −70°C.
9. If water-soluble fluorography solutions are used (e.g., Fluoro-Hance from R.P.I. or equivalent), the gel must be equilibrated in water after destaining, and steps 10 and 11 should be followed.
10. Discard the destaining solution, and wash the gel in distilled water for 30 min at room temperature, with shaking.
11. Discard the water and impregnate the gel with the enhancer for 30 min at room temperature with shaking. Remove the enhancer, place the gel over two wet pieces of filter paper, cover with a plastic wrap, and dry under vacuum with heat (60–80°C)

for 2 h (*see* **Note 3**). Expose the gel as described above. (Flouro-Hance can be reused, but should be discarded as soon as the solution shows sign of discoloration) (*see* **Notes 2–7**).

If the gels are not stained with Coomassie blue, after electrophoresis, place the gel in SDS-PAGE fixing solution, and incubate for 45 min at room temperature, with gentle shaking. After incubation, discard the fixing solution and impregnate the gel with enhancer as described (**steps 5** or **9**).

12. Radioactivity incorporated into specific proteins can be determined by cutting out the radioactive bands from the dried fluorographed gel.
13. Precisely position the film over the gel. With a sharp blade or scalpel, cut out the area of the gel corresponding to the band on the film. Also cut out an area of the gel free from radioactivity immediately below (or above) the radioactive band, for subtraction of background.
14. Place each gel slice into a scintillation vial (detaching the filter paper from the slice is not necessary), add 1 mL of a 15% solution of hydrogen peroxide, and incubate overnight in a water bath at 60°C to digest the gel and release the radioactivity.
15. After incubation, allow the vials to cool down to room temperature, add scintillation fluid, and measure the radioactivity in a scintillation counter. Alternatively, autoradiographic images can be quantitated by densitometric scanning of different exposures of the film (*see* **Note 8**).

3.3. Double Silver Staining (see Note 9)

1. After electrophoresis, transfer the gel in a glass tray containing 40% methanol and 10% acetic acid, and incubate at room temperature for at least 30 min (longer periods of time have no detrimental effect).
2. Discard this solution, and incubate for 15 min in 10% ethanol, 5% acetic acid.
3. Repeat **step 2** one more time.
4. Add Oxidizer (diluted according to the manufacturer's protocol) and incubate 5 min, taking care that the gel is completely submerged in the solution.
5. Rinse the gel twice in distilled water.
6. Incubate 15 min in double-distilled water.
7. Repeat step 6 until the yellow color is completely removed from the gel.
8. Add Silver reagent (diluted according to the manufacturer's protocol), and incubate for 15 min.
9. Wash the gel once in double-distilled water.
10. Add developer (prepared according to the manufacturer's protocol), swirl the gel for 30 s, discard the solution, and wash once in double-distilled water.
11. Repeat **step 10** and develop the gel until bands appear and the mol-wt markers become clearly visible.
12. Stop the reaction with 5% acetic acid, incubate 5 min, and wash with double-distilled water.
13. Add 3.5% solution A and 3.5% solution B, and incubate 5–10 min, or until the gel is clear.
14. Incubate two times in 10% acetic acid, 30 min each time.

15. Restain the gel by repeating **steps 1–12**.
16. Dry the gel in a slab dryer with heat and vacuum, or use a gel rap (Bio-Rad or equivalent), and dry overnight.

4. Notes

1. Autoradiography of SDS-PAGE is a powerful technique that permits detection of very low amounts of protein. However, in some instances, radioactive protein labeling cannot be easily accomplished. For example, metabolic labeling requires active protein synthesis ***(12)***; thus, proteins present in body fluids or in tissue biopsy cannot be labeled ***(13)***. Moreover, in in vivo animal experiments, it is often difficult to obtain radiolabeled proteins with high specific activity. In this case, silver staining of gels can be used as an alternative method, since it approaches the sensitivity of autoradiography ***(14)***. We have developed a double silver-staining technique that is about 10-fold more sensitive than the conventional silver staining. This method has not been previously published in detail, except for figures presented elsewhere ***(15)*** (*see* **Subheading 3.3.**).
2. Gels of high polyacrylamide concentration (>10%) or gradient gels (acrylamide concentration 5–15%) may crack when dried. This problem is reduced by adding glycerol (1–5%) before drying. When acid-based fluorography enhancers are used, the glycerol should be added during the fluors precipitation step in water after removal of the enhancer. When water-soluble enhancers are used, the glycerol is added during equilibration of the gel in water, before addition of the enhancer. If the concentration of glycerol is too high, gels are difficult to dry, and they may stick to the film. Addition of the enhancer does not increase the cracking. We currently use water-based enhancers for our experiments, because they give sharp autoradiography images and good sensitivity, and can be reused for several gels. Fluorography with commercially available enhancers is simpler and less tedious than the traditional method with PPO-DMSO, and the results are as good as, or better than, those obtained with this method.
3. Enhancers are also used to increase the sensitivity of the autoradiograpy of DNA and RNA of agarose, acrylamide, or mixed gels. When enhancers are used, the gels must be dried at the suggested temperature, because excessive heat will cause damage of the fluors crystal of the enhancer and formation of brown spots on the surface of the gel.
4. Cracking may also be owing to the formation of air bubbles between the gel and the rubber cover of the dryer. This is generally caused by a weak vacuum that is insufficient to maintain the gel well adherent to the paper filter and to the dryer's tray. Air bubbles can be eliminated by rolling a pipet over the rubber cover while the vacuum is being applied.

5. Also, excessive stretching of the gel during the transfer to the filter paper may contribute to cracking, particularly for gels that contain high acrylamide concentration. A filter paper should be placed under the gel when removing it from the solution, and the method described in **Subheading 3.1.2.** should be used for larger gels.
6. It is always necessary to cover the gel with a plastic wrap to prevent sticking to the cover of the dryer. In addition, the vacuum should never be released during the drying procedure until the gel is completely dry, since this will cause the gel to shatter.
7. Staining of the gels with Coomassie blue before fluorography may quench the effect of the enhancer, particularly when low amounts of radioactivity are used. Therefore, the gels must be destained thoroughly, until the background is clear and only the protein bands are stained.
8. X-ray films that are not pre-exposed to light respond to radiation in a sigmoidal fashion, because the halide crystals of the emulsion are not fully activated ***(10)***. In contrast, in a pre-exposed film, the response becomes linear and proportional to the amount of radioactivity, therefore, allowing precise quantitative measurement of radioactivity by scanning the autoradiography ***(11)***. In addition, pre-exposure (preflashing) of the film results in a two-to threefold increase in sensitivity, for levels of radioactivity near the minimum level of detectability ***(7)***, enabling autoradiography of gels containing ^{14}C and ^{3}H radioisotopes to be performed at room temperature, instead of −70°C. To pre-expose a film, a stroboscope or a flash of light (<1 ms) from an electronic flash unit can be used, but it is necessary to reduce the light emission with a Deep Orange Kodak Wratten No. 22, or an Orange Kodak Wratten No. 21 filter, and to diffuse the image of the bulb with two pieces of Whatman No. 1 filter paper placed over the light-emitting lens. The distance between the film and the light source should be determined empirically ***(11)***.
9. In silver staining, surface artifacts can be caused by pressure, fingerprints, and surface drying. Gloves should always be worn when handling the gel. A gray precipitate on the gel may be owing to insufficient washing.

Acknowledgment

Proteolytic Activity Detection by Two-Dimensional Zymography

Jeff Wilkesman

1. Introduction

Proteases, also known as proteinases, proteolytic enzymes or peptidases, are enzymes that hydrolyze the peptide bond of proteins (generally peptide bonds); hence, they are all hydrolases. Proteases are normally generated as an inactive proenzyme (zymogene), and according to requirements, converted into the active form through limited proteolysis. Proteolytic enzymes are ubiquitous, being distributed in all biological fluids and tissues ***(1).***

In general, proteases accomplish two major functions: (a) a regulatory function, which involves activation or inactivation of specific proteins by selective proteolysis, and (b) a general proteolytic function, which is a less specific process, resulting in the bulk breakdown of cellular proteins. These degradative mechanisms remove denatured proteins as well as facilitate adaptive responses by destroying native proteins no longer needed by the cell. Both types of proteolysis are highly regulated ***(2).***

According to the enzyme nomenclature of the International Union of Biochemistry and Molecular Biology ***(3),*** hydrolases belong to class 3, and peptidases to the subclass 3.4. This subclass can be divided depending on the type of reaction catalyzed into: (a) exopeptidases or peptidases, which are proteases catalyzing the splitting of peptide bonds at either the N- or C- terminus of the substrate (EC 3.4.11-17.X); and (b) endopeptidases or proteinases, which are proteases splitting the peptide bonds within the protein substrate (EC 3.4.21-24.X). The term protease is used only when the specificity and mechanism of hydrolysis of an enzyme are unknown ***(4).*** Endopeptidases are further classified, according to their active site, into serine, cysteine, aspartic or metallo-endopeptidases.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

The analysis of proteases by two-dimensional zymography has not been studied thoroughly, still some articles had been published ***(5, 6, 7, 8, 9).*** Widespread is, however, the study of serine and metalloproteases by one-dimensional zymography (***10, 11, 12, 13, 14,*** among many others). This chapter focuses on the analysis of protease activities by applying a simple methodology consisting on an isoelectric focusing, followed by a gel electrophoresis with a substrate copolymerized, often called zymogram. The net technique is called two-dimensional zymography, giving valuable information about the enzymatic activity, as M_r and p*I*, without the need to purify the enzyme to a high degree. In order to correlate spots pattern obtained in the zymogram, a parallel run of the sample on a normal SDS-PAGE (2D-electrophoresis) is strongly recommended.

The general methodology implies first to prepare the sample appropriately (low ionic strength, no heat treatment), then the sample is submitted to isoelectric focusing using IPG (immobilized pH gradients) strips, which generally over 12 h. During this time, SDS-PAGE and zymogram gels are polymerized. After focusing, IPG-strips must be equilibrated prior submitting them to the second dimension. Once the strips are equilibrated, they are put over the gel matrix of the zymogram and run. Subsequently, the zymogram is washed to remove the excess of SDS that might interfere with enzymatic activity, and afterwards, incubated in an activation buffer for enzyme (partial) renaturalization. Finally, zymograms can be stained with Coomassie blue. Enzymatic activity is visualized as translucent spots over a deep blue background.

2. Materials

2.1. Reagents and Equipment

1. Reagents: Tris-HCl, SDS, acrylamide:bisacrylamide mix 29:1, gelatin, TEMED, $CaCl_2$, Tween-20, Coomassie brilliant blue G-250, ethanol, 2-propanol, acetic acid, glycerol, bromophenol blue (BrPhBlue), agarose, molecular weight standards (for 1 and 2-D), urea, CHAPS, DTT, Bio-Lytes™ (Ampholytes), IPG-strips for IEF, iodoacetamide (IAA).
2. Equipment: Electrophoresis gel apparatus, power supply, incubator, shaker, isoelectric focusing apparatus.

2.2. Sample Preparation

1. Buffer A: 8 M urea, 1% CHAPS, 10 mM DTT, 0.25% Bio-Lytes™ (Ampholytes) 3–10, final volume including sample: 250 µL (*see* **Note 1**). Solution must be fresh prepared.

2.3. SDS-PAGE Preparation

1. **Table 1** shows the components needed for gel preparation for normal (substrate-free) SDS-PAGE and for gelatin copolymerized zymogram.

Table 1
Preparation of SDS-PAGE and Zymogram Minigels (8×6 cm²)

Stock solution component	Stock concentration	Stability of stock	Volume (mL)	
			7.5% SDS-PAGE	7.5% Zymogram
H_2O (d)	-	-	2.45	1.95
Acrylamide mix	30%	for months at 4°C	1.25	1.25
Tris-HCl pH 8.8	1.5 M	for months at 4°C	1.25	1.25
APS	10%	15–30 days at 4°C	0.05	0.05
TEMED	100%	for months at 4°C	0.004	0.004
Gelatin*	1%	one month at 4°C, one year at −20°C	-	0.5
		Final volume	5 mL	5 mL

see* **Note 2

Table 2
Preparation of Equilibration Buffers

Buffer component	Stock concentration	Final concentration	Buffer	
			B	C
Urea	-	6 M	1.8 g	1.8 g
Tris-HCl p H 8.8	1.5 M	0.375 M	1.25 mL	1.25 mL
SDS	10%	2%	1 mL	1 mL
Glycerol	100%	20%	1 mL	1 mL
DTT	-	2%	0.1 g	-
IAA	-	2.5%	-	0.125 g
BrPhBlue	1%	BrPhBlue	-	25 µL
		Final volume	5 mL	5 mL

2.4. Strips Equilibration for SDS-PAGE

1. **Table 2** shows the components needed for the elaboration of buffer B and C for strips equilibration. Buffers must be prepared immediately before use.
2. Running buffer: 196 m*M* glycine, 0.1% (w/v) SDS, 50 m*M* Tris pH 8.3.

2.5. Zymogram Treatment and Staining

1. Washing solution: 2.5 % (v/v) Triton X-100 (stable for several months at 4°C).
2. Activation buffer, Buffer D: 0.1 *M* Tris-HCl pH 8.0, 0.01 *M* $CaCl_2$ (stable for several months at 4°C).
3. Staining solution: 0.5 % Coomassie Brilliant Blue G-250, 40% ethanol, 10% acetic acid (stable for several months at room temperature. Can be repeatedly reused).

4. Destaining solution: 40% ethanol, 10% acetic acid (stable for several months at room temperature. Can be recovered and reused if active charcoal is added after use. A clear solution is obtained after 2–3 weeks).

3. Methods

3.1. Sample Preparation

1. Adjust the conditions of your sample according to purity and ionic strength (*see* **Note 3**).
2. Select an amount of sample to apply (active rehydration conditions are recommended). Prepare 5–100 µg protein dissolved in buffer A (*see* **Note 4**).
3. Centrifuge sample briefly.
4. Rinse IEF-focusing tray with water, 2-propanol, and water again, and then dry carefully.
5. Pipette a determined volume of sample into the line of the tray (*see* **Note 5**).
6. Select a strip with the appropriated characteristics for your sample. For easier manipulation following characteristics (for the first try) are recommended: length 7 cm, thickness: 0.5 mm (hydrated), pH range: 3–10. Remove the IPG-strip cover sheet carefully.
7. Place the IPG-strip with the gel side down in the tray (*see* **Note 6**).
8. Overlay with mineral oil (500 µL). Clean the walls of the tray with a soft paper napkin or cotton hyssops.
9. Rehydrate the strip under active conditions: 50 V, 20°C, for 10–12 h, with maximal amperage of 50 µA per strip.

3.2. Focusing

1. Saturate 2 wicks per strip with water and blot the excess of water.
2. Place wicks over electrodes.
3. Design the running program. For a 7 cm strip, theoretically the recommended program is showed in **Table 3.** A final [V•h] range between 8,000 and 35,000 should be achieved (*see* **Note 7**).

3.3. PAGE preparation

1. Prepare gels (1 mm thickness) according to **Table 1.** Pour gel solution into the glasses. No comb is needed (*see* **Note 8**). Leave a ~1 mL space for placing the strip. Cover top of gel with water. Polymerization occurs in ~30 min.

Table 3
Running Program for Focusing

Step	Voltage (V)	Time	T (°C)
1. Conditioning	250	15 min	20
2. Ramping	250 → 4000	2 h	20
3. Final focusing	4000	5 h	20

3.4. IPG-Strips Equilibration for SDS-PAGE

1. Prepare equilibration buffer B and C in 6-mL tubes according to **Table 2** (*see* **Note 9**).
2. With the forceps, carefully take strips away from the focusing tray and eliminate the excess of mineral oil by passing the strip cautiously over a napkin. Wash the strip briefly with water (d).
3. Incubate strip in buffer B for 10–15 min with constant orbital shaking. For this purpose employ 10- or 15-mL test tubes.
4. Remove strip from buffer B and incubate it now in buffer C for the same time, with gently shaking at RT.
5. While incubation is being held, heat a 1% agarose solution (*see* **Note 10**) up to 80°C.
6. While incubation, begin to prepare the gels for strip application. Wash the gels overlay with water and carefully dry the space in between the glasses with filter paper.
7. Once the surface is dried, remove the strip from buffer C and wipe the excess of liquid with a napkin. Now insert the strip between the glasses, taking special care not to touch the surface of the acrylamide gel (*see* **Note 11**).
8. Pour now carefully the agarose solution over the strip (*see* **Note 12**). Avoid any kind of bubble formation. Write down the position of the strip (*see* **Note 13**). Polymerization should occur within 15 min.
9. If wished, and if a well is available, apply molecular weight standards (*see* **Note 14**).
10. Ensemble the electrophoretic unit. Add the running buffer and run gel at constant 70 V, 4°C with maximal amperage of 40 mA for both gels, until the front dye reaches the bottom of the gel. Do not let the front leave the gel.

3.5. Zymogram Treatment and Staining

1. After run, incubate the zymogram 2 times for 30 min each with 2.5% (v/v) Triton X-100 solution, and then 3 times for 5 min with water (d) (*see* **Note 15**). The substrate-free gel run can be directly stained (by Coomassie or silver stain, according to the amount of sample added at the beginning).
2. Leave the zymogram overnight in buffer D (*see* **Note 16**).
3. Wash zymogram gels 3 times for 5 min with water.
4. Stain zymogram with a 0.5% Coomassie solution. Staining time is about 1 h. Afterwards, add destaining solution. Destain until white spots, corresponding to enzymatic activity, appear over a deep blue background. Fig. 1 shows an example of a proteolytic activity after 2-D zymography. Determination of p*I* and M_r can be now performed with specialized software available from several manufacturers. Comparisons can be hold with parallel runs done with molecular weight standards for 1-D and 2-D electrophoresis.

4. Notes

1. Concentrations of buffer components may vary, according to sample characteristics. Urea solubilizes proteins but also denatures it. Up to 9.8 M urea may be used. The use of thiourea instead of urea has also been proposed (15). Non-ionic or zwitterionic detergents are recommended in concentrations range from 0.5 until 4%. Concentration of carrier ampholytes can also be

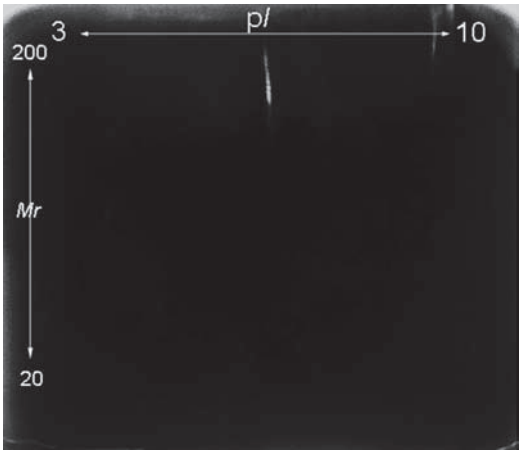

Fig. 1. 2-D zymogram of an unknown sample with proteolytic activity. About 25 µg of (total) protein was added. A p*I* ~7 and 145 kDa were determined using molecular weight standards run on a separate gel. A 10% SDS-PAGE was used copolymerized with 1% gelatin.

varied in the range 0.1 – 0.25%. Up to 100 mM DTT can also be used. Consult the instruction manual of the manufacturer of the IPG-strips in order to review the best conditions for the sample to be analyzed. It is strongly recommended to test each buffer component over the enzyme activity, as proposed by Wilkesman et al. ***(6)***.

2. Other suitable substrates besides gelatin are casein or hemoglobin. However, gelatin is highly recommended for giving very good and reproducible results. Substrate must be selected according to the type of protease to be analyzed.
3. The sample does not have to be previously purified. Experiments carried with unpurified sample should be done in order to avoid extra purification work. However, depending on the sample, some minor purification process should be done to avoid loss of biological activity, due to the presence of natural inhibitors or concomitant proteases in the biological matrix. To guarantee a good run, the protein sample must be basically salt free, with very low buffer concentration (~50 mM Tris-HCl or less)], otherwise, the strip might burn during IEF. Active rehydration is preferred as high molecular weight proteases are improved to enter into the IPG-strip ***(16)***.
4. Weigh all solids in 1.5 mL caps. Dissolve solids first in water and then add sample. Do NOT vortex the sample. Avoid bubble formation. Dissolve solids by warming the tube with the hand and with gentle up and down movements. Do NOT heat up the sample. When dissolved, let stay over ice.
5. According to strip size and tray size, volumes vary (~130 µL for 7 cm strip). Consult the instruction manual of your equipment. The mini-tray e.g., has a

minimal volume of 125 µL and a maximal of 250 µL). Use gloves for all of the following steps.

6. Avoid bubbles at this stage as best as possible. Remember (+) side over anode (red/+). Be careful with strip identification.
7. Variations are possible. For example, **Table 4** includes the rehydration step and a second conditioning step.
8. Some companies offer special combs for 2-D electrophoresis. These are useful, but not mandatory. Ready-to-use gels for 2-D purposes are also purchasable.
9. Buffers must be freshly prepared.
10. Prepare the 1% agarose solution in water or running buffer.
11. Optional: if you have not used a special comb, you may insert at this point a "tooth" of a comb to run MW markers in parallel. For easier manipulation and later interpretation, it is recommended to insert acidic (+) extreme of the strip on the left side of the gel. Remember at this step to identify which glasses contain the substrate-free gel, and which the zymogram (!).
12. Agarose temperature should be close to 80°C. A lower temperature will cause agarose to polymerize, a higher temperature could melt the polyacrylamide matrix of the gel.
13. It is recommend to put the acidic (+) extreme of the strip beside the molecular weight markers, for later identification.
14. Some companies offer special protease-molecular-weight-standards. The presence of standards in the gel is not mandatory, especially if a parallel 2-D electrophoresis is being done. Remember that normal MW standards are useless, as the whole gel will stain blue, for gelatin was copolymerized.
15. The objective to incubate with Triton is to eliminate by displacement the SDS present in the gel. SDS may inhibit protease activity. However, some proteases are detergent-resistant. If this is the case, you may jump this step.
16. This is an activation buffer. Components of the buffer, as well as incubation time, may vary according to particularities of the enzyme. These factors must be determined according to enzymatic characteristics.

Table 4
Alternative running program for focusing

Step	Voltage (V)	Time (h)	T (°C)
Active rehydration	50	12.5	20
1st Conditioning	200	2	20
2nd Conditioning	500	2	20
Ramping	500→4000	1	20
Final focusing	4000	3	20

Protein Blotting by Electroblotting

Mark Page and Robin Thorpe

1. Introduction

Identification of proteins separated by gel electrophoresis or isoelectric-focusing is often compounded by the small pore size of the gel, which limits penetration by macromolecular probes. Overcoming this problem can be achieved by blotting the proteins onto an adsorbent porous membrane (usually nitrocellulose or diazotized paper), which gives a mirror image of the gel ***(1)***. A variety of reagents can be incubated with the membrane specifically to detect and analyze the protein of interest. Antibodies are widely used as detecting reagents, and the procedure is sometimes called Western blotting. However, protein blotting or immunoblotting is the most descriptive.

Electroblotting is usually preferred for immunoblotting in which proteins are transferred to the membrane support by electrophoresis ***(2)***. A possible exception to this is in transfer from isoelectric focusing gels, where the proteins are at their isoelectric points and uncharged. Therefore, there is considerable delay before the proteins start to migrate in an electric field; also they can migrate in different directions and their rate of transfer can vary. For these reasons, transfer from isoelectric focusing gels by capillary blotting (*see* Chapter 60) may be preferable, particularly if very thin gels are used.

Electroblotting has the advantage that transfer takes only 1–4 h, and lateral diffusion of proteins (which causes diffuse bands) is reduced. Overall, nitrocellulose membranes are recommended. These are efficient protein binders and do not require activation, but are fragile and need careful handling. Nitrocellulose membranes, such as Hybond-C extra, are more robust. If the antigens of interest do not bind efficiently or if the blot is to be reused, then diazotized paper, or possibly nylon membranes, can be used. A suitable electrophoretic transfer chamber and power pack are required; these are available commercially or can be made in a laboratory work shop. The apparatus consists of a tank containing buffer, in which is located a cassette, clamping the gel and membrane tightly together.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

A current is applied from electrodes situated at either side of the cassette. The buffer is often cooled during transfer to avoid heating effects.

2. Materials

1. Transfer apparatus.
2. Orbital shaker.
3. Nitrocellulose sheet, 0.45-µm pore size, e.g., Hybond-C extra.
4. Filter paper, Whatman 3 MM (Maidstone, UK).
5. Plastic box large enough to hold the blot and allow movement on agitation.
6. Transfer buffer: 0.025 *M* Tris, 0.052 *M* glycine, 20% methanol.
7. Blocking buffer: PBS (0.14 *M* NaCl, 2.7 m*M* KCl, 1.5 m*M* KH_2PO_4, 8.1 m*M* Na_2HPO_4) containing 5% dried milk powder.

3. Method

1. Assemble transfer apparatus and fill the tank with transfer buffer (*see* **Note 1**). If a cooling device is fitted to the apparatus, switch on before it is required to allow the buffer to cool down sufficiently (to ~8–15°C).
2. Cut two pieces of filter paper to the size of the cassette clamp, soak in transfer buffer, and place one on the cathodal side of the cassette on top of a wetted sponge pad (*see* **Note 2**).
3. Place the gel on the filter paper covering the cathodal side of the cassette (*see* **Note 3**). Keep the gel wet at all times with transfer buffer. Soak the nitrocellulose sheet (cut to the same size as the gel) in transfer buffer, and place it on the gel, i.e., on the anodal side (*see* **Note 4**). Avoid trapping air bubbles throughout the process.
4. Place the remaining filter paper over the nitrocellulose, and expel all air bubbles between the nitrocellulose and gel. This is achieved by soaking the gel/nitrocellulose/filter paper assembly liberally with transfer buffer and then pressing with a small hand roller.
5. Finally, place a wetted sponge pad on top of the filter paper, and clamp securely in the cassette. This should be a tight fit (*see* **Note 5**).
6. Place the cassette in the tank and fit the lid. Recirculate the transfer buffer either by a recirculating pump or a magnetic stirrer.
7. Electrophorese for 1–4 h at 0.5 A (*see* **Note 6**).
8. Turn off power, remove nitrocellulose sheet, and agitate in 50–200 mL of PBS containing 5% dried milk powder (*see* **Note 7**).
9. Process nitrocellulose sheet as required (*see* Chapters 71–80).

4. Notes

1. Methanol prevents polyacrylamide gels, removes SDS from polypeptides, and enhances the binding of proteins to the membrane, but it reduces the efficacy of transfer of larger proteins. It can be omitted from the transfer buffer with no adverse effects, but this has to be established empirically. Methanol is not necessary for non-SDS gels or isoelectric focusing gels.

2. Cassette clamps are normally provided with two sponge pads that fit either side of the gel/membrane/filter paper assembly to fill any dead space to squeeze the gel and membrane tightly together during electrophoresis.
3. Handle the gel and nitrocellulose sheet with gloved hands to prevent contamination with finger-derived proteins.
4. Cut a small piece of the bottom corner of the gel and nitrocellulose to orient the assembly.
5. If the gel and nitrocellulose are not clamped tightly together, then the proteins migrating from the gel can move radially and give a smeared blot.
6. Higher current can be used, but may result in uneven heating effects and blurred or distorted blots. The use of lower currents is not recommended, since transfer efficiency is reduced and poor quality blots are obtained. Overnight transfer can be used, but is not generally recommended. The time required for efficient transfer depends on the acrylamide concentration, gel thickness, gel buffer system, and the molecular size and shape of the proteins. Most proteins will pass through the nitrocellulose sheet if transfer is continued for too long. Proteins migrate faster from SDS gels (they are coated with SDS and highly charged), and transfer from non-SDS gels takes longer (around 4–5 h).
7. Other proteins can be used for blocking (e.g., albumin, hemoglobin), but dried milk powder is usually the best option. Thirty-minute incubation with blocking protein is sufficient to saturate all the protein binding sites on the blot. Longer times and overnight incubation can be used if this is more convenient. Protein blocked sheets can be stored frozen for long periods. For this, drain excess blocking solution and place in a plastic bag when required, wash with blocking buffer for 10 min, then continue with the next processing steps.

Protein Blotting by the Semidry Method

Patricia Gravel

1. Introduction

Protein blotting, also known as Western blotting, refers to the transfer of proteins to an immobilizing membrane. The most widely used blotting method is the electrophoretic transfer of resolved proteins from a polyacrylamide gel to a nitrocellulose or polyvinylidene difluoride (PVDF) sheet and is often referred to as "Western blotting." Electrophoretic transfer uses the driving force of an electric field to elute proteins from gels and to immobilize them on a matrix. This method is fast, efficient and maintains the high resolution of the protein pattern ***(1).*** There are currently two main configurations of electroblotting apparatus: (1) tanks of buffer with vertically placed wire (*see* Chapter 58) or plate electrodes and (2) semidry transfer with flat-plate electrodes.

For semidry blotting, the gel and membrane are sandwiched horizontally between two stacks of buffer-wetted filter papers which are in direct contact with two closely spaced solid-plate electrodes. The name semidry refers to the limited amount of buffer which is confined to the stacks of filter paper. Semidry blotting requires considerably less buffer than the tank method, the transfer from single gels is simpler to set up, it allows the use of multiple transfer buffers (i.e different buffers in the cathode and anode electrolyte stacks) and it is reserved for rapid transfers because the amount of buffer is limited and the use of external cooling is not possible. Nevertheless, both techniques have a high efficacy and the choice between the two types of transfer is a matter of preference.

Once transferred to a membrane, proteins are more readily and equally accessible to various ligands than they were in the gel. The blot (i.e., the immobilizing matrix containing the transferred proteins) is therefore reacted with different probes, such as antibody for the identification of the corresponding antigen, lectin for the detection of glycoproteins or ligand for the detection of blotted

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

receptor components, as well as for studies of protein-ligand associations (*see* **ref 2**). The blot is also widely used with various techniques of protein identification, from which the measurement of protein mass (by mass spectrometry using nitrocellulose or PVDF membrane), or the determination of the protein sequence (N-terminal Edman degradation, C-terminal sequence or amino acid analysis). Recently, a novel approach has been described for the sensitive analysis and identification of proteins, separated by 2-D PAGE, transferred onto a PVDF membrane, incubated with succinic acid and then scanned with IR-MALDI-MS (infrared matrix-assisted laser desorption/ ionisation - mass spectrometer). They demonstrated that the sensitivity for protein detection was comparable if not better than that of sensitive silver stained gels ***(3).***

The blot analysis generally requires small amounts of reagents, the transferred proteins on membrane can be stored for many weeks prior to their use and the same blot can be used for multiple successive analyses. For reviews on the basic principles involved in performing protein blotting and for an overview of some possible applications, see articles by Garfin et al. ***(1),*** Beisiegel ***(4),*** Gershoni et al. ***(5),*** Gravel ***(6),*** and Wilkins et al. ***(7).***

In the following sections, we describe a protocol for semidry blotting which uses a simple buffer system ***(8).*** The efficacy of this method is illustrated in **Fig. 1** with human plasma proteins separated by two-dimensional polyacrylamide gel

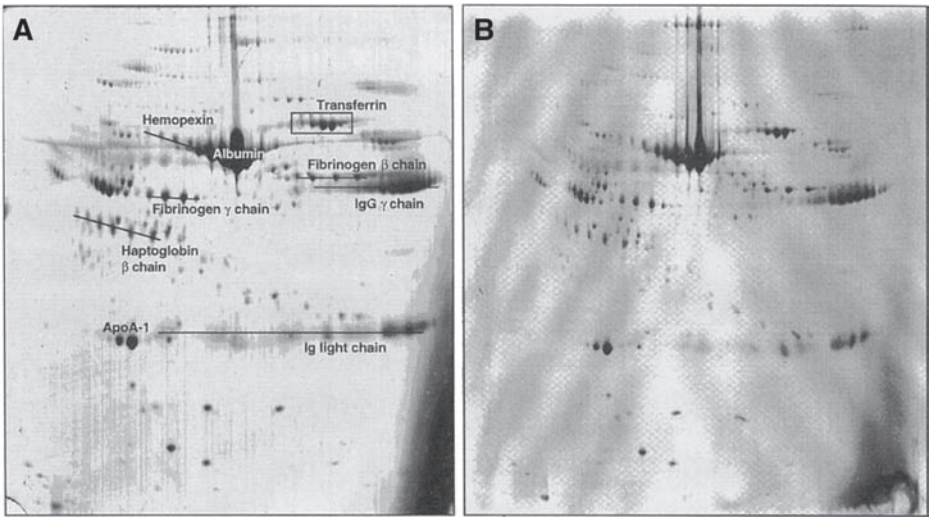

Fig. 1. Plasma proteins separated by two-dimensional polyacrylamide gel electrophoresis and (A) stained with Coomasie Brilliant Blue R250 or **(B)** transferred to PVDF membrane using the semidry system (2h, 15V) with Towbin buffer diluted 1:2 in water and stained with Coomasie Blue.

electrophoresis (2-D PAGE), transferred on PVDF membrane and stained with coomasie blue. The blot pattern is compared to the coomasie blue staining of the same protein sample before transfer from 2-D PAGE. The resolution, shape and abundance of protein spots on membrane are comparable to the 2-D polyacrylamide gel pattern. This blotting procedure allows a good and almost complete elution of proteins from the gel and their immobilization on the membrane. We will also review in **Subheading 4** the principal types of transfer matrix and the different discontinuous or continuous buffers that can be used with this technique.

2. Materials

1. Buffer: The transfer and equilibration buffer is the Towbin buffer diluted 1:2 with distilled water: 12.5 m*M* Tris, 96 mM glycine and 10% (v/v) methanol (9) (*see* **Note 1** and **Table 1**).
2. Membranes and filter papers: PVDF (0.2 µm, 200 × 200 mm, Bio-Rad) or nitrocellulose (0.45 µm, Schleicher & Shuell). Filter papers are chromatography papers (grade 3 MM CHr, Whatman). Thicker blotting papers can also be used (Pharmacia-LKB, filter paper for blotting, 200 × 250 mm).
3. Electroblotting apparatus: Proteins are transferred with a Trans-Blot SD semidry cell (Bio-Rad). The anode of the apparatus is made of platinum-coated titanium and the cathode is made of stainless steel. The maximum gel size that can be used with this apparatus is 25 cm × 18.5 cm.
4. Coomasie staining: Proteins in the 2-D gel and on the blot **(Fig. 1)** are stained with a 0.025% (w/v) solution of coomasie brilliant blue R250 solubilized in 43% (v/v) methanol and 7% (v/v) acetic acid. The destaining solution contains 30% (v/v) methanol and 7% (v/v) acetic acid.

All chemicals and methanol are of analytical reagent grade. Metallic contaminants in low grade methanol normally deposit on the electrodes.

3. Method

Note: *To avoid membrane contamination, always use forceps or wear gloves when handling membranes*.

3.1. Preparation for Semidry Blotting

1. Prepare the transfer buffer the day preceding the blotting experiments and store it at 4°C.
2. After the separation of proteins by SDS-PAGE or 2-D PAGE, the gel is briefly rinsed in distilled water for a few seconds and then equilibrated in transfer buffer for 10 minutes under gentle agitation (*see* **Note 2**).
3. During the equilibration, the filter paper and the transfer membrane are cut to the dimensions of the gel. Six pieces of filter paper per gel are needed for each gel/membrane sandwich (or two pieces of thick filter papers).

4. If the hydrophobic PVDF membrane is used, it should be prewetted prior to equilibration in transfer buffer. Immerse the membrane in a small volume of 100% methanol for a few seconds, until the entire membrane is translucent, rinse it in deionized water and then equilibrate it in transfer buffer for 3–5 minutes. It is important to keep the membrane wet at all times since proteins will not bind to the dried PVDF membrane (*see* **Note 3**).

   For hydrophilic nitrocellulose membrane, wet it in transfer buffer directly and allow it to soak for approximately 5 minutes (*see* **Notes 4** and **5** and **Table 2** for the description of the different transfer membranes).
5. If multiple full-size gels are to be transferred at one time, there is a necessity to interleave a dialysis membrane between the gel-membrane pairs to prevent proteins being driven through membranes into subsequent stacks.

   Cut a piece of dialysis membrane with the appropriate molecular weight cut-off to the dimensions of the gel and soak it in the transfer buffer (*see* **Note 6**).

3.2. Assembly of the Semidry Unit

The assembly of a semidry electroblotting apparatus is represented in **Fig. 2**. Four minigels can also be transferred at the same time by placing them side-by-side on the anode platform.

1. The filter papers are briefly soaked in transfer buffer for a few seconds.
   Place a prewetted filter paper onto the anode. Use a pipette or a painter roller to eliminate all air bubbles by pressing firmly all over the area of the paper (*see* **Note 7**). If a thin filter paper is used, add two more sheets and remove air bubbles between each layer.
2. Place the preequilibrated transfer membrane on top of the filter paper.
3. Place the equilibrated gel on top and on the center of the membrane.
4. Place another wetted sheet of filter paper on top of the gel. If a thin filter paper is used, add 2 additional sheets. Roll out air bubbles.
5. Place the cathode onto the stack.

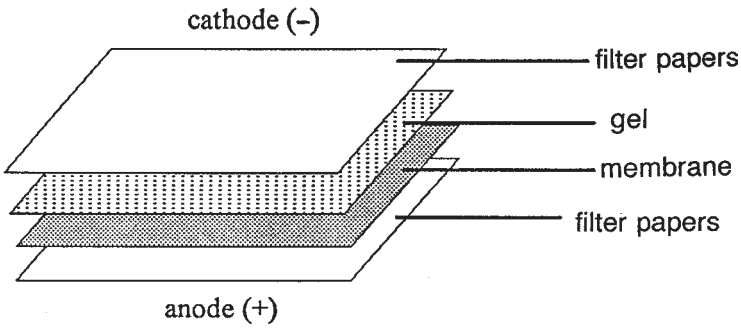

Fig. 2. Assembly of a horizontal electroblotting apparatus.

6. The blotting unit is then connected to a power supply and proteins are transferred for 2 h at a constant voltage of 15 V and at room temperature.
7. After protein blotting, the membrane is rinsed (3 × 5 min) with distilled water and is then ready for blot analysis. Following transfer, the first step for blot analysis is to block unoccupied binding sites on the membrane to prevent non-specific binding of probes, most of which are proteins (antibody, lectin). *See* **Note 8** and **Table 3** for a description of the blocking procedure.
8. The blots can be stored for many weeks prior to their use. *See* **Note 9** for storage conditions.

4. Notes

1. Since the introduction of western blotting in 1979 by Towbin et al. ***(10),*** many other buffer systems have been developed in order to improve electrophoretic transfer of proteins. The most common systems used with semidry apparatus are listed in **Table 1**.

   The two critical factors during transfer are the elution efficacy of proteins out of the gel and the binding capacity of the matrix for proteins. The elution efficacy is mainly determined by the acrylamide concentration of the gel, the ionic strength, the pH of the buffer and additional constituents of the transfer buffer such as sodium-dodecyl-sulfate (SDS) and methanol.

   The binding capacity is mainly determined by the character of the membrane but also by the transfer buffer composition ***(5).***

   Alkaline pH and SDS favour the elution of the proteins from the gel, whereas acidic pH and methanol favour their adsorption on the negatively charged membrane ***(19).*** Methanol increases the binding capacity of matrix presumably by exposing hydrophobic protein domains, so that they can interact with the matrix. Also, methanol decreases the elution efficacy by fixing the proteins in the gel and by reducing the gel pore size ***(1, 5).*** When there is SDS in transfer buffer (up to about 0.1% w/v), the proteins are negatively charged and elute efficiently from the gel.

   Semidry conditions for blotting allow the use of multiple transfer buffers (discontinuous buffer systems) to ensure a faster and better electrotransfer ***(18).*** Examples of discontinuous buffer systems are listed in **Table 1**. However, Bjerrum and Schafer-Nielsen ***(13)*** showed that there is no advantage in using different buffers in the cathode and anode electrolyte stacks. They found comparable transfer efficiencies for semidry blots performed in continuous and discontinuous buffers. We tested different buffer systems (Towbin buffer; Towbin buffer diluted 1:2 with water and Laurière buffer) for transferring plasma proteins from 2-D PAGE by semidry method and we similarly found no advantage in using discontinuous buffer systems (unpublished results).
2. Rinsing and equilibrating the gel facilitate the removal of electrophoresis buffer salt and excess of detergent. If salts are still present, the conductivity of the transfer buffer increases and excessive heat is generated during the transfer. Also, an equilibration period allows the gel to adjust to its final size prior to electroblotting because the gel shrinks in methanol-containing transfer buffer.

The duration of equilibration depends on the gel thickness. For a 1.5 mm thick gel, 10 minutes of equilibration are enough.

Recently, poly(ethylene glycol) polymers (PEG 1000–2000) have been used to complete electroblotting, in order to obtain better resolution and enhancement of sensitivity of proteins on membrane. PEG reduces background, raises signal-to-noise ratio and sharpens protein band ***(20).*** After polyacrylamide gel electrophoresis, 30 % (w/v) PEG (solubilized in transfer buffer: 12.5 mM Tris, 96 mM glycine and 15% (v/v) methanol) is applied to reversibly fix proteins within the gel. The intragel proteins can then be electroblotted directly onto membranes using the same transfer buffer containing PEG.

3. If the PVDF membrane does dry out during use it can be rewet in methanol. Membranes that contain adsorbed proteins and that have been allowed to dry can also be wet again in methanol. In our experience, we have not seen any difficulty in protein staining, glycoprotein detection and immunostaining after this re-wetting procedure in methanol.
4. Nitrocellulose membrane was the first matrix used in electroblotting ***(10)*** and is still the support used for most protein blotting experiments. It has a high binding capacity, the non-specific protein binding sites are easily and rapidly blocked, allowing low background staining and it is not expensive. For blotting with mixtures of proteins, standard nitrocellulose with a pore size of 0.45 µm should be used first. However, membranes having 0.1 µm and 0.2 µm pore sizes should be tried if some low-molecular weight proteins do not bind efficiently to the standard membrane ***(1).*** After staining, the nitrocellulose membranes become transparent simply by impregnating the membrane with concentrated Triton X-114 ***(21).*** The blot can thus be photographed by transillumination or scanned with a densitometer for quantitative analysis. Long term stability (several months) of transparent stained blots is possible if they are stored at −20°C.

   PVDF membranes are more expensive but have high mechanical strength, high protein binding capacity and are compatible with most commonly used protein stains and immunochemical detection systems. The chemical structure of the membrane offers excellent resistance to acidic and organic solvents. This makes PVDF membrane an appropriate support for N-terminal protein sequencing and amino acid composition analysis. Another interesting advantage of PVDF matrix over the nitrocellulose is the possibility to visualize the protein pattern on the blot without staining. After blotting, the PVDF membrane should be placed on top of a vessel containing distilled water. The immersion of the membrane in water should be avoided. It should be laid down at the surface. The protein spots (or bands) contrast with the remainder of the membrane and can be visualized. To obtain a clear image of the protein pattern, the surface of the membrane should be observed from different angles and under appropriate lighting. This procedure, which was found unintentionally, is easy to perform and allows rapid and good evaluation of the transfer quality.

   Table 2 summarizes the most common matrices that can be used for transferring proteins from polyacrylamide gels.

5. Whatever the membrane used, exceeding its binding capacity tends to reduce the signal eventually obtained on blots. It can be assumed that excess protein, weakly associated with the membrane, may be readily accessible to react with the probe in solution, but the probe-protein complexes formed may then be easily washed off during the further processing of the membrane ***(5).*** This situation does not occur if the proteins are initially in good contact with the membrane.

   For 2-D PAGE, the best recovery and resolution of proteins are obtained when loading 120 µg of human plasma or platelet proteins. When 400 µg of protein are separated by 2-D PAGE and transferred on membrane, the spots are diffused and the basic proteins poorly transferred (not shown). This could be attributed to overloading which prevents a good separation of proteins and an adequate binding to transfer matrix.
6. It is very difficult to form large stacks of gel-membrane pairs. Even 2 pairs are often associated with the introduction of air bubbles. We prefer to use a semidry unit to transfer proteins from a single gel only.
7. Air bubbles create points of high resistance and this results in spot (or band) areas of low efficacy transfer and spot (or band) distortion.
8. The quality or extent of the blocking step determines the level of background interference. It has been recognized that the blocking step may also promote renaturation of epitopes ***(23).*** This latter aspect is particularly important when working with monoclonal antibodies (which often fail to recognize the corresponding antigenic site after electroblotting). Hauri and Bucher ***(23)*** suggest that monoclonal antibodies may have individual blocking requirements, probably due to different degrees of epitope renaturation and/or accessibility of antibody under the various blocking conditions.

   Some common blocking agents are listed in **Table 3**.

   For immunoblotting on nitrocellulose membrane we obtain good results by using a blocking solution made of 0.5% (w/v) BSA, 0.2% (w/v) Tween-20 and 5% (w/v) non fat dried milk in PBS buffer (137 m*M* NaCl, 27 m*M* KCl, 10 m*M* Na_2HPO_4, 1.8 m*M* KH_2PO_4, pH 7.4) ***(29).*** For lectin blotting on PVDF membrane, we use 0.5% (w/v) Tween-20 in PBS buffer ***(8).***
9. We store the blots at 4°C in PBS containing 0.005% (w/v) sodium azide. To evaluate the effect of storage on blotted proteins, we stained with colloidal gold a nitrocellulose blot of platelet proteins stored for a period of 4 months in PBS/azide at 4°C. We observed a protein pattern identical to the same blot stained immediately after western blotting (not shown).

   On the other hand, when we dried a nitrocellulose blot at room temperature and stained 24 hours later the proteins with colloidal gold, we observed important contaminating spots on the blots.

   Only one point should be kept in mind when storing blots in PBS/azide. Sodium azide inhibits peroxidase activity and therefore good washing of the membrane with PBS is necessary before blot analysis using probe labeled with peroxidase.

   As an alternative to blot storage, the gel can be frozen at −80°C. Immediately after electrophoresis, the gel should be rinsed in distilled water for a few seconds

and placed in a plastic bag between two precooled glass plates. It is important to precool glass plates at −80°C, otherwise the gel will crack when thawed. These frozen gels can be stored at −80°C for at least 3 months ***(19)***. Before the transfer procedure, the frozen gels are thawed in their plastic bags and then equilibrated as described in Subheading 3.

Protein Blotting by the Capillary Method

John M. Walker

1. Introduction

The ability to transfer (blot) separated proteins from a polyacrylamide gel matrix onto a sheet of nitrocellullose paper (where the proteins bind to the surface of the paper) has provided a powerful tool for protein analysis. Once immobilized on the surface of the nitrocellulose sheet, a variety of analytical procedures may be carried out on the proteins that otherwise would have proven difficult or impossible in the gel. Such procedures may include hybridization with labeled DNA or RNA probes, detection with antibodies (probably the most commonly used procedure), detection by specific staining procedures, autoradiographic assay, and so forth. The most commonly used, and indeed most efficient, methods for transferring proteins from gels to nitrocellulose (blotting) are by electrophoresis, and these methods are described in Chapters 58 and 59. An alternative method, capillary blotting, is described here. Although this method takes longer than electroblotting methods (it takes overnight) and transfer of proteins from the gel is not as complete as it is for electroblotting (although sufficient protein is transferred for most purposes) the method does have its uses. It is of course ideal for those who only wish to carry out occasional blotting experiments and therefore do not wish to commit themselves to the purchase or the purpose-built apparatus (plus power pack) needed for electroblotting. Second, this method is particularly useful for blotting isoelectric focusing gels where the proteins are at their isoelectric point (i.e., they have zero overall change) and are not easy therefore to transfer by electrophoresis. The method simply involves placing the gel on filter paper soaked in buffer. Buffer is drawn through the gel by capillary action by placing a pad of **dry** absorbent material on top of the gel. As the buffer passes through the gel, it carries the protein bands

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

with it, and these bind to the nitrocellulose sheet that is placed between the top of the gel and the dry absorbent material.

2. Materials

1. Blotting buffer: 20 m*M* Tris, 150 m*M* glycine, 20% methanol, pH 8.3. Dissolve 4.83 g of Tris base, 20.5 g of glycine, and 400 mL of methanol in 2 L of distilled water. The solution is stable for weeks at 4°C.
2. Nitrocellulose paper.
3. Whatman 3 MM filter paper.
4. Absorbent material: e.g., a wad of filter paper or paper towels; this author uses baby diapers.

3. Method

1. Place two sheets of 3 MM filter paper on a glass plate, and thoroughly soak them in blotting buffer. The ends should be dipped in reservoirs containing blotting buffer to ensure this filter paper pad remains wet overnight (*see* **Fig. 1**).
2. Place the gel to be blotted on top of this filter paper bed. Make sure the bed is fully wetted, and that no bubbles are trapped between the gel and filter paper. Thoroughly wet the top of the gel with blotting buffer.
3. Cut a piece of nitrocellulose paper to the size of the gel to be blotted. Wet the paper by dipping it in blotting buffer. **(Care: Use gloves; there are more proteins on your fingers than you are blotting from the gel!)** Then lay the nitrocellulose sheet on the gel surface. Take great care to ensure no air bubbles are trapped (buffer cannot pass through an air bubble).
4. Now dry material must be placed on top of the nitrocellulose. Start with three sheets of 3 MM filter paper, cut to the same size as the gel, and then place on top of this a pad of your absorbent material (*see* **item 4, Subheading 2.**).
5. Finally, place a heavy weight on top of the absorbent rnaterial, e.g., a sheet of thick glass that supports a 2–3 L flask filled with water (*see* **Note 1**).
6. Allow blotting to take place overnight (preferably for 24 h). The setup may then be dismantled. the nitrocellulose sheet stained for protein to confirm that transfer has been achieved (e.g., with 0.2% Ponceau S in 10% acetic acid), and then the

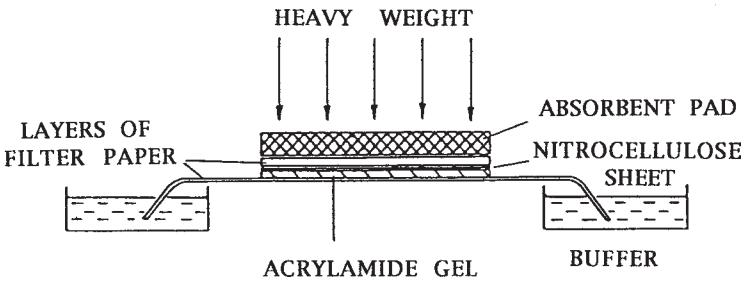

Fig. 1. A typical arrangement for capillary blotting.

nitrocellulose sheet blocked and probed using any of the methods described in Chapters 74–80.

4. Note

1. The only error you can make with this method is to have any of your dry material (e.g., filter paper or absorbance pad) overhanging the gel and making contact with the wet base of filter paper. In this case, buffer preferentially travels around the gel into the absorbant pad, rather than through the gel. When the heavy weight is applied to the setup check that this is not happening (the absorbent pad often "sags" quite easily). If there is overlap, simply trim with scissors. Do not expect the absorbent pad to be particularly wet after an overnight blot. It should be barely damp after an overnight run. If it is soaking wet, then this indicates that buffer has traveled around the gel. However, even if this is the case, it is probably worth proceeding since some protein will have transferred nevertheless and this can probably still be detected with your probe.

Western Blotting of Basic Proteins Electrophoretically Resolved on Acid-Urea-Triton-Polyacrylamide Gels

Geneviève P. Delcuve and James R. Davie

1. Introduction

The electrophoretic resolution of histones on acetic acid-urea-Triton (AUT) polyacrylamide gels is the method of choice to separate basic proteins such as histone variants, modified histone species, and high mobility group proteins 14 and 17 (***1-6***). Basic proteins are resolved in this system on the basis of their size, charge and hydrophobicity. In previous studies, we analyzed the abundance of ubiquitinated histones by resolving the histones on two-dimensional (AUT into SDS) polyacrylamide gels, followed by their transfer to nitrocellulose membranes, and immunochemical staining of nitrocellulose membranes with an anti-ubiquitin antibody (***7-9***). However, transfer of the basic proteins directly from the AUT polyacrylamide gel circumvents the need to run the second dimension SDS gel and accomplishes the analysis of several histone samples. We have described a method that efficiently transfers basic proteins from AUT polyacrylamide gels to nitrocellulose membranes (***10***). This method has been used in the immunochemical detection of modified histones isoforms and histone H1 subtypes (***6, 11-14***).

To achieve satisfactory transfer of basic proteins from AUT gels to nitrocellulose, polyacrylamide gels are submerged in 50 mM acetic acid, 0.5% SDS (equilibration buffer 1; 2 × 30 min) to displace the Triton X-100, followed by a 30 min incubation in a Tris-SDS buffer (equilibration buffer 2). The transfer buffer is an alkaline transfer buffer (25 mM CAPS, pH 10, 20% (v/v) methanol). Szewczyk and Kozloff (***15***) reported that alkaline transfer buffers increase the efficiency of transfer of strongly basic proteins from SDS gels to nitrocellulose

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

membranes. We reasoned that this transfer buffer would improve the transfer of histones from AUT gels that had been treated with SDS.

2. Materials

Buffers are made from analytical grade reagents dissolved in double distilled water.

1. Equilibration buffer 1: 0.575 ml of glacial acetic acid (50 m*M*), 10 mL of 10% (10 g in 100 mL of water) SDS (0.5%), and water to 200 mL.
2. Equilibration buffer 2: 6.25 mL of 1 *M* Tris-HCl (62.5 mM), pH 6.8, 23 mL of 10% (w/v) SDS (2.3%), 5 mls of β-mercaptoethanol (5%), and water to 100 mL. 1 *M* Tris-HCl: 121 g of Tris base in 800 mL of water and adjusted to pH 6.8 with hydrochloric acid. The buffer is made up to 1000 mL.
3. Transfer membrane: Nitrocellulose membranes (0.45 µm pore size, Schleicher & Schuell, BA85) are used.
4. Transfer buffer: 187 mL of Caps (3-(cyclohexylamino)-1-propanesulfonic acid) stock (16X) solution (final concentration, 25 m*M*), 600 mL of methanol (20%), and water to 3 L. Caps stock solution (400 m*M*): 88.5 g of Caps dissolved in 800 mL of water and adjusted to pH 10 with 10 *M* NaOH. The buffer is made up to 1000 mL.
5. Electroblotting equipment: Proteins are transferred with the Bio-Rad Trans-Blot transfer cell containing a super cooling coil (Bio-Rad). Cooling is achieved with a Lauda circulating bath.
6. Protein stain: Proteins in the AUT or SDS polyacrylamide gel are stained with Coomassie Blue (Serva Blue G). Proteins on the membrane are stained with Indian ink (Osmiroid International Ltd.) (0.01% v/v in TBS-TW). TBS-TW: 20 m*M* Tris-HCl, pH 7.5, 500 m*M* NaCl, and 0.03% (v/v) Tween-20.

3. Method

3.1. Protein Blotting

1. Nitrocellulose membranes are cut to size of gel at least a day before transfer and stored in water at 4°C.
2. The proteins are electrophoretically resolved on AUT- or SDS-polyacrylamide minislab gels (6 mm long, 10 mm wide, 0.8–1.0 mm thick).
3. Following electrophoresis the AUT polyacrylamide gel is gently shaken in 100 mL of equilibration buffer 1 for 30 min at room temperature. This solution is poured off, and another 100 mL of equilibration buffer 1 is added. The gel is again shaken for 30 min. The solution is discarded and replaced with equilibration buffer 2. The gel is agitated in this solution for 30 min.
4. Onto the gel holder place the porous pad that is equilibrated with transfer buffer. Three sheets of 3 MM paper soaked in transfer buffer are placed on top of the porous pad. The treated AUT or SDS slab gel is placed onto the 3 MM paper sheets. Nitrocellulose membrane is placed carefully on top of the gel, avoiding the trapping of air between the gel and nitrocellulose membrane. One sheet of 3 MM paper soaked

in transfer buffer is placed on top of the nitrocellulose membrane, followed by the placement of a porous pad which has been equilibrated with transfer buffer.

5. The gel holder is put into the transblot tank with the polyacrylamide gel facing the cathode and the nitrocellulose membrane facing the anode. The tank is filled with transfer buffer. Protein transfer is carried out at 70 V for 2 h and/or at 30 V overnight with cooling at 4°C.
6. Following transfer, the nitrocellulose membrane is placed onto a sheet of 3 MM paper and allowed to dry for 30 min at room temperature. The gel is stained with Coomassie Blue. The air-dried nitrocellulose membrane is placed between two sheets of 3 MM paper. This is wrapped with aluminum foil and baked at 65°C for 30 min. The proteins transferred onto the nitrocellulose membrane may be visualized by staining the nitrocellulose membrane with India ink (*see* **Subheading 3.2**).

3.2. Protein Staining

1. The nitrocellulose membrane is agitated in TBS-TW (0.7 ml per cm^2) for 10 min at room temperature in a sealed plastic box. The solution is discarded and fresh TBS-TW is added. These steps are repeated twice more for a total of four washes of the membrane in the TBS-TW solution.
2. The India ink stain is added to the nitrocellulose membrane (0.56 ml/cm^2) which is agitated for 30 min to 2 h at room temperature.
3. The stain is discarded and the nitrocellulose membrane is shaken in water for 5 min at room temperature.
4. The nitrocellulose membranes are dried and stored.

4. Notes

1. Nitrocellulose membranes have been used in the majority of our studies. However, these membranes are fragile and must be handled with care. An alternate membrane, which is stronger than nitrocellulose, is PVDF (Bio-Rad). The PVDF membranes are wetted with 100% methanol for 3 min and then equilibrated with transfer buffer for 3 min.
2. The efficiency of transfer of basic proteins (histones) from AUT polyacrylamide slab gels to nitrocellulose membranes is shown in **Fig. 1**. Most of the histones were efficiently transferred. The efficiency of elution was poorest for histone H1. **Figure 1C** demonstrates that the histone variants of histone H2A (H2A, H2A.Z) and of histone H3 (H3.1, H3.2, H3.3) and the modified histone species (e.g., ubiquitinated histone H2A, acetylated histone H4) were transferred. Densitometric tracings of the gel patterns before and after transfer demonstrated that greater than 90% of the histones H2A, H2B, H3, and H4 and approximately 80% of histone H1 were eluted from the AUT gel.
3. The transfer efficiency of basic proteins from AUT minislab polyacrylamide gels to nitrocellulose membranes was poor when a Tris-glycine-methanol

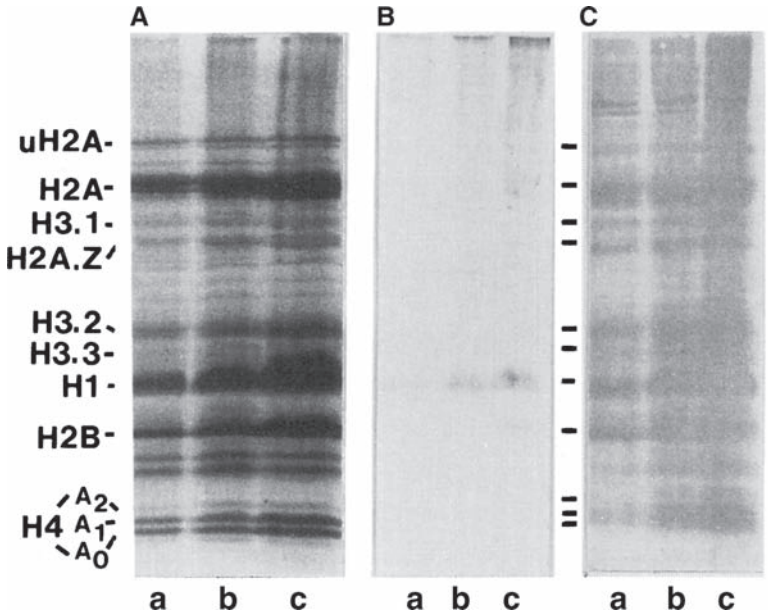

Fig. 1. Electrophoretic transfer of histones from AUT minislab gels. **(A)** Histones (9, 18 and 36 µg in lanes a, b and c, respectively) isolated from T-47D-5 human breast cancer cells were electrophoretically resolved on AUT minislab gels. The gel was stained with Coomassie Blue. **(B)** The Coomassie Blue-stained AUT minislab gel pattern of histones remaining after transfer (30 V overnight) to nitrocellulose is shown. **(C)** The India ink-stained nitrocellulose pattern of histones transferred from the AUT minislab gel in B is shown. A_0, A_1 and A_2 correspond to the un-, mono- and diacetylated species of histone H4, respectively. The ubiquitin adduct of histone H2A is denoted as uH2A. Reprinted with permission from ***ref. 10*** (copyright by the Academic Press).

(25 m*M* Tris, 192 m*M* glycine, 20% (v/v) methanol, and 0.1% SDS) transfer buffer was used.

4. With the Bio-Rad Trans-Blot cassette, four minislab gels can be easily accommodated.
5. Following transfer and baking, the nitrocellulose membrane may be stored for several weeks at room temperature before proceeding with immunochemical staining.
6. Leaving the nitrocellulose membrane in water for too long after staining with India ink will result in removal of the stain.
7. We have used this alkaline transfer buffer to transfer histones from SDS slab gels to nitrocellulose membranes. Pre-treatment of the SDS slab gel is not required. However, we have found that washing the SDS slab gel in equilibration buffer 2 for 30 min improved the efficiency of elution of the histones from the SDS gel.

Immunoblotting of 2-DE Separated Proteins

Barbara Magi and Laura Bianchi

1. Introduction

Immunoblotting technique, also dubbed "Western blotting," exploits antibody specificity to identify target proteins among a number of unrelated protein species ***(1,2).*** Traditionally used for mapping known proteins on electrophoretically-resolved mixtures, in the proteome era immunoblotting has been combined with 2-D gel electrophoresis for rapid visualization and identification of target proteins ***(3),*** protein adducts with drugs ***(4)*** and antigenic proteins associated to pathogens, allergens as well as tumours, with patient serum used as primary antibody ***(5–9).***

In the postgenomic era, gene expression is becoming a focus of attention and it is widely accepted that one gene does not necessarily encode a single protein product, as molecular mechanisms generating different isoforms from the same gene have been described in many different organisms. Although the relation between number of genes and number of potentially encoded proteins has yet to be clarified, it is usually recognized that the number of polypeptides expressed by a genome is greater than expected on the basis of calculated gene numbers. In fact, it has been estimated that the average number of alternates spliced from the transcript of a single mammalian gene may be two to three or more ***(10)*** and that many proteins may be subject to co- and posttranslational modifications and proteolytic processing. For example, up to 20% of protein is acetylated in yeast ***(11).*** Several preliminary proteome projects have also shown that prokaryotic organisms can express more than one protein isoform from a single gene and posttranslationally modified gene products have been reported ***(12).*** Moreover, compared to completely sequenced genome of other organisms, the unexpected low number of potential protein-coding genes in the human genome makes molecular mechanisms generating different isoforms from the same gene

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

particularly interesting. As shown in Scheler et al. ***(13)*** and Janke et al. ***(14),*** simultaneous 2-D gel analysis of cross-reactive protein isoforms derived from a single gene may produce very complex isoforms patterns: more than 50 and 80 2-D electrophoretic protein spots were observed using specific antibodies for HSP27 and Tau protein, respectively. 2-D immunoblotting combined with mass spectrometry-based identification methods has been widely applied to the characterization of 2-D electrophoretic cross-reactive isoforms of the same protein, e.g. due to alternative splicing, co- and/or posttranslational modifications and proteolytic cleavages ***(15-21).***

Western blotting analysis is also the method of choice for simultaneous visualization of 1-D and 2-D separated proteins sharing common epitopes related to specific post-translationally-modified aminoacids or to specific functional/structural domains, e.g. anti-phosphoresidues and anti-O-linked N-acetylglucosamine antibodies ***(22-24).*** This approach has been widely used to differentially visualize tyrosine-phosphorylation profiles in cells and tissues under different conditions ***(17,22),*** as well as for studying signal transduction pathways following stimulation ***(25).*** The dynamic and reversible nature of several known post-translational modifications makes their characterization possible only at protein level, as these features characterize mature gene products and cannot be inferred from crude genome-derived aminoacid sequence stored in sequence databases. 2-D immunoblotting is therefore a powerful method for rapid visualization of target proteins, sharing a common feature, to be identified and characterized by microchemical analysis, e.g. by mass spectrometry.

Immunoblotting techniques involve identification of protein target via antigen-antibody specific reactions. Proteins are typically separated by electrophoresis in polyacrylamide gels, then transferred ("blotted") onto chemically resilient membranes (nitrocellulose, PVDF…) where they bind in the pattern they took in the gel. The membrane is overlaid with a primary antibody directed to the specific target, then with a secondary antibody (anti-immunoglobulin) labeled with radioisotopes, enzymes…

A semplified procedure in which protein samples are not separated electrophoretically but are spotted directly onto the membrane is called "dot blot" and is a good preliminary experiment to detect the presence of a certain antigen in a sample.

A number of related techniques for probing membranes containing transferred protein with specific ligands have been described:

- In "Far-Western blotting" the membrane is probed with another protein to detect specific protein:protein interactions ***(26-28).*** The reaction can be revealed using biotinylated or GST-tagged bait or "probe" protein followed by a streptavidin-HRP or a anti-GST-HRP chemiluminescent detection system, respectively.

- Blot overlays include the probing of membrane with various molecules to detect the presence of specific binding domains, e.g. with GTP ***(29,30)*** or proteoglycans ***(31).*** In the south- or north-western blotting the membrane is probed with DNA or RNA molecules to detect nucleic-acid binding proteins ***(32).***
- In glycoprotein detection systems the carbohydrate portions of proteins are oxidized with sodium metaperiodate to generate aldehydes that can react with hydrazides. A biotin hydrazide is used to attach biotin onto the oxidized carbohydrates and horseradish peroxidase-conjugated streptavidin is used for chemiluminescence-based detection (Glycoprotein Detection Module, Amersham Biosciences, Uppsala, Sweden).
- A recently developed technique, is high-throughput western blotting, also known as western array screening of total cell or tissue lysate. It includes polyacrylamide gel electrophoresis and electroblotting, followed by screening of the blots with hundreds of high-quality antibodies, combined in unique cocktails ***(33).***

2. Materials

2.1. Equipment

1. Blotting apparatus: transfer cell, gel holder, magnetic stirrer, refrigerated thermostatic circulator unit.
2. Power supply.
3. Rocking agitator.
4. Computing Densitometer and/or a gel and blot image acquisition system.
5. PC with a computer program for 2-D gel analysis.

2.2. Reagents

1. Distilled water.
2. Nitrocellulose membrane.
3. Transfer buffer: 25 m*M* Tris, 192 m*M* glycine, 20% (v/v) methanol. Do not adjust pH, it is about 8.3.
4. Filter paper for blotting (Whatman 17 Chr).
5. Ponceau S solution: 0.2% (w/v) Ponceau S in 3% (w/v) trichloroacetic acid (TCA).
6. Coomassie blue solution: 0.1% Coomassie blue R-250 in 40% methanol, 1% acetic acid.
7. Destaining solution: 50% methanol.
8. Phosphate buffered Saline (PBS): 0.15 *M* NaCl, 10 m*M* NaH_2PO_4: bring to pH 7.4 with NaOH.
9. Blocking solution: 3% (w/v) nonfat dry milk in PBS, 0.1% (w/v) Triton X-100.
10. Primary antibody solution (primary antibody, appropriately diluted in blocking solution).
11. Secondary antibody solution (secondary antibody, appropriately diluted in blocking solution).
12. Washing solution: 0.5% (w/v) Triton X-100 in PBS.

13. 0.05 *M* Tris-HCl, pH 6.8.
14. Amersham Biosciences ECL (enhanced chemiluminescence) kit, cat. no. RPN 2106.
15. Saran Wrap or other cling-films.
16. X-ray films, 18 cm × 24 cm (Amersham Hyper film ECL, cat. no RPN 3103).
17. Developer and fixer for X-ray film (Developer replenisher; fixer and replenisher, 3M, catalogue numbers XAF 3 and XAD 3) (3M Italia S.p.A., Segrate, Italy).
18. Stripping buffer: 100 m*M* 2-mercaptoethanol, 2% (w/v) SDS, 62.5 m*M* Tris-HCl pH 6.8.

3. Methods

3.1. Transfer

To avoid membrane contamination wear gloves during all the steps of the experiment.

1. Prepare the transfer buffer (*see* **Notes 1-3**) and cool it to 4°C before the end of the electrophoretic run.
2. Cut to the dimension of the gel, two pieces of filter paper and one piece of nitrocellulose/gel (*see* **Note 4**).
3. Following electrophoresis (*see* **Note 5**), wash the gel in distilled water and then equilibrate it in transfer buffer. The ideal time for 1.5 mm gels is 10 to15 min (*see* **Note 6**).
4. Soak the nitrocellulose membrane for 15–20 min in transfer buffer. Also wet two "Scotch-Brite" pads/gel and filter papers in transfer buffer.
5. Assemble the "sandwich" for transfer in this order: fiber pad, filter paper, nitrocellulose, gel, filter paper, fiber pad. Remove all air bubbles between membrane and gel and between paper and gel.
6. Put the blot sandwich in the gel holder and hold it firmly, to ensure a tight contact between gel and membrane.
7. Fill the cell with transfer buffer and place a stir bar inside the transfer cell, so that the buffer is stirred during electrotransfer and temperature and conductivity are uniform during electrotransfer.
8. Place the gel holder in the transfer cell with the sandwich oriented as follows: ANODE /fiber pad, filter paper, nitrocellulose, gel, filter paper, fiber pad/ CATHODE.
9. Carry out blotting at a constant current until it reaches a total of 1.5–2.0 Å (*see* **Note 7),** refrigerating the buffer to 4°C (*see* **Note 8**) for gels of 16 × 18 cm (such as two-dimensional gels) or at constant voltage (100 V) for 1 h for minigels (*see* **Note 9**).
10. After electrotransfer, disassemble the blotting apparatus and remove the nitrocellulose membrane. To mark the orientation of the membrane, cut away the lower right corner, corresponding to low M_r, high pH.

The membrane can be processed immediately for immunoblotting or can be air-dried and stored at −20°C, within parafilm sheets for extended periods ***(34).***

Though electroblot is by far the most widely used technique, there are also alternative methods, as discussed in a recent review ***(35).***

3.2. Staining of Total Protein Pattern on Membrane

3.2.1. SDS-PAGE and IEF Gels

In the case on one-dimensional gel (IEF or SDS PAGE), staining of total protein pattern can be done on one lane of the gel in which the sample or MW standard or pI standard have been loaded. Nonreversible stains more sensitive than Ponceau Red can be used (*see* **Note 10**).

1. Cut the nitrocellulose lane to be stained and immerse it in Coomassie blue solution for 3 min.
2. Destain for 30 min destaining solution and air dry.

3.2.2. Two-dimensional gels

1. Before the immunodetection, stain the nitrocellulose membrane in 0.2% w/v Ponceau S in 3% w/v trichloroacetic acid for 3 min ***(36)*** (*see* **Note 11**)**.**
2. Destain with several changes of distilled water to diminish background color. Because the red spots will disappear in the blocking step, save the image with a chemiluminescence image acquisition system or circle with a waterproof pen some spots before the next steps of immunostaining. Spot stained with Ponceau S will be used as landmarks to match total protein pattern on nitrocellulose against immunoreactive pattern and against silver stained polyacrylamide gel pattern (*see* **Note 11**).

3.3. Immunodetection

3.3.1. Incubation with Antibodies

All steps are carried out at room temperature and with gentle agitation on a rocking agitator.

1. Block nonspecific binding sites in the membrane with three washing steps, each 10 min in duration, in blocking solution (*see* **Notes 12, 13** and **14**).
2. Incubate overnight in the primary antibody solution at the suitable dilution (*see* **Note 15**) in blocking solution.
3. Wash 3 × 10 min in blocking solution.
4. Incubate for 2 h in the secondary antibody solution (*see* **Notes 16** and **17**).
5. Wash 3 × 10 min in blocking solution.
6. Wash 30 min in washing solution.
7. Wash 2 × 30 min in 0.05 M Tris-HCl pH 6.8.

After this step one can go forward with ECL detection (*see* **Notes 18** and **19**). Alternatively, one can choose detection with the chromogenic substrate (*see* **Note 20**).

3.3.2. Enhanced Chemiluminescent Detection

To detect the immunoreactive spot(s) with a chemiluminescent method it is necessary to wear gloves to prevent hand contact with film. We routinely use Enhanced Chemiluminescet detection (Amersham Biosciences) because it offers a bigger sensitivity and the possibility of quantification of immune reaction (*see* **Notes 18, 21,** and **22**).

Mix equal volumes of detection reagent 1 and detection reagent 2 from the Amersham ECL kit and immerse the membrane in this solution for 1 min, ensuring that all the surface of the membrane is covered with solution. The chemiluminescent signal can be acquired by a chemiluminescence image acquisition system or by the following procedure:

1. Place the membrane on a glass and cover it with a layer of Saran Wrap.
2. Cut away a corner from a piece of autoradiography film to define its orientation (*see* **Subheading 3.1, step 10**). Superimpose the autoradiography film on the nitrocellulose membrane beginning from the upper left corners. Nitrocellulose membrane and X-ray film may have different dimensions. Superimposing at the upper left corner for ECL impression will allow subsequent matching of images.
3. Expose the film for a time variable from 5 s to several minutes. It is convenient to begin with short exposure, develop the film, and then try longer exposures, if necessary.
4. Develop the film with the suitable reagents (*see* **Subheading 2.2, item 17**).

3.4. Stripping

At the end of a cycle of immunodetection, it is possible to strip the membrane with indicated solution and to carry out subsequent cycles incubating with different primary antibodies (*see* **Note 23**).

The procedure for the stripping we use is:

1. Incubate the membrane in stripping buffer at 70°C for 30 min, with occasional shaking.
2. Wash the nitrocellulose 2 × 10 min in large volumes of washing solution at room temperature.
3. Block the membrane and perform immunodetection as described in **Subheading 3.3.**

3.5. Matching

3.5.1. SDS-PAGE and IEF Gels

For SDS-PAGE gels (or IEF gels), a MW or pI standard is normally run in one lane. The following procedure is used to identify the immunoreactive band and determine its MW or pI.

1. Scan the ECL-developed film, the Coomassie-stained nitrocellulose membrane or a lane of the Coomassie-stained gel (in which standard proteins or the sample were separated) with a computing densitometer of sufficient resolution.

2. Use a graphics programme to make the images the same length (all were originally from the same gel and are therefore of the same size, but nitrocellulose shrinks when stained)
3. When the images are perfectly aligned, the immunoreactive band can be distinguished in the Coomassie stained lane and its MW or pI determined by comparison with the appropriate lane.

3.5.2. Two-Dimensional Gels

For an accurate matching process we use a computer program (*see* **Note 24**) that permits matching the digitized images, using as landmarks the spots stained with Ponceau S (*see* **Note 25**).

To perform this operation we suggest the following procedure:

1. Scan the ECL-developed film, the Ponceau S-stained nitrocellulose membrane, and the silver-stained gel of the same sample with a computing densitometer with a sufficient resolution (*see* **Notes 26** and **27**).
2. Rotate left-right the nitrocellulose membrane, with an appropriate program, in order to have the three images with the cut lower corner on the right. In fact, the nitrocellulose membrane has the spots only in one face and the scanning process generates an image with the cut lower corner placed on the left.
3. Stack together the film and nitrocellulose membrane images, aligning the upper left corners and the two corresponding borders and placing the cut lower right corner in the same orientation for both.
4. Add "manually," with appropriate software tool, the Ponceau S spots chosen as landmarks onto the image of the ECL film.
5. Find the spots on the gel corresponding to landmarks on the film (*see* **Note 28**) and modify the size of the silver nitrate image adjusting it to the smaller one of film by the mean of adequate software. Actually the gel is larger then the film due to silver staining procedure.
6. Stack together the equalized ECL film and gel images, superimpose the landmarks carefully and run the automatic match program. This operation permits automatically highlighting the silver-stained spots paired with the immunoreactive ones present on the ECL film (*see* **Note 29**).

4. Notes

1. We perform electrotransfer from gels to nitrocellulose membrane, using a "wet" or "tank" apparatus, where the gel is submerged in a large volume of buffer during the transfer. For two dimensional gel or gel with big sizes, we use a BioRad transfer cell with 3 L of transfer buffer or an ISODALT cell (Hoefer Scientific Instruments) with 20 L of transfer buffer. ISODALT cells allows the simultaneously transfer of 5 gels. For minigels we use Mini Trans-Blot cell (7.5 × 10 cm blotting area). The transfer buffer can be used several times, if stored at 4°C.

"Semidry" electroblotters require smaller volumes of buffer, since only the membrane and filter paper have to be wet and the procedure is faster. However, the "wet" method is recommended when antigen is present in small quantities (such as low abundance spots in 2-D gels) and/or its molecular weight is high ***(37).*** It offers more options, such as temperature, time and voltage control.

2. The transfer buffer we use was first described by Towbin et al. ***(1)***. Methanol is toxic and it can be omitted ***(38-40)***. Still, we use it to reduce swelling of the gel during transfer and to increase the binding of proteins to nitrocellulose ***(2, 38, 41)***. When working with high molecular weight proteins, elimination of the methanol results in a significant increase in protein transfer efficiency. Some recipes recommend the addition of low concentration of SDS to the buffer to help the transfer of high molecular weight proteins ***(36)*** and to improve the transfer of a variety of proteins ***(38)***. However SDS reduces the amount of protein bound to the membrane ***(2)*** and may adversely affect immunoreactivity by inhibiting renaturation of antigenic sites ***(42)***.

   For semidry blotting it is possible to use discontinuous buffer and/or "elution promoting" buffer on the gel side and a "retention promoting" buffer on the membrane side ***(43)***.

   To transfer hydrophobic proteins, such as membrane proteins, special buffers and transfer conditions are necessary ***(44)***.
3. Reagent grade methanol only is to be used because trace impurities in methanol can increase the conductivity of transfer buffer and decrease transfer efficiency.
4. Polyvinylidene difluoride (PVDF) may also be used ***(45, 46)***. Remember that unlike nitrocellulose, PVDF is a hydrophobic membrane and it must to be prewetted in methanol before use with aqueous solution. The buffer generally used to transfer proteins to PVDF is 10 m*M* 3-(cyclohexylamino)-1-propanesulfonic acid, 10% (v/v) methanol, pH 11 (47), although it is possible also the buffer described in Towbin et al. ***(1).***

   A noncostly modified western blot protocol, which uses metal nanoparticle-coated PVDF membranes, was recently described. It enables detection of small peptides (down to 2 kDa) with a sensitivity similar to that obtained for high molecular weight proteins. This modified PVDF prevents passage of small proteins through the membrane during electrotransfer and their loss during washing steps ***(48)***.
5. Electrotransfer is usually carried out immediately after the electrophoretic run from unstained gels. However, transfer of proteins from polyacrylamide gels after Coomassie blue or silver staining, has also been reported ***(49-51)***. Proteins can also be transferred for immunodetection from gels previously stained in a reverse (negative) way, e.g., with imidazole-zinc

salts ***(52).*** In these procedures, immunoreactivity pattern on the membrane, and total protein pattern can be obtained from the same gel from which spots have been transblotted, facilitating matching even with not easily reproducible 2-D separations.

6. Polyacrilamide IEF gels should be preequilibrated with transfer buffer containing 1% SDS and 20% glycerol, instead of methanol (to prevent swelling), since the focused proteins are at their isoelectric point and do not transfer well without equilibration. If it is desired to maintain the proteins in their native conformation, the SDS may be omitted, but the pH of the transfer buffer should be increase to pH 8.8 and the transfer may be less efficient ***(53)***.
7. The transfer efficiency is adversely affected by high molecular weight and basic pI of proteins. Therefore, while attempting to transfer slow proteins it may happen that fast proteins cross the nitrocellulose membrane and are lost. In these cases, one can use two stacked membranes, or membranes with smaller pore diameter which would also prevent loss of small polypeptides during membrane manipulation ***(54, 55)***. *See* **ref**. ***(56)*** for information on blotting on various membranes.

   Some low molecular weight, basic proteins, such as histones, lysozymes, cytochromes and so forth., do not transfer well because they may be near their pI in currently used buffers, as SDS is lost during the transfer in methanol. Transfer of these proteins can be improved, without impairing transfer of other proteins, by introducing a more basic transfer buffer and/or omitting the equilibration (**Subheading 3.1**, **step 3**) ***(57)***. Alternative buffers have also been proposed (e.g., ***(58)***).
8. When the transfer is conducted at high voltage it is necessary to refrigerate the transfer tank with a thermostatic circulator. If possible, avoid transfer in the cold room.
9. If it is only desired to check the immunoreactivity of an antibody towards a mixture of antigens, without attributing it to a particular protein, the antigen mixture (2–5 µl) can be spotted directly on the membrane. This technique, known as dot blotting ***(59)*** is useful for fast screenings of many antibodies simultaneously, for example in production of monoclonal antibodies.
10. In SDS gels, multicolored proteins can be used to provide a visual display of marker proteins on the transfer membrane. Various companies sell precolored standards and there is in the literature ***(60)*** a procedure for generating multicolored molecular weight proteins using a variety of Remazol-reactive textile dyes.
11. Chemical staining of proteins patterns transblotted onto the nitrocellulose or other membrane plays an important role in 2-D immunoaffinity identification, since it provides "landmark" spots to match immunoreactivity patterns to silver-staining patterns (cf. **Subheading 3.5** and **Note 18**). Several staining

procedures can be chosen. This step is usually carried out before the incubation of transblotted membranes with antibodies, employing dyes (e.g. Ponceau S, Fast Green, Amido black) or metal-chelates, which do not interfere with protein immunoreactivity ***(54, 61-64).*** Staining with substances such as Ponceau S, Fast Green, and metal-chelates is reversible, eliminating interference in the immunoreactivity pattern obtained with chromogenic substrates, but it is not very sensitive. A dye-based staining method, using Direct Blue 71 was recently developed. It is reversible, compatible with immunodetection and with sensitivity tenfold higher than Ponceau S ***(65)***. Permanent staining can also be used if the immunoreactivity pattern is collected from ECL-impressed films, but the stain must not interfere with immunoreaction.

Fluorescent dyes were also recently introduced for membrane staining. For example, SYPRO Ruby protein blot stain is a new, luminescent metal chelate stain composed of ruthenium in an organic complex that interacts no covalently with proteins. This stain is more sensitive than Ponceau, Coomassie Blue, Amido Black or India Ink and nearly as sensitive as colloidal gold stain procedures. This fluorescent stain is fully compatible with immunoblotting ***(66).***

When radioactive labelling is possible, most accurate total protein patterns can be collected from transblotted membranes by phosphor-imaging. The two images have the same dimensions so that general alignment and recognition of immunoreactive spots in the total protein pattern can be easily achieved. However the requirement of radioactive proteins is a huge limitation.

Perfect alignment of immunoreactive spots to total protein pattern can be obtained, at least with PVDF membranes, by the conjunction of colloidal gold staining for total protein detection and ECL for immunoreactivity on the same membrane ***(67).*** This procedure produce an ECL-impressed film with low exposure allowing the detection of immunoreactive spots and a ECL-impressed film with a strong exposure that produces a background pattern. The final result is a single image where immunoreactive spots appears as dark black spots and general protein pattern appears as light grey spots.

Colloidal gold ***(68, 69)*** and India Ink staining ***(70)*** can be applied also after immunodetection. The latter approach is possible if membrane saturation is achieved by Tween 20, omitting proteins ***(71, 72).***

Finally another method has been proposed by Zeindl-Eberhart ***(73)*** to localise easily antigen on 2-D gels. Proteins are transferred to PVDF membrane, immunostained with specific antibodies using Fast Red or 5-bromo-4-chloro-3-indolyl phosphate/nitroblue tetrazolium as a detection system, and then counterstained with Coomassie Brilliant Blue. The membrane appears with immunostained spots colored in red or black and the total protein pattern in blue. The blocking proteins are removed during the staining with Coomassie and so do not create a background staining.

In all these methods proteins are transferred onto one membrane and both total protein staining and immunostaining are performed on the same membrane. "Double replica" blotting methods were also developed, in order to obtain a membrane with all the proteins stained and that is an almost identical copy of the immunostained one. The first of its kind was described by Johansson ***(74)*** who found that by changing the direction of the blotting current the proteins could be transferred simultaneously from one gel onto two membranes, on either sides of the gel. A second method described by Neumann and Mullner ***(75)*** combines the usual electroblotting procedure with the generation of a "contact copy" from a gel. Both systems enable one membrane to be immunostained while the second membrane is stained by highly sensitive total protein staining methods. Protein identification is then carried out by comparing the signals of both matrices.

Similarly, a fast and simple method to produce print-quality like Ponceau replicas from blots was recently described ***(76).*** The positive replicas are the same size as blots and can be stored without loss of intensity. This makes them useful for localizing immunoreactive spots in complex 2-D electrophoretograms.

12. For a membrane from an one-dimensional SDS-gel or IEF gel we use 3–5 ml of solution according the dimension of the membrane in each washing and incubation step. For a 16 × 18 -cm membrane, we use 50 ml of solution. In general, volumes can be proportionally adjusted to other membrane dimension. It is important that the membrane is entirely soaked in solution during washing and incubation step.
13. Our blocking procedure is suitable for routine use. However, special conditions and reagents are required for immunoblotting with some antibodies, such as anti-phosphotyrosine antibodies ***(22, 77, 78).*** Information on different blocking conditions can be found in references ***(58, 79-81).*** Chemicon have developed a new blocking agent, composed of nonanimal proteins, that ensure uniform blocking, without nonspecific-binding, eliminating all cross-reactivity with animal source antigens, primary and secondary antibodies. Blocking with a nonionic detergent such as Tween 20, without added protein has also been used with the advantage that after immunodetection the blot can be stained for total protein pattern ***(71, 82, 83)*** (*see* **Note 10**). On the other hand, it has been found that blocking with detergent alone may cause loss of transblotted proteins ***(83, 84).*** Using PVDF membrane it is possible to employ a nonblock technique: this method incorporates 3 cycles of methanol-water hydration of the membrane, allowing multiple erasure and probing of the same blot with little or no loss of signal ***(85).***

A modified Western Blotting protocol has been developed to increase the binding specificity of antigens and antibodies and clear the background.

The method is based on intermittent microwave irradiation of the blotting membrane in the immunoblotting step, using 5% skim milk as the diluting buffer ***(86)***. A simple method to improve western blotting and reduce background has been developed by Wu et al. ***(87)***, that consists in few modifications to the washing steps and buffer conditions.

14. Fixation of proteins to the membrane can be used to prevent their elution during washing and incubation steps. Some methods have been tried ***(42, 88)***, but the epitopes are sensitive to this treatment and may no longer be detectable by antibody. Another method is to fix the antibody-antigen complexes to the nitrocellulose membrane with glutaraldehyde, after they had been formed ***(89)***.
15. Optimal dilution of the primary and secondary antibody should be determined by immunoblotting of one-dimensional gels or dot blot analysis can be used. A technique called line blot assay has been developed to assess the optimal dilution of primary and secondary antibodies simultaneously ***(90)***. Working solutions of antibodies can be stored at −20°C and used several times ***(91)***.
16. Secondary antibodies often give problems of cross-reactivity, especially in the analysis of samples containing antibodies (such as immunoprecipitates, immune tissue, plasma, etc.), even when antibodies from different species are used. Langstein and Schwarz proposed a method to avoid this problem, that consist in preconjugating the primary and secondary antibody before incubation. In this way, signals from secondary antibodies are completely quenched ***(92)***. An other solution to this problem is "double-blotting". After the membrane has been incubated with the primary antibody, it is blotted a second time under acidic conditions. Antigen and interfering proteins remain bound to the first membrane, and the primary antibodies were transferred to the second one, that can be probed with secondary antibodies, without nonspecific binding ***(93)***.

    Alternatively, HRP-conjugated protein A and protein G, which detect intact antibody molecules almost exclusively, can be used to obtain clean and specific western blot signals of target proteins ***(94)***.
17. A novel cross-linked enzyme-antibody conjugates has been developed for Western blot and ELISA ***(95)***. It was prepared by cross linking of HRP to a high molecular weight polyglutamic acid polymer followed by the cross linking of a limiting amount of antibody to yield a complex with a detection signal 100-fold greater than that of 1:1 enzymes conjugates usually prepared by cross-linking.
18. The secondary antibody we use is labelled with peroxidase. The major drawback of this approach is that the range of protein loading that gives a linear relationship between the amount of target protein and the signal

is quite limited. Considerable advantage for quantitative analysis can be gained by the use of a secondary antibody coupled to fluorophores that allow quantification of fluorescent signal, e.g. by means of a phosphor imager device. This approach theoretically gives a linear signal through a broad range of protein loading ***(96, 97)***.

19. ECL detects horseradish peroxidase-conjugated antibodies through oxidation of luminol, in the presence of hydrogen peroxide and a phenolic enhancer under alkaline conditions. ECL reagents are capable of detecting 1–10 pg of protein antigen. Alternative enhancers that extend the duration of light emission and enable such system is ECL plus (Amersham Biosciences) ***(98).*** These systems are suitable for use of charge-coupled device (CCD) camera that require longer exposure times for good quantification of immunoreaction.
20. In case chemiluminescence is too strong or background is too high, one can switch to detection with a chromogenic substrate.

    We use 4-chloro1-naphthol ***(99)*** as chromogenic substrate, according to the following protocol:
    (a) After ECL detection (or after step 7 of **Subheading 3.3.1**), wash the membrane briefly with 0.05 M Tris-HCl, pH 6.8.
    (b) Soak it in developing solution (20 ml 0.05 M Tris-HCl pH 6.8, 7 µl H_2O_2 30% (v/v), 5 ml 4-chloro1-naphthol 0.3% (w/v) in methanol) until the color appears. Stop the reaction with washes in distilled water.
    (c) Air dry the membrane and photograph it as soon as possible, because the color fades with time.
21. Chemiluminescent probes enable highly sensitive quantitative analysis of proteins blotted from electrophoretic gels onto a supporting matrix. For a quantitative comparison, it is important to be able to correct for the variations introduced by variables such as antibody titre, temperature, substrate etc.. Comparison of separate blots completed on different days requires a chemiluminescent standard. The situation is more complex with 2 D gels, where only one sample per gel/blot is used. A method has been published for preparing chemiluminescent standard for quantitative comparison of 2D western blot ***(100)***.
22. In detection of Western blots of total cell lysates there is the problem of nonspecific background chemiluminescence, due to nonspecific binding of primary and secondary antibody. A noncommercial ECL solution that provides strong signals and low background for western blot detection was recently developed ***(101)***. This alternative solution does not contain chemicals which harm the blots, making it possible redetect them after stripping up to five times. Due to the strong signals and low background of this ECL-solution, the primary and secondary antibodies used for detection can also be used at lower concentrations.

23. It is also possible to perform stripping with kits as the CHEMICON ReBlot™ western blot recycling kit. Stripping of antibodies also elutes antigens from the membrane and signal intensity decreases in successive cycles. It is important therefore to remember that stripping should be used only for qualitative purpose.

    As alternatives to stripping, one can use: (a) different chromogenic substrates for peroxidase at each cycle (rainbow blotting, ***(91)***), (b) ECL and inactivating peroxidase after each cycle ***(91),*** (c) different labels and detection methods at each cycle ***(102).***
24. To perform the matching process we use the software Melanie 4 (Gene Bio).
25. Matching can also be done by simple eye inspection directly on nitrocellulose and ECL film when the sample contains relatively few spots, all of them detectable by chemical staining of nitrocellulose. In the majority of cases samples are very complex and many low abundance proteins occur. In these cases matching by computer is mandatory, in order to identify immunoreactive spots in silver-stained patterns. The following manual procedure is suggested:
    (a) Match the exposed film with nitrocellulose membrane, aligning the upper left corner and the two corresponding borders and placing the cut lower right corner in the same orientation for both.
    (b) Using a waterproof pen, mark the other two borders of the nitrocellulose on the film and transfer the chemically stained spot present on nitrocellulose on the ECL film in order to use them as landmarks for the next matching with the silver nitrate stained gel.
    (c) Nitrocellulose membrane and film maintain the initial size, but the size of the gel increases after silver-staining. Size equalization can be obtained by photographic or photocopy procedures.
    (d) On a transilluminator match all the landmarks with the corresponding spots on the silver nitrate stained gel to identify the immunoreactive spots.

    When the area of the membrane containing the protein of interest is known, another procedure, described by Lindahl ***(103),*** can be used. Only a limited area of the nitrocellulose containing the proteins is cut out and incubated with antibodies. The rest of the membrane is stained with one of the methods described in **Note 10** (a method not compatible with immunodetection, but much more sensitive than Ponceau S, can be used). Thus the protein spots could be located in the 2-DE pattern, matched with a corresponding silver stained gel and translated into protein pattern. This method allows also a considerable saving of antibodies.
26. We use a computing densitometer 300 S from Molecular Dynamics with a resolution of 4000 × 5000 pixels, 12 bits/pixel, which generate 40 megabytes images on 16 bits.

27. The silver stained image used for matching can be taken from your archive of files or from images available in Internet, provided that the identical electrophoretic procedures have been applied. The possibility to match images deriving from different 2-D electrophoretic procedures has been studied by Lemkin P. ***(104).***
28. This step may be difficult if the "landmark" spots stained by Red Ponceau on the nitrocellulose membrane are few. To aid recognition of the spots chosen as landmarks on the silver stained gel, we suggest also staining with silver the gel from which the proteins are transferred, in which the amount of proteins loaded must be twice that used for a silver-stained gel. Most spots will be still visible on the transferred gel and can be used for a first matching with the membrane. Using the gel from which the membrane was obtained, the landmarks can be localized correctly. The landmarks are then easily transferred to the silver stained gel by computer matching.
29. The mapping of immunoreactive spots on 2-D silver-stained reference images can be improved if the images of the Ponceau- and immunostained membranes are acquired with the same system, enabling detection of total protein pattern directly on the membrane where the immunoreaction takes place. In commercially available gel and blot image acquisition systems, images generated in different ways can be readily acquired on the same instrument.

High-Efficiency Blotting of High-Molecular Weight Proteins

Marion L. Greaser and Darl R. Swartz

1. Introduction

The technique of protein electrophoresis in the presence of sodium dodecyl sulfate has now been conducted for more than 40 years. Early work employed single layer gel systems ***(1,2).*** It was subsequently shown that a stacking/ discontinous gel system gave superior results, and the method of Laemmli ***(3)*** has been widely adopted. Numerous modifications of this original system have developed through the years, although many investigators continue to use the Laemmli procedures as originally described.

Adaptations to the Laemmli system have been made in our laboratory specifically to address difficulties in resolving proteins in muscle tissue. Changes in acrylamide to bisacrylamide ratio to 200:1 (vs 37.5 to 1 in the Laemmli system) and increasing the buffer concentration in the separating gel were found to aid in resolution of proteins in the 75 to 10 kDa range ***(4).*** Solubilization of the tough, fibrous heart and skeletal muscle was improved by using an "industrial strength" sample buffer containing non-ionic denaturants (urea and thiourea) in addition to SDS plus a sulfhydryl reducing agent ***(5).*** A further adaptation has been made to increase the migration of very high molecular weight protein into a polyacrylamide gel. Muscle contains two extremely large proteins, titin (Mr ~ 3500K Da) and nebulin (Mr 900 KDa), that barely enter a typical Laemmli gel because they do not stack properly in a conventional bisacrylamide cross-linked stacking gel. This adaptation involves the use of DATD (N, N -diallyltartardiamide) as the stacking gel cross-linking agent ***(6).***

A further modification that has ramifications in regard to blotting high molecular weight proteins is the inclusion of a reducing agent in the upper reservoir buffer during electrophoresis and in the subsequent protein transfer

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

to the membrane ***(6).*** Conditions during electrophoresis and blotting favor formation of inter and intramolecular disulfide crosslinks. Although the electrophoresis and blotting systems described here were designed primarily for work with muscle, the methods work equally well with other tissues. A particular advantage is the wide molecular weight range achieved without the use of a gradient gel system **(Fig. 1).**

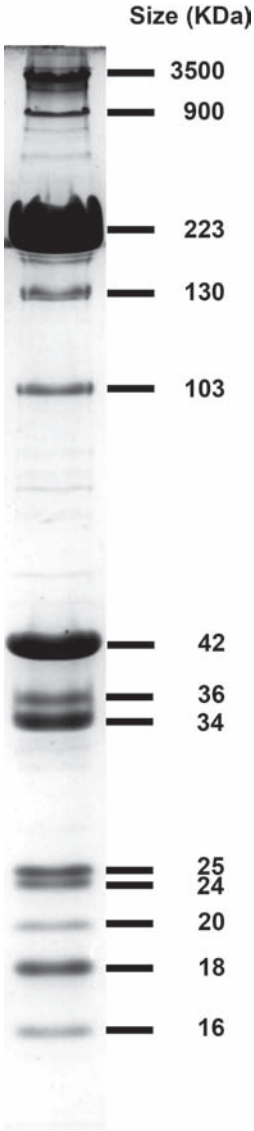

Fig. 1. Rabbit skeletal muscle myofibril proteins on a SDS 10% polyacrylamide gel (200:1 ratio of acrylamide to bisacrylamide separating gel; 3% acrylamide with DATD cross-linker in the stacking gel), separating gel pH 9.3. Only the separating gel is shown. Proteins with sizes from 15 to 3500 KDa can be resolved on gels with a single concentration of acrylamide.

2. Materials

2.1. Apparatus

1. Mighty Small II (SE 250 or 260) Slab Gel Unit (Hoefer – http://www.hoeferinc.com/ or a similar commercial gel unit).
2. A constant current power supply – available from above company as well as other sources.
3. TE62 Tank Blotting Unit (Hoefer).

2.2. Stock Solutions

1. Resolving gel acrylamide; 30% T – 0.5% C. Weight 29.85 g of acrylamide and 0.15 g Bis-acrylamide into a beaker, add about 50 ml of water, stir till dissolved, dilute to 100 ml. Filter through a 0.45 micron filter (such as a Millex-HA, Millipore Corporation, Bedford, MA 01730). Store in a brown bottle in the cold room (4°C). Danger! Avoid skin contact (*see* **Note 1**).
2. Stacking gel acrylamide; 10% T – 15% C. Weigh 4.25 g acrylamide and 0.75 g of DATD into a beaker, add 25 ml of water, stir till dissolved, dilute to 50 ml. Filter as above, store in brown bottle at 4°C, avoid skin contact (*see* **Note 2**).
3. 3 *M* Tris-HCl, pH 9.3; Dissolve 32.2 g Trizma base (desiccated) and 5.4 g Tris-HCl (desiccated) in water, dilute to 100 ml. Store at room temperature (shelf life of about 1 month). If desiccated reagents are used, no pH adjustment is necessary. Alternative solution; 3M Tris-HCl, pH 8.8; use 26.16 g Trizma base and 13.26 g Tris-HCl per 100 ml (*see* **Note 3**).
4. 0.5 *M* Tris-HCl, pH 6.8; Dissolve 0.075 g Trizma base (desiccated) and 3.85 g Tris-HCl (desiccated) in water, dilute to 50 ml. Store in the cold.
5. 10% (w/v) SDS; Dissolve, filter through 0.45 micron filter. Store at room temperature.
6. Reservoir buffer concentrate (5X); 0.25 *M* Tris base, 1.92 M glycine, 0.5% SDS. Store at room temperature.
7. Ammonium persulfate; 100 mg/ml solution in water; store frozen in 0.5 ml aliquots (stable indefinitely at –20°C) (*see* **Note 4**).
8. Sample buffer A; 8 *M* urea, 2 M thiourea, 0.05 *M* Tris-HCl (pH 6.8), 75 m*M* DTT, 3% SDS, 0.05% bromophenol blue ***(5)*** (*see* **Note 5**).

Recipe for 100 ml of sample buffer:

a. Weigh 48g urea (ACS grade) and 15.2g thiourea into a clean 150ml glass beaker, add a stir bar, and 40ml of water (careful! Do not add too much water; the urea plus thiourea takes up over half the final volume). Use latex gloves to avoid contamination of the sample buffer with skin proteins. Also avoid skin contact with the thiourea since it is a suspected carcinogen.
b. Stir gently on a hot plate until the solution is at room temperature and all the solids are dissolved (watch carefully, avoid temperatures above 40°C - heating urea speeds the formation of cyanate).
c. Add 10 g of a mixed bed resin (Biorad AG 501-X8 or Thermo Fisher Rexyn 300), stir mixture at room temperature for 15 min. If you have a conductivity meter the conductivity should be less than 5 µmhos (*see* **Note 6**).

d. Filter the mixture through filter paper into a 100ml graduated cylinder. The volume should be 80–90 ml. Carefully rinse the resin with one or two 5 ml aliquots of de-ionized water. Transfer the filtered solution back to a clean 150 ml beaker.
e. Weigh 0.605 g Trizma base, and 3 g SDS; add to the urea-thiourea solution and stir till dissolved. Adjust pH to 7.5 carefully; add 12M HCl 100 µl at a time (300 to 400 µl required). Add 1.155g of solid DTT and stir till dissolved.
f. Continue adjusting pH down to 6.8 using 20 µl aliquots of 2 *M* HCl (the buffer capacity rapidly declines as the pH is lowered- use care not to overshoot!). However if you mistakenly go past 6.8, adjust back up with 2 *M* Tris base. Add 2–4 mg bromophenol blue, stir till dissolved.
g. Transfer solution back to the 100 ml graduated cylinder, add water to 100ml, mix. Filter through a Millex HA 0.45 or 0.22 µm filter (Millipore) to remove any fine particulate material. Transfer filtered sample buffer to 1ml or 0.5ml Microfuge vials; store at (–) 20°C, thaw amount needed just before use.
9. Sample buffer B; 0.05 *M* Tris-HCl (pH 6.8), 75 m*M* DTT, 3% SDS, 10% glycerol, 0.1% bromophenol blue.
10. 50% v/v glycerol.
11. Staining solution; Weigh 0.5 g of Coomassie brilliant blue R-250 and dissolve in 500 ml of methanol, add 400 ml H_2O, and 100 ml acetic acid. Store at room temperature. Use once and discard. The stock solution should be discarded if a scum appears on top of the solution.
12. Transfer buffer: 20 m*M* Tris base, 150 m*M* glycine, 20% v/v methanol ***(7, 8)*** (or 10 m*M* CAPS pH 11, 10% methanol) ***(9)***. For high molecular weight proteins, add SDS and 2-mercaptoethanol to 0.1% and 10 m*M* respectively to the transfer buffer.

3. Methods

3.1. Gel Preparation

1. Resolving gel for four Mighty Small gels, 0.75 mm thick (12% acrylamide); Into a 125 ml filtering flask, add the following: 9.6 ml of 30% Resolving gel acrylamide, 6.0 ml of 3 *M* Tris, pH 9.3 or 8.8 (see above), 0.24 ml of 10% SDS, 0.15 ml of 100 mg/ml ammonium persulfate, 3.20 ml of water, 4.80 ml of 50% v/v glycerol. (Total acrylamide concentration can be varied, but sum of acrylamide and water volumes should be 14.4 ml). Swirl to mix thoroughly, attach to a water aspirator to degas the solution (1 min) **(***see* **Note 7).**
2. Add 0.015 ml of TEMED, swirl to mix, immediately pour solution into the previously assembled slab gel casting unit (use clear plastic spacers between the gel sandwiches rather than wax paper to prevent the gel sandwiches from sticking together) and cover each gel with 0.075 ml of water-saturated isobutanol. Allow to polymerize. The optimal time is 10 to 20 min. If the gel sets more quickly, decrease the amount of ammonium persulfate; if the gel takes longer, increase the ammonium persulfate. There is considerable batch to batch variation in the acrylamide and ammonium persulfate so the levels need to be readjusted with your own reagents. Also the degree of degassing affects the polymerization rate – dissolved oxygen retards polymerization. The acrylamide is gelled when a clear line can be observed

1–2 mm below the isobutanol or the remaining acrylamide mixture has polymerized in the flask.

3. Rinse off isobutanol and unpolymerized upper layer with water. Disassemble the casting unit (use gloves to handle the plates). The gel plus glass plates can be used immediately or stored for several days at 4°C in a closed plastic bag (to avoid evaporation). For immediate use, place the rinsed gel sandwich(s) in the Mighty Small unit. If only one gel is used, it is best to place a blank plate on the opposite side to prevent a direct current connection to the lower chamber.
4. Stacking gel for two Mighty Small gels (3% acrylamide); Into a 50 ml filtering flask, add the following: 0.750 ml of 10% Stacking gel acrylamide, 0.625 ml of 0.5 *M* Tris (pH 6.8), 0.025 ml of 10% SDS, 0.015 ml of 100 mg/ml ammonium persulfate, 0.572 ml of water, 0.500 ml of 50% v/v glycerol, a couple drops of bromophenol blue. Swirl to mix, degas 1 min (optional), add 0.012 ml TEMED, swirl to mix, immediately transfer to the top of the slab gel. Insert the sample combs, avoid trapping air bubbles. Allow to polymerize (*see* **Note 8**).

3.2. Sample Preparation

1. Whole tissue (fresh or frozen); Portions (25 to 35 mg) of whole tissue are weighed into a preweighed 5 ml glass homogenizing tube. Add 140 mg (or µl) of sample buffer A per mg tissue, homogenize to disperse tissue chunks, transfer sample to a Microfuge tube, and then heat in a block heater set at 100°C for 3 min. (Avoid heating proteins in sample buffer for more than 5 min at 100°C; the urea will form cyanate which reacts with proteins and alters migration rates.) Cool to room temperature. Samples should be prepared immediately before application to the gels. If specimens must be stored before analysis, it is better to keep the *tissue* at –20°C or –80°C rather than storing the proteins in sample buffer. Samples in sample buffer can be stored at –80°C; it is not necessary or advisable to heat them again other than for thawing.
2. Tissue homogenates; Mix tissue suspensions (1–5 mg/ml) with an equal volume of sample buffer A in a Microfuge tube. Heat 3 min in a block heater or boiling water bath (*see* **Note 9**).
3. Soluble proteins; Pipette 0.05 ml of protein solution (1 to 5 mg/ml) into a Microfuge tube. Add 0.05 ml of sample buffer A or B, mix. Heat for 3 min in a block heater or boiling water bath.

With all kinds of samples, avoid protein concentrations exceeding 5mg/ml.

3.3. Sample Loading and Electrophoretic Separation

After polymerization, fill the upper and lower reservoirs with buffer (0.05 M Tris, 0.384 M glycine, 0.1% SDS). Add 10 mM 2-mercaptoethanol to the upper reservoir solution (stock solution is 14.3 molar). Gently remove the gel combs after upper reservoir is filled. Load sample wells using either a thin tipped Pipetman or 10 µl glass syringe. Best resolution is achieved if the sample is deposited in a narrow zone at the bottom of the well. Apply constant current (20 mA/per gel) until dye front moves to the bottom of the separating gel (run time usually about 1 h).

3.4. Western blotting

After electrophoresis, the gel is removed from the plates, submerged in transfer buffer for 15 min with gently shaking. The gel is next placed over either a sheet of nitrocellulose or PVDF (polyvinylidene difluoride) and moved to the transfer tank. Transfers were completed using a current of 0.5 A for 30 to 60 min with circulated water cooling. The CHAPS transfer buffer with added 0.1% SDS and 10 m*M* 2-mercaptoethanol works best for transfer of high molecular weight proteins. It is recommended that the gel be stained after the transfer to assess if protein remains in the gel. Usually all proteins are fully transferred except titin (*see* **Notes 10** and **11**).

4. Notes

1. Increasing the Tris concentration in the separating gel (compared to the Laemmli method) improves the resolution of lower molecular weight proteins.
2. Use of DATD instead of bisacrylamide as the cross-linker for the stacking gel was found to be important to get proper migration of the very high molecular weights into the separating gel. It appears that the stacking gel pore size in a conventional Laemmli type system retards titin and nebulin so these proteins do not stack properly. If the protein is lost from the "stack" during the stacking process, it is subjected to a much different electrophoretic conditions than those in the stack and thus lags behind. A simple test for the performance of the stacking gel is to stain the entire gel and look for proteins in the stacking gel. If it is working properly, there should no protein in the stacking gel.
3. Using desiccated and weighed Tris base and Tris-HCl to make the separating and stacking gel buffers is both convenient and eliminates buffer pH variations. Also many pH electrodes do not respond well to high concentrations of Tris, so pH adjustment becomes problematic. The pKa of Tris has a high temperature coefficient, and this further complicates use of a pH electrode. The pH of the resolving gel can be lowered to about 8.6 to increase the migration at the cost of a longer run time. The acrylamide percentage of the resolving gel may also be reduced to about 8% to improve migration. Combinations of lower pH and lower acrylamide may also be employed to optimize resolution of the high molecular weight size range of interest. For high resolution electrophoresis and blotting of very high MW proteins, an agarose gel system has been developed ***(11).***
4 Preparing a large batch of ammonium persulfate stock solution and storing aliquots frozen at −20°C saves time (compared to repeated weighings) and gives repeatable polymerization conditions each time gels are poured.
5. Solubilization of tough, fibrous tissues like cardiac or skeletal muscle is facilitated by using an SDS buffer containing urea and thiourea. Whole tissue chunks need to be mechanically dispersed using some type of

homogenizer to dissolve all the protein. The Dounce type homogenizer seems to work best since it avoids excessive foaming that can occur with spinning blade type homogenizers. Non-urea-thiourea sample buffers often contain tissue fragments that must be removed by 2–5 min centrifugation in a Microfuge at 14,000 × g. If these fragments are not removed, they lead to protein streaking on gels. Use of the industrial strength sample buffer reduces this problem and samples usually do not require centrifugation. DTT is the preferred reducing agent in the sample buffer as it is much better at reducing intra/inter molecular disulfides than 2-mecaptoethanol and is not volatile.

6. Treatment of the urea and thiourea solutions with a mixed bed ion exchange resin is necessary to remove ionic contaminants from these reagent grade chemicals.
7. Inclusion of glycerol in the separating and stacking gel layers increases the viscosity and results in sharper protein bands. Thin (0.75 mm) and small for-

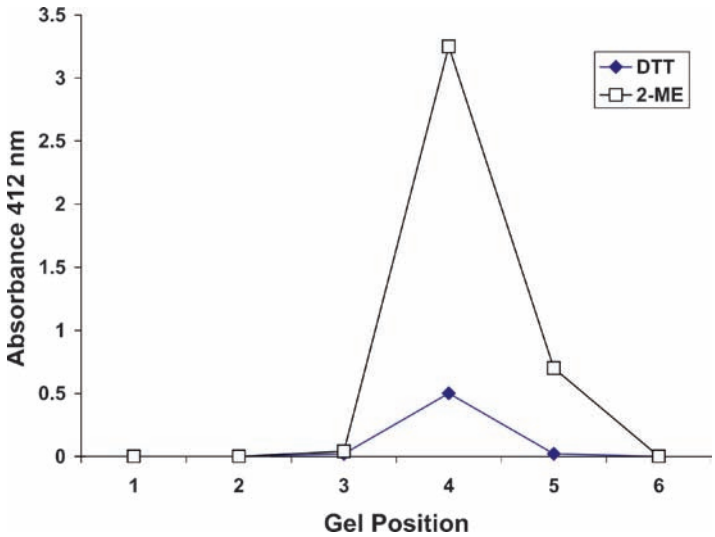

Fig. 2. Reducing agent migration through a polyacrylamide gel. Reducing agents, either 37.5 m*M* dithiothreitol or 0.35 *M* 2-mercaptoethanol, were added along with bromophenol blue tracking dye to the sample wells (gel position 1). Current was applied until the tracking dye migrated half way down the gel (gel position 4). The presence of reducing agent was determined by cutting out gel slices and incubating them with Ellman's reagent ***(7)*** to detect free sulfhydryl groups (re-drawn from ***[6]***). Both reducing agents migrated at the same position as the tracking dye. Inclusion of a reducing agent in the upper reservoir buffer during electrophoresis results in the proteins being continuously bathed in reductant throughout the electrophoresis run.

mat gels (8 × 10 cm) are preferred as their run time is short and transfer of proteins is more complete.

8. We add a couple drops of 0.05% bromophenol blue to the stacking gel mixture before polymerization. This makes the stacking gel slightly blue and aids in identifying the well positions for subsequent sample application.
9. Samples with high KCl concentrations should be diluted with water or dialyzed to remove the KCl as the potassium forms a precipitate with SDS. Alternatively, protein samples in high KCl can be mixed with 4 volumes of methanol (−20°C), microfuged for 1 min, the solution discarded, and the methanol removed by brief vacuum treatment. The pellets can then be dissolved in the urea-thiourea sample buffer diluted 1:1 with water. The methanol precipitation procedure can also be employed to concentrate proteins that are too dilute.
10. Addition of mercaptoethanol to the upper reservoir buffer has been found to be important to get migration of the very large molecular weight proteins into the separating gel. The reducing agents, such as 2-mercaptoethanol or dithiothreitol typically used in sample buffers, are charged at pH values between 8 and 10 and move though the gel with the tracking dye front ***(6)*** (Fig. 2). The poor protein migration (smearing, retardation, additional bands of still higher molecular weight) of very large proteins when the upper reservoir does not include a sulfhydryl reducer suggests that intermolecular and intramolecular disulfide bonds are being formed during the electrophoresis run.
11. The disulfide bond formation of large proteins during electrophoresis also retards their migration out of the gel onto blots during transfer. Thus inclusion of 2-mercaptoethanol in the transfer buffer improves efficiency of transfer of high molecular weight proteins. Semidry blotting equipment can substituted for the tank system.

Alkaline Phosphatase Labeling of IgG Antibody

G. Brian Wisdom

1. Introduction

Alkaline phosphatase (EC 3.1.3.1) from bovine intestinal mucosa has proven, over several decades, to be a very valuable label for antibodies. It is stable, has a moderate size (140 kDa), a high turnover number, and can be assayed using a variety of different substrates which are measured by changes in absorbance, fluorescence, or luminescence. The most common method of labeling immunoglobulin G (IgG) antibody with this enzyme uses the homobifunctional reagent glutaraldehyde.

The chemistry of glutaraldehyde is complex. It reacts with the amino group and, to a lesser extent, the thiol group of proteins and when two proteins are mixed in its presence, stable conjugates are produced without the formation of Schiff bases. Self-coupling can be a problem unless the proteins are at appropriate relative concentrations. In the method described ***(1)*** there is usually little self-coupling of the enzyme or the IgG antibody, however, the size of the conjugate is large ($>10^6$ Da) as several molecules of each component are linked. This is the most simple labeling procedure to carry out and, although the yields of enzyme activity and immunoreactivity are small, the conjugates obtained are stable and practical reagents.

Alkaline phosphatase may also be coupled using heterobifunctional reagents containing the *N*-hydroxysuccinimide and maleimide groups, for example, succinimidyl 4-(*N*-maleimidyl)-cyclohexane-1-carboxylate. However, because the enzyme has no free thiol groups this approach is usually used for the labeling of $F(ab')_2$ fragments of IgG via their thiols ***(2)***.

2. Materials

1. Alkaline phosphatase from bovine intestinal mucosa. 2000 U/mg (with 4-nitrophenyl phosphate as substrate). There are numerous commercial sources of labeling-grade enzyme; it is usually supplied at a concentration of 10 mg/mL in phosphate or triethanolamine buffer (this avoids interference with the conjugation). If ammonium sulfate, Tris or primary or secondary amine is present, it must be removed (*see* **Note 1**).
2. IgG antibody. This should be the pure IgG fraction or, better, affinity-purified antibody from serum or pure monoclonal antibody (*see* Chapters 179–190).
3. Phosphate-buffered saline (PBS): 20 m*M* sodium phosphate buffer, pH 7.2, containing 0.15 *M* NaCl.
4. Glutaraldehyde.
5. 50 m*M* Tris-HCl buffer, pH 7.5, containing 1 m*M* $MgCl_2$, 0.02% NaN_3, and 2% bovine serum albumin (BSA).

3. Methods

1. Add 0.5 mg of IgG antibody in 100 µL of PBS to 1.5 mg of alkaline phosphatase.
2. Add 5% glutaraldehyde (about 10 µL) to give a final concentration of 0.2% (v/v) and stir the mixture for 2 h at room temperature.
3. Dilute the mixture to I mL with PBS and dialyze against PBS (2L) at 4°C overnight (*see* **Note 1**).
4. Dilute the solution to 10 mL with 50 m*M* Tris-HCl buffer, pH 7.5, containing 1 m*M* $MgCl_2$, 0.02% NaN_3, and 2% BSA, and store at 4°C.

4. Notes

1. Dialyses of small volumes can be conveniently done in narrow dialysis tubing by placing a short glass tube, sealed at both ends, in the tubing so that the space available to the sample is reduced. Transfer losses are minimised by carrying out the subsequent steps in the same dialysis bag. There are also various microdialysis systems available commercially such as the Slide-A-Lyzer units from Pierce Biotechnology (Rockford, IL).
2. The conjugates are stable for several years at 4°C as the NaN_3 inhibits microbial growth and the BSA minimizes denaturation and adsorption loses. The conjugates should not be frozen.
3. Purification of the conjugates is usually unnecessary; however, if there is evidence of free antibody it can be removed by size-exclusion chromatography in Sepharose CL-6B (GE Healthcare Bio-sciences, Uppsala, Sweden and Piscataway, NJ) or a similar gel with PBS as solvent.
4. The efficacy of the enzyme-labeled antibody can be tested by immobilizing the appropriate antigen on the wells of a microtiter plate or strip, incubating various dilutions of the conjugate for a few hours, washing the wells, adding substrate, and measuring the amount of product formed. This

approach may also be used for monitoring conjugate purification of chromatographic fractions.

β-Galactosidase Labeling of IgG Antibody

G. Brian Wisdom

1. Introduction

The *Eschericia coli* β-galactosidase (EC 3.2.1.23) is a large enzyme (465 kDa) with a high turnover rate and wide specificity which allows it to be measured conveniently in several different ways. Unlike several other enzyme labels β-galactosidase is not found in mammalian tissues or fluids hence background contributions are negligible when this label is measured at a neutral pH. This can be advantageous as peroxidase activities (due to various heme proteins) and alkaline phosphatase are frequently present in these samples.

The heterobifunctional reagent, *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS), is of value when one of the components of a conjugate has no free thiol groups eg. IgG. In this method ***(1)*** the IgG antibody is first modified by allowing the *N*-hydroxysuccinimide ester group of the MBS to react with amino groups in the IgG; the β-galactosidase is then added and the maleimide groups on the modified IgG react with thiol groups in the enzyme to form thioether links. This procedure produces conjugates with molecular weights in the range 0.6-1 $\times 10^6$.

$F(ab')_2$ fragments of IgG have been labeled via the β-galactosidase's amino groups with sulfo-succinimidyl 4-(N-maleimidomethyl) cyclohexane-1-carboxylate ***(2)*** and there are various other heterobifunctional reagents that may be used for β-galactosidase labelling ***(3)***.

2. Materials

1. β -Galactosidase from *E. coli*, 600 U/mg or greater (with 2-nitrophenyl-β -galactopyranoside as substrate) (*see* **Note 1**).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2. IgG antibody. This should be the pure IgG fraction or, better, affinity-purified antibody from an antiserum or pure monoclonal antibody.
3. 0.1 *M* Sodium phosphate buffer, pH 7.0, containing 50 mM NaCl
4. MBS.
5. Dioxan.
6. Sephadex G25 (GE Healthcare Bio-sciences, Uppsala, Sweden and Piscataway, NJ) or an equivalent gel.
7. 10 m*M* Sodium phosphate buffer, pH 7.0, containing 50 m*M* NaCl and 10 m*M* $MgCl_2$.
8. 2-Mercaptoethanol.
9. DEAE-Sepharose (GE Healthcare Bio-sciences) or an equivalent ion-exchange medium.
10. 10 m*M* Tris-HCl buffer, pH 7.0, containing 10 m*M* $MgCl_2$ and 10 m*M* 2-mercaptoethanol.
11. Item 10 containing 0.5 *M* NaCl.
12. Item 10 containing 3% bovine serum albumin (BSA) and 0.6% NaN_3.

3. Methods

1. Dissolve 1.5 mg of IgG in 1.5 mL of 0.1 *M* sodium phosphate buffer, pH 7.0, containing 50 m*M* NaCl.
2. Add 0.32 mg of MBS in 15 µL of dioxan, mix, and incubate for 1 h at 30°C.
3. Fractionate the mixture on a column of Sephadex G25 (approx. 0.9 × 20 cm) equilibrated with 10 m*M* sodium phosphate buffer, pH 7.0, containing 50 m*M* NaCl and 10 m*M* $MgCl_2$, and elute with the same buffer. Collect 0.5 mL fractions, measure the A_{280} and pool the fractions in the first peak (about 3 mL in volume).
4. Add 1.5 mg of enzyme, mix, and incubate for 1 h at 30°C.
5. Stop the reaction by adding 1 *M* 2-mercaptoethanol to give a final concentration of 10 m*M* (about 30 µL).
6. Fractionate the mixture on a column of DEAE-Sepharose (approx. 0.9 × 15 cm) equilibrated with 10 m*M* Tris-HCl buffer, pH 7.0, containing 10 m*M* $MgCl_2$ and 10 m*M* 2-mercaptoethanol; wash the column with this buffer (50 mL) followed by the buffer containing 0.5 *M* NaCl. (50 mL). Collect 3 mL fractions in tubes with 0.1 mL of Tris buffer containing 3% BSA and 0.6% NaN_3. Pool the major peak (this is eluted with 0.5 M NaCl), and store at 4°C (*see* **Notes 2** and **3**).

4. Notes

1. The thiol groups of β-galactosidase may become oxidized during storage thus diminishing the efficacy of the labeling. It is relatively easy to measure these groups using 5,5 -dithiobis(2-nitrobenzoic acid) (*see* Chapter 93); about 10 thiol groups per enzyme molecule allow the preparation of satisfactory conjugates.

2. The conjugates are stable for a year at 4°C as the NaN_3 inhibits microbial growth and the BSA minimizes denaturation and adsorption losses.
3. The activity of the conjugate can be checked by the method described in **Note 4** of Chapter 64.

Horseradish Peroxidase Labeling of IgG Antibody

G. Brian Wisdom

1. Introduction

Horseradish peroxidase (HRP; EC 1.11.1.7) is probably the most widely used enzyme label. This protein is relatively small (44 kDa), stable, and has a broad specificity which allows it to be measured by absorption, fluorescence or luminescence. Some of its products are intensely coloured, which makes this enzyme suitable for immunocytochemical or immunoblotting applications.

The most popular method ***(1)*** for labeling IgG antibody molecules with HRP exploits the glycoprotein nature of the enzyme. The saccharide residues are oxidized with sodium periodate to produce aldehyde groups that can react with the amino groups of the IgG molecule, and the Schiff bases formed are then reduced to give a stable conjugate of high molecular weight ($0.5–1.0 \times 10^6$). The enzyme has few free amino groups so self-coupling is not a significant problem.

Other methods have been described for using this enzyme as a horseradish peroxidase as a label. IgG may be labeled with HRP using glutaraldehyde in a two-step proecure ***(2)*** and, when partially reduced, IgG has been labelled using the heterobifunctional succinimidyl 4-(*N*-maleimidyl)-cyclohexane-1-carboxylate ***(3)***.

2. Materials

1. Horseradish peroxidase, 1000 U/mg or greater (with 2,2´-azino-bis-[3-ethylbenzthiazoline-6-sulfonic acid] as substrate) (*see* **Note 1**).
2. IgG antibody. This should be the pure IgG fraction or, better, affinity purified antibody from an antiserum or pure monoclonal antibody (*see* Chapters 179–189).
3. 0.1 *M* Sodium periodate, freshly prepared.
4. 1 m*M* Sodium acetate buffer, pH 4.4.
5. 10 m*M* Sodium carbonate buffer, pH 9.5.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

6. 0.2 *M* Sodium carbonate buffer, pH 9.5.
7. Sodium borohydride, 4 mg/mL (freshly prepared).
8. Sepharose CL-6B (GE Healthcare Bio-sciences, Uppsala, Sweden and Piscataway, NJ) or a similar gel.
9. PBS: 20 mM sodium phosphate buffer, pH 7.2, containing 0.15 *M* NaCl.
10. Bovine serum albumin (BSA).

3. Method

1. Dissolve 2 mg of peroxidase in 500 µL of water.
2. Add 100 µL of freshly prepared 0.1 *M* sodium periodate, and stir the solution for 20 min at room temperature. (The color changes from orange to green).
3. Dialyze the modified enzyme against 1 m*M* sodium acetate buffer, pH 4.4 (2 L) overnight at 4°C (*see* **Note 2**).
4. Dissolve 4 mg of IgG in 500 µL of 10 m*M* sodium carbonate buffer, pH 9.5.
5. Adjust the pH of the dialyzed enzyme solution to 9.0–9.5 by adding 10 µL of 0.2 *M* sodium carbonate buffer, pH 9.5, and immediately add the IgG solution. Stir the mixture for 2 h at room temperature.
6. Add 50 µL of freshly prepared sodium borohydride solution (4 mg/mL), and stir the mixture occasionally over a period of 2 h at 4°C.
7. Fractionate the mixture by size-exclusion chromatography in a column (approx. 1.5 × 85 cm) of Sepharose CL-6B in PBS. Determine the A_{280} and A_{403} (*see* **Note 3**)
8. Pool the fractions in the first peak (both A_{280} and A_{403} peaks coincide), add BSA to give a final concentration of 5 mg/mL, and store the conjugate in aliquots at −20°C (*see* **Notes 4** and **5**).

4. Notes

1. Preparations of horseradish peroxidase may vary in their carbohydrate content and this can affect the oxidation reaction. Free carbohydrate can be removed by size exclusion chromatography. Increasing the sodium periodate concentration to 0.2 *M* can also help, but further increases lead to inactivation of the peroxidase.
2. Dialysis of small volumes can be conveniently done in narrow dialysis tubing by placing a short glass tube, sealed at both ends, in the tubing so that the space available to the sample is reduced. There are also various microdialysis systems available commercially such as the Slide-A-Lyzer units from Pierce Biotechnology (Rockford, IL).
3. The absorbance at 403 nm is caused by the peroxidase's heme group. The enzyme is often specified in terms of its RZ value; this is the ratio of A_{280} and A_{403}, and it provides a measure of the heme content and purity of the preparation. Highly purified peroxidase has an RZ of about 3. Conjugates with an RZ of 0.4 perform satisfactorily.
4. BSA improves the stability of the conjugate and minimizes loses due to adsorption and denaturation. NaN_3 should not be used with peroxidase

conjugates because it inhibits the enzyme. If an antimicrobial agent is required, 0.2% sodium merthiolate (thimerosal) should be used.

5. The activity of the conjugate can be checked by the method described in **Note 4** of Chapter 64.

Digoxigenin Labeling of IgG Antibody

G. Brian Wisdom

1. Introduction

Digoxigenin (DIG) is a plant steroid (390 Daltons) which can be used as a small, stable label of IgG molecules. It is a valuable alternative to biotin as the biotin-streptavidin system can sometimes give high backgrounds due, for example, to the presence of biotin-containing enzymes in the sample. There is a range of commercially available mouse and sheep anti-DIG Fab antibody fragments labeled with various enzymes and fluorescent molecules for the detection of the DIG-labeled IgG antibody in many applications *(**1**)*.

The IgG molecule is labeled, via its amino groups, with an *N*- hydroxysuccinimide ester derivative of the steroid containing the 6-aminocaproate spacer.

2. Materials

1. Digoxigenin-3-*O*-succinyl-ε-aminocaproic acid-*N*-hydroxysuccinimide ester (Roche Applied Science, Indianapolis, IL).
2. IgG antibody. This should be the pure IgG fraction or, better, affinity purified antibody from an antiserum or pure monoclonal antibody.
3. Dimethylsufoxide (DMSO).
4. PBS: 20 m*M* sodium phosphate buffer, pH 7.2, containing 0.15 *M* NaCl.
5. 0.1 *M* ethanolamine, pH 8.5.
6. PBS containing 0.1% bovine serum albumin (BSA).
7. Sephadex G-25 (GE Healthcare Bio-sciences, Uppsala, Sweden and Piscataway, NJ) or similar gel (*see* **Note 1**).

3. Method

1. Dissolve 1 mg of the antibody in 1 mL of PBS.
2. Prepare the digoxigenin-3-O-succinyl-*O*-minocaproic acid-*N*-hydroxysuccinimide ester immediately prior to use by dissolving it at a concentration of 2 mg/mL in DMSO.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Add 24 µL of the DIG reagent to the antibody solution slowly with stirring and incubate at room temperature for 2 h.
4. Terminate the reaction by adding 0.1 mL of 0.1 *M* ethanolamine and incubate for 15 min.
5. Remove the excess DIG reagent by size-exclusion chromatography in a small column of Sephadex G-25 equilibrated with PBS containing 0.1% BSA. The IgG is in the first A_{280} peak.
6. Store the labeled antibody at 4°C with 0.05% NaN_3 or in aliquots at −20°C or lower.

4. Note

1. Suitable ready-made columns of cross-linked dextran are available from GE Biosciences (PD-10 or HiTrap columns) and from Pierce Biotechnology (Rockford, IL) (Presto and Kwik columns).

Conjugation of Fluorochromes to Antibodies

Su-Yau Mao

1. Introduction

The use of specific antibodies labeled with a fluorescent dye to localize substances in tissues was first devised by A. H. Coons and his associates. At first, the specific antibody itself was labeled and applied to the tissue section to identify the antigenic sites (direct method) ***(1)***. Later, the more sensitive and versatile indirect method ***(2)*** was introduced. The primary, unlabeled, antibody is applied to the tissue section, and the excess is washed off with buffer. A second, labeled antibody from another species, raised against the IgG of the animal donating the first antibody, is then applied. The primary antigenic site is thus revealed. A major advantage of the indirect method is the enhanced sensitivity. In addition, a labeled secondary antibody can be used to locate any number of primary antibodies raised in the same animal species without the necessity of labeling each primary antibody.

Four fluorochromes are commonly used: fluorescein, rhodamine, Texas red, and phycoerythrin ***(3)***. They differ in optical properties, such as the intensity and spectral range of their absorption and fluorescence. Choice of fluorochrome depends on the particular application. For maximal sensitivity in the binding assays, fluorescein is the fluorochrome of choice because of its high quantum yield. If the ligand is to be used in conjunction with fluorescence microscopy, rhodamine coupling is advised, since it has superior sensitivity in most microscopes and less photobleaching than fluorescein. Texas red ***(4)*** is a red dye with a spectrum that minimally overlaps with that of fluorescein; therefore, these two dyes are suitable for multicolor applications. Phycoerythrin is a 240-kDa, highly soluble fluorescent protein derived from cyanobacteria and eukaryotic algae. Its conjugates are among the most sensitive fluorescent probes available ***(5)*** and are frequently used in flow cytometry and immunoassays ***(6)***. In addition, the Alexa fluorochromes are a series of fluorescent dyes with

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

excitation/emission spectra similar to those of commonly used ones, but are more fluorescent and more photostable *(7)*.

Thiols and amines are the only two groups commonly found in biomolecules that can be reliably modified in aqueous solution. Although the thiol group is the easiest functional group to modify with high selectivity, amines are common targets for modifying proteins. Virtually all proteins have lysine residues, and most have a free amino terminus. The ε-amino group of lysine is moderately basic and reactive with acylating reagents. The concentration of the free-base form of aliphatic amines below pH 8.0 is very low. Thus, the kinetics of acylation reactions of amines by isothiocyanates, succinimidyl esters, and other reagents is strongly pH-dependent. Although amine acylation reactions should usually be carried out above pH 8.5, the acylation reagents degrade in the presence of water, with the rate increasing as the pH increases. Therefore, a pH of 8.5–9.5 is usually optimal for modifying lysines.

Where possible, the antibodies used for labeling should be pure. Affinity-purified, fluorochrome-labeled antibodies demonstrate less background and nonspecific fluorescence than fluorescent antiserum or immunoglobulin fractions. The labeling procedures for the isothiocyanate derivatives of fluorescein and sulfonyl chloride derivatives of rhodamine are given below *(8)*. The major problem encountered is either over- or undercoupling, but the level of conjugation can be determined by simple absorbance readings.

2. Materials

1. IgG.
2. Borate buffered saline (BBS): 0.2 *M* boric acid, 160 m*M* NaCl, pH 8.0.
3. Fluorescein isothiocyanate (FITC) or Lissamine rhodamine B sulfonyl chloride (RBSC).
4. Sodium carbonate buffer: 1.0 *M* $NaHCO_3$-Na_2CO_3 buffer, pH 9.5, prepared by titrating 1.0 *M* $NaHCO_3$ with 1.0 *M* Na_2CO_3 until the pH reaches 9.5.
5. Absolute ethanol (200 proof) or anhydrous dimethylformamide (DMF).
6. Sephadex G-25 column.
7. Whatman DE-52 column.
8. 10 m*M* Sodium phosphate buffer, pH 8.0.
9. 0.02% Sodium azide.
10. UV spectrophotometer.

3. Methods

3.1. Coupling of Fluorochrome to IgG

1. Prior to coupling, prepare a gel-filtration column to separate the labeled antibody from the free fluorochrome after the completion of the reaction. The size of the column should be 10 bed volumes/sample volume (*see* **Note 1**).

2. Equilibrate the column in phosphate buffer. Allow the column to run until the buffer level drops just below the top of bed resin. Stop the flow of the column by using a valve at the bottom of the column.
3. Prepare an IgG solution of at least 3 mg/mL in BBS, and add 0.2 vol of sodium carbonate buffer to IgG solution to bring the pH to 9.0. If antibodies have been stored in sodium azide, the azide must be removed prior to conjugation by extensive dialysis (*see* **Note 2**).
4. Prepare a fresh solution of fluorescein isothiocyanate at 5 mg/mL in ethanol or RBSC at 10 mg/mL in DMF immediately before use (*see* **Note 3**).
5. Add FITC at a 10-fold molar excess over IgG (about 25 µg of FITC/mg IgG). Mix well and incubate at room temperature for 30 min with gentle shaking. Add RBSC at a 5-fold molar excess over IgG (about 20 µg of RBSC/mg IgG), and incubate at 4°C for 1 h.
6. Carefully layer the reaction mixture on the top of the column. Open the valve to the column, and allow the antibody solution to flow into the column until it just enters the bed resin. Carefully add phosphate buffer to the top of the column. The conjugated antibody elutes in the excluded volume (about one-third of the total bed volume).
7. Store the conjugate at 4°C in the presence of 0.02% sodium azide (final concentration) in a light-proof container. The conjugate can also be stored in aliquots at −20°C after it has been snap-frozen on dry ice. Do not refreeze the conjugate once thawed.

3.2. Calculation of Protein Concentration and Fluorochrome-to-Protein Ratio

1. Read the absorbance at 280 and 493 nm. The protein concentration is given by **Eq. 1**, where 1.4 is the optical density for 1 mg/mL of IgG (corrected to 1-cm path length).

$$\text{Fluorescein-conjugated IgG conc. (Fl IgG conc.) (mg/mL)} = (A_{280\,\text{nm}} - 0.35 \times A_{493\,\text{nm}})/1.4 \quad (1)$$

The molar ratio (F/P) can then be calculated, based on a molar extinction coefficient of 73,000 for the fluorescein group, by **Eq. 2** (*see* **Notes 4** and **5**).

$$\text{F/P} = (A_{493\,\text{nm}}/73{,}000) \times (150{,}000/\text{Fl IgG conc.}) \quad (2)$$

2. For rhodamine-labeled antibody, read the absorbance at 280 and 575 nm. The protein concentration is given by **Eq. 3**.

$$\text{Rhodamine-conjugated IgG conc. (Rho IgG conc.) (mg/mL)} = (A_{280\,\text{nm}} - 0.32 \times A_{575\,\text{nm}})/1.4 \quad (3)$$

The molar ratio (F/P) is calculated by **Eq. 4**.

$$F/P = (A_{575\ nm}/73{,}000) \times (150{,}000/\text{Rho IgG conc.}) \quad (4)$$

4. Notes

1. Sephadex G-25 resin is the recommended gel for the majority of desalting applications. It combines good rigidity, for easy handling and good flow characteristics, with adequate resolving power for desalting molecules down to about 5000 Dalton mol wt. If the volume of the reaction mixture is <1 mL, a prepacked disposable Sephadex G-25 column (PD-10 column from Pharmacia, Piscataway, NJ) can be used conveniently.
2. When choosing a buffer for conjugation of fluorochromes, avoid those containing amines (e.g., Tris, azide, glycine, and ammonia), which can compete with the ligand.
3. Both sulfonyl chloride and isothiocyanate will hydrolyze in aqueous conditions; therefore, the solutions should be made freshly for each labeling reaction. Absolute ethanol or dimethyl formamide (best grade available, stored in the presence of molecular sieve to remove water) should be used to dissolve the reagent. The hydrolysis reaction is more pronounced in dilute protein solution and can be minimized by using a more concentrated protein solution. Caution: DMSO should not be used with sulfonyl chlorides, because it reacts with them.
4. An F/P ratio of two to five is optimal, since ratios below this yield low signals, whereas higher ratios show high background. If the F/P ratios are too low, repeat the coupling reaction using fresh fluorochrome solution. The IgG solution needs to be concentrated prior to reconjugation (e.g., Centricon-30 microconcentrator from Amicon Co., Beverly, MA, can be used to concentrate the IgG solution).
5. If the F/P ratios are too high, either repeat the labeling with appropriate changes or purify the labeled antibodies further on a Whatman DE-52 column (diethylaminoethyl microgranular preswollen cellulose, 1-mL packed column/1–2 mg of IgG). DE-52 chromatography removes denatured IgG aggregates and allows the selection of the fraction of the conjugate with optimal modification. Equilibrate and load the column with 10 m*M* phosphate buffer, pH 8.0. Wash the column with equilibrating buffer and elute with the same buffer containing 100 m*M* NaCl (first) and 250 m*M* NaCl (last). Measure the F/P ratios of each fraction, and select the appropriate fractions.
6. Alexa fluorochromes are available only as a protein labeling kit from Molecular Probes, Inc. (Eugene, Oregon, USA; www.probes.com). The reactive

dye has a succinimidyl ester moiety that reacts with primary amines of proteins. The conjugation steps are similar to those for fluorescein isothiocyanate.

Coupling of Antibodies with Biotin

Rosaria P. Haugland and Wendy W. You

1. Introduction

The avidin–biotin bond is the strongest known biological interaction between a ligand and a protein (K_d = 1.3 × 10^{-15} *M* at pH 5) ***(1)***. The affinity is so high that the avidin–biotin complex is extremely resistant to any type of denaturing agent ***(2)***. Biotin (**Fig. 1**) is a small, hydrophobic molecule that functions as a coenzyme of carboxylases ***(3)***. It is present in all living cells. Avidin is a tetrameric glycoprotein of 66,000–68,000 mol wt, found in egg albumin and in avian tissues. The interaction between avidin and biotin occurs rapidly, and the stability of the complex has prompted its use for *in situ* attachment of labels in a broad variety of applications, including immunoassays, DNA hybridization ***(4–6)***, and localization of antigens in cells and tissues ***(7)***. Avidin has an isoelectric point of 10.5. Because of its positively charged residues and its oligosaccharide component, consisting mostly of mannose and glucosamine ***(8)***, avidin can interact nonspecifically with negative charges on cell surfaces and nucleic acids, or with membrane sugar receptors. At times, this causes background problems in histochemical and cyto-chemical applications. Streptavidin, a near-neutral, biotin binding protein ***(9)*** isolated from the culture medium of *Streptomyces avidinii,* is a tetrameric nonglycosylated analog of avidin with a mol wt of about 60,000. Like avidin, each molecule of streptavidin binds four molecules of biotin, with a similar dissociation constant. The two proteins have about 33% sequence homology, and tryptophan residues seem to be involved in their biotin binding sites ***(10, 11)***. In general, streptavidin gives less background problems than avidin. This protein, however, contains a tripeptide sequence Arg-Tyr-Asp (RYD) that apparently mimics the binding sequence of fibronectin Arg-Gly-Asp (RGD), a universal recognition domain of the extracellular matrix that specifically

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

promotes cell adhesion. Consequently, the streptavidin–cell-surface interaction causes high background in certain applications ***(12)***.

As an alternative to both avidin and streptavidin, a chemically modified avidin, NeutrAvidin™ (NeutrAvidin™ is a trademark of Pierce Chemical Company, Rockford, IL) and its conjugates with enzymes or fluorescent probes are available from both Molecular Probes and Pierce. NeutrAvidin™ consists of chemically deglycosylated avidin, which has been modified to reduce the isoelectric point to a neutral value, without loss of its biotin binding properties and without significant change in the lysines available for derivatization ***(13)***. (Fluorescent derivatives and enzyme conjugates of NeutraLite avidin, as well as the unlabeled protein, are available from Molecular Probes [Eugene, OR].)

As shown in **Fig. 1**, biotin is a relatively small and hydrophobic molecule. The addition to the carboxyl group of biotin of one (*X*) or two (*XX*) aminohexanoic acid "spacers" greatly enhances the efficiency of formation of the complex between the biotinylated antibody (or other biotinylated protein) and the avidin–probe conjugate, where the probe can be a fluorochrome or an enzyme ***(14, 15)***. Each of these 7- or 14-atom spacer arms has been shown to improve the ability of biotin derivatives to interact with the binding cleft of avidin. The comparison between streptavidin binding activity of proteins biotinylated with biotin-*X* or biotin-*XX* (labeled with same number of moles of biotin/mol of protein) has been performed in our laboratory (**Fig. 2**). No difference was found between the avidin or streptavidin–horseradish peroxidase conjugates in their ability to bind biotin-*X* or biotin-*XX*. However, biotin-*XX* gave consistently higher titers in enzyme-linked immunosorbent (ELISA) assays, using biotinylated goat antimouse IgG (GAM), bovine serum albumin (BSA), or protein A (results with avidin and with protein A are not presented here). Even nonroutine conjugations performed in our laboratory have consistently yielded excellent results using biotin-*XX*.

Biotin, biotin-*X,* and biotin-*XX* have all been derivatized for conjugation to amines or thiols of proteins and aldehyde groups of glycoproteins or other

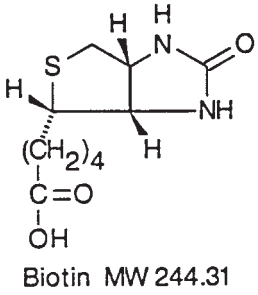

Fig. 1. Structure of biotin.

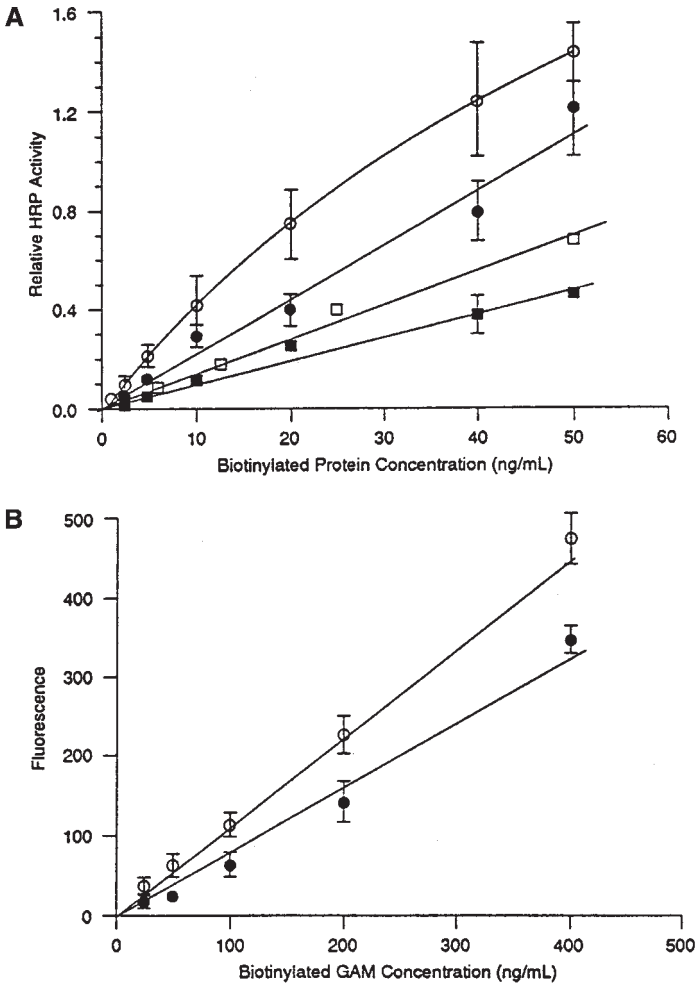

Fig. 2. (**A**) ELISA-type assay comparing the binding capacity of BSA and GAM biotinylated with biotin-*X* or biotin-*XX*. The assay was developed using streptavidin-HRP conjugate (0.2 µg/mL) and *o*-phenylenediamine dihydro-chloride (OPD). The number of biotin/mol was: 4.0 biotin-*X*/GAM (●), 4.4 biotin-*XX*/GAM (○), 6.7 biotin-*X*/BSA (■), and 6.2 biotin-*XX*/BSA (▤). Error bars on some data points have been omitted for clarity. (**B**) Similar assay using GAM biotinylated with biotin-*X* (●) or biotin-*XX* (○). The assay was developed with streptavidin–R-phycoerythin conjugate (25 µg/mL using a Millipore CytoFluor™ fluorescence microtiter plate reader).

polymers. The simplest and most popular biotinylation method is to label the ε-amino groups of lysine residues with a succinimidyl ester of biotin. Easy-to-use biotinylation kits are commercially available that facilitate the biotinylation of

1–2 mg of protein or oligonucleotides ***(16)***. One kit for biotinylating smaller amounts of protein (0.1–3 mg) utilizes biotin-*XX* sulfosuccinimidyl ester ***(17)***. This compound is water-soluble and allows for the efficient labeling of dilute protein samples. Another kit uses biotin-*X* 2,4-dinitrophenyl-X-lysine succinimidyl ester (DNP-biocytin) as the biotinylating reagent. DNP-biocytin was developed by Molecular Devices (Menlo Park, CA) for their patented Threshold-Immunoligand System ***(18)***. DNP-biocytin permits the direct measurement of the degree of biotinylation of the reaction product by using the molar extinction coefficient of DNP (15,000 M^{-1} cm^{-1} at 364 nm). Conjugates of DNP-biocytin can be probed separately or simultaneously using either anti-DNP antibodies or avidin/streptavidin; this flexibility is useful when combining techniques such as fluorescence and electron microscopy. Biotin iodoacetamide or maleimide, which could biotinylate the reduced sulfhydryls located at the hinge region of antibodies, is not usually used for this purpose. More examples in the literature describe biotinylation of antibodies with biotin hydrazide at the carbohydrate prosthetic group, located in the Fc portion of the molecule, relatively removed from the binding site. Conjugation of carbohydrates with hydrazides requires the oxidation of two adjacent hydroxyls to aldehydes and optional stabilization of the reaction with cyanoborohydride ***(19)***.

Because of its strength, the interaction between avidin and biotin cannot be used for preparing matrices for affinity column purification, unless columns prepared with avidin monomers are used ***(20)***. The biotin analog, iminobiotin, which has a lower affinity for avidin, can be used for this purpose ***(21, 22)***. Iminobiotin in reactive form is commercially available, and the procedure for its conjugation is identical to that used for biotin. Detailed, practical protocols for biotinylating antibodies at the lysine or at the carbohydrate site, and a method to determine the degree of biotinylation are described in detail in this chapter (*see* **Notes 1–10** for review of factors that affect optimal conjugation and yield of biotinylated antibodies).

2. Materials

2.1. Conjugation with Amine-Reactive Biotin

1. Reaction buffer: 1 *M* sodium bicarbonate, stable for about 2 wk when refrigerated. Dissolve 8.3 g of $NaHCO_3$ in 100 mL of distilled water. The pH will be about 8.3. Dilute 1:10 before using to obtain a 0.1 *M* solution. Alternate reaction buffer: 0.1 *M* sodium phosphate, pH 7.8. Dissolve 12.7 g Na_2HPO_4 and 1.43 g NaH_2PO_4 in 800 mL of distilled water. Adjust pH to 7.8 if necessary. Bring the volume to 1000 mL. This buffer is stable for 2 mo when refrigerated.
2. Anhydrous dimethylformamide (DMF) or dimethyl sulfoxide (DMSO).
3. Phosphate-buffered saline (PBS): Dissolve 1.19 g of K_2HPO_4, 0.43 g of $KH_2PO_4 \cdot H_2O$ and 8.8 g NaCl in 800 mL of distilled water, adjust the pH to 7.2 if necessary or to the desired pH, and bring the volume to 1000 mL with distilled water.

4. Disposable desalting columns or a gel-filtration column: Amicon GH-25 and Sephadex G-25 or the equivalent, equilibrated with PBS or buffer of choice.
5. Good-quality dialysis tubing as an alternative to the gel-filtration column when derivatizing small quantities of antibody.
6. Biotin, biotin-*X* or biotin-*XX* succinimidyl ester: As with all succinimidyl esters, these compounds should be stored well desiccated in the freezer.

2.2. Conjugation with Biotin Hydrazide at the Carbohydrate Site

1. Reaction buffer: 0.1 *M* acetate buffer, pH 6.0. Dilute 5.8 mL acetic acid in 800 mL distilled water. Bring the pH to 6.0 with 5 *M* NaOH and the volume to 1000 mL. The buffer is stable for several months when refrigerated.
2. 20 m*M* Sodium metaperiodate: Dissolve 43 mg of $NaIO_4$ in 10 mL of reaction buffer, protecting from light. Use fresh.
3. Biotin-*X* hydrazide or biotin-*XX* hydrazide.
4. DMSO.
5. Optional: 100 m*M* sodium cyanoborohydride, freshly prepared. Dissolve 6.3 mg of $NaBH_3CN$ in 10 mL of 0.1 m*M* NaOH.

2.3. Determination of the Degree of Biotinylation

1. 10 m*M* 4′ -Hydroxyazobenzene-2-carboxylic acid (HABA) in 10 m*M* NaOH.
2. 50 m*M* Sodium phosphate and 150 m*M* NaCl, pH 6.0. Dissolve 0.85 g of Na_2HPO_4 and 6.07 g of NaH_2PO_4 in 800 mL of distilled water. Add 88 g of NaCl. Bring the pH to 6.0 if necessary and the volume to 1000 mL.
3. 0.5 mg/mL Avidin in 50 m*M* sodium phosphate and 150 m*M* NaCl, pH 6.0.
4. 0.25 m*M* Biotin in 50 m*M* sodium phosphate, and 150 m*M* NaCl, pH 6.0.

3. Methods

3.1. Conjugation with Amine-Reactive Biotin

1. Calculate the amount of a 10 mg/mL biotin succinimidyl ester solution (biotin-NHS) needed to conjugate the desired quantity of antibody at the chosen biotin/antibody molar ratio, according to the following formula:

$$\begin{aligned}&(\text{mL of 10 mg/mL biotin-SE}) = \{[(\text{mg antibody} \times 0.1)/\text{mol wt}\\ &\text{of antibody}] \times R \times \text{mol wt of biotin-SE})\}\end{aligned} \quad (1)$$

where R = molar incubation ratio of biotin/protein. For example, using 5 mg of IgG and a 10:1 molar incubation ratio of biotin-*XX*-SE, **Eq. (1)** yields:

$$\begin{aligned}&(\text{mL of 10 mg/mL biotin-}XX\text{-SE})\\ &= \{[(5 \times 0.1)/145{,}000] \times (10 \times 568)\} = 0.02\ \text{mL}\end{aligned} \quad (2)$$

2. Dissolve the antibody, if lyophilized, at approx 5–15 mg/mL in either of the two reaction buffers described in **Subheading 2.1.** If the antibody to be conjugated is already in solution in 10–20 m*M* PBS, without azide, the pH necessary for the reaction can be

obtained by adding 1/10 vol of 1 *M* sodium bicarbonate. IgM should be conjugated in PBS, pH 7.2 (*see* **Note 3**).

3. Weigh 3 mg or more of the biotin-SE of choice, and dissolve it in 0.3 mL or more of DMF or DMSO to obtain a 10 mg/mL solution. **It is essential that this solution be prepared immediately before starting the reaction,** since the succinimidyl esters or any amine-reactive reagents hydrolyze quickly in solution. Any remaining solution should be discarded.
4. While stirring, slowly add the amount of 10 mg/mL solution, calculated in **step 1**, to the antibody prepared in **step 2**, mixing thoroughly.
5. Incubate this reaction mixture at room temperature for 1 h with gentle stirring or shaking.
6. The antibody conjugate can be purified on a gel-filtration column or by dialysis. When working with a few milligrams of dilute antibody solution, care should be taken not to dilute the antibody further. In this case, dialysis is a very simple and effective method to eliminate unreacted biotin. A few mL of antibody solution can be effectively dialyzed in the cold against 1 L of buffer with three to four changes. Small amounts of concentrated antibody can be purified on a prepackaged desalting column equilibrated with the preferred buffer, following the manufacturer's directions. Five or more milligrams of antibody can be purified on a gel-filtration column. The dimensions of the column will have to be proportional to the volume and concentration of the antibody. For example, for 5–10 mg of antibody in 1 mL solution, a column with a bed vol of 10 × 300 mm will be adequate. To avoid denaturation, dilute solutions of biotinylated antibodies should be stabilized by adding BSA at a final concentration of 0.1–1%.

3.2. Conjugation with Biotin Hydrazide at the Carbohydrate Site

1. It is essential that the entire following procedure be carried out with the sample completely protected from light (*see* **Note 9**).
2. Dissolve antibody (if lyophilized) or dialyze solution of antibody to obtain a 2–10 mg/mL solution in the reaction buffer described in **Subheading 2.1., item 1**. Keep at 4°C.
3. Add an equal volume of cold metaperiodate solution. Incubate the reaction mixture at 4°C for 2 h in the dark.
4. Dialyze overnight against the same buffer protecting from light, or, if the antibody is concentrated, desalt on a column equilibrated with the same buffer. This step removes the iodate and formaldehyde produced during oxidation.
5. Dissolve 10 mg of the biotin hydrazide of choice in 0.25 mL of DMSO to obtain a 40 mg/mL solution, warming if needed. This will yield a 107 m*M* solution of biotin-*X* hydrazide or an 80 m*M* solution of biotin-*XX* hydrazide. These solutions are stable for a few weeks.
6. Calculate the amount of biotin hydrazide solution needed to obtain a final concentration of approx 5 m*M*, and add it to the oxidized antibody. When using biotin-*X* hydrazide, 1 vol of hydrazide should be added to 20 vol of antibody solution. When using biotin-*XX* hydrazide, 1 vol of hydrazide should be added to 15 vol of antibody solution.

7. Incubate for 2 h at room temperature with gentle stirring.
8. This step is optional. The biotin hydrazone–antibody conjugate formed in this reaction (**steps 6** and **7**) is considered by some researchers to be relatively unstable. To reduce the conjugate to a more stable, substituted hydrazide, treat the conjugate with sodium cyanoborohydride at a final concentration of 5 m*M* by adding a 1/20 vol of a 100-m*M* stock solution. Incubate for 2 h at 4°C (*see* **Note 5**).
9. Purify the conjugate by any of the methods described for biotinylating antibodies at the amine site (*see* **Subheading 3.1., step 6**).

3.3. Determination of the Degree of Biotinylation

The dye HABA interacts with avidin yielding a complex with an absorption maximum at 500 nm. Biotin, because of its higher affinity, displaces HABA, causing a decrease in absorbance at 500 nm proportional to the amount of biotin present in the assay.

1. To prepare a standard curve, add 0.25 mL of HABA reagent to 10 mL of avidin solution. Incubate 10 min at room temperature and record the absorbance at 500 nm of 1 mL avidin–HABA complex with 0.1 mL buffer, pH 6.0. Distribute 1 mL of the avidin–HABA complex into six test tubes. Add to each the biotin solution in a range of 0.005–0.10 mL. Bring the final volume to 1.10 mL with pH 6.0 buffer, and record the absorbance at 500 nm of each concentration point. Plot a standard curve with the nanomoles of biotin vs the decrease in absorbance at 500 nm. An example of a standard curve is illustrated in **Fig. 3.**
2. To measure the degree of biotinylation of the sample, add an aliquot of biotinylated antibody of known concentration to 1 mL of avidin–HABA complex. For example,

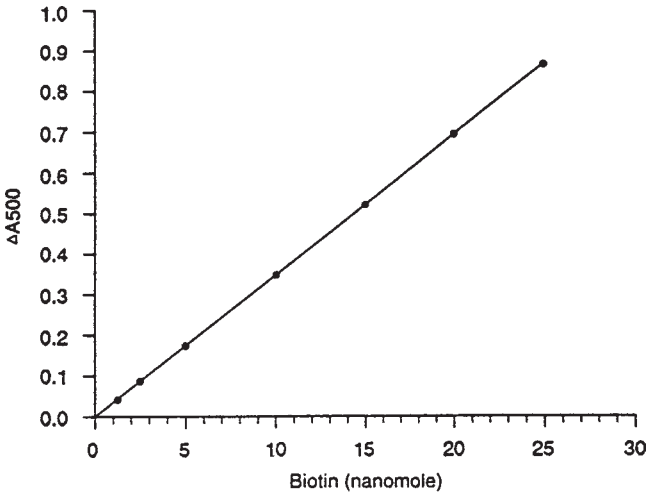

Fig. 3. Examples of standard curve for biotin assay with avidin-HABA reagent, obtained as described in **Subheading 3.3.**

add 0.05–0.1 mL of biotinylated antibody at 1 mg/mL to 1 mL of avidin–HABA mixture. Bring the volume to 1.10 mL, if necessary, incubate for 10 min, and measure the decrease in absorbance at 500 nm.

3. Deduct from the standard curve the nanomoles of biotin corresponding to the observed change in absorbance. The ratio between nanomoles of biotin and nanomoles of antibody used to displace HABA represents the degree of biotinylation, as seen from the following equation:

$$[(\text{nmol biotin} \times 145{,}000 \times 10^{-6})/(\text{mg/mL antibody} \times 0.1\ \text{mL})] = (\text{mol of biotin/mol of antibody}) \quad (3)$$

where 145,000 represents the mol wt of the antibody and 0.1 mL is the volume of 1 mg/mL of biotinylated antibody sample.

4. Notes

4.1. Factors that Influence the Biotinylation Reaction

1. Protein concentration: As in any chemical reaction, the concentration of the reagents is a major factor in determining the rate and the efficiency of the coupling. Antibodies at a concentration of 5–20 mg/mL will give better results; however, it is often difficult to have such concentrations or even such quantities available for conjugation. Nevertheless, the antibody should be as concentrated as possible. In the case of solutions of antibody <2–3 mg/mL, the molar ratio of biotinylating reagent (or of both the oxidizing and biotinylating reagent, in the case of labeling the carbohydrate region) should be increased. It is also essential that the antibody solutions do not contain gelatin or BSA, which are often added to stabilize dilute solutions of antibodies. These proteins, generally present at a 1% concentration, will also react with biotinylating reagents.
2. pH: The reactivity of amines increases at basic pH. Unfortunately, so does the rate of hydrolysis of succinimidyl esters. We have found that the best pH for biotinylation of the ε-amino groups of lysines is 7.5–8.3. IgM antibodies, which denature at basic pH, can be biotinylated at pH 7.2 by increasing the molar ratio of the biotinylating reagent to antibody to at least 20. The optimum pH for oxidation and conjugation with hydrazides is 5.5–6.0.
3. Buffer: Bicarbonate or phosphate buffers are suitable for biotinylation. Organic buffers, such as Tris which contain amines, should be avoided, because they react with amino-labeling reagents or interfere with the reaction between aldehydes and hydrazides. However, HEPES and EPPS, which contain tertiary amines, are suitable. Antibodies dissolved in 10–20 m*M* PBS can be readily prepared for conjugation at the lysine site by adding 1/10–1/5 of the volume of 1 *M* sodium bicarbonate. As noted, because IgM antibodies are unstable in basic solution, biotinylation at the ε-amino group

of lysines should be attempted in PBS or equivalent buffer at pH 7.2. Reactions of antibodies with periodate and biotin hydrazide can be performed in PBS at pH 7 or in acetate buffer, pH 6.0 (*see* **Subheading 2.2**).

4. Temperature: Biotinylations at the amino group sites are run at room temperature, at the carbohydrate site at 0–4°C.
5. Time: Succinimidyl ester derivatives will react with a protein within 1 h. Periodate oxidation will require 2 h at pH 6.0. Reaction with biotin hydrazide can be performed in a few hours. Stabilization with cyanoborohydride requires <2 h.
6. Desired degree of biotinylation and stability of the conjugate: Reaction of an antibody with biotin does not significantly alter the size or charge of the molecule. However, because of the size of avidin or its analogs (mol wt = 60,000–68,000), an increase in the number of biotins per antibody will not necessarily increase the number of avidins capable of reacting with one antibody molecule. Because biotin, biotin-*X*, and biotin-*XX* are very hydrophobic molecules, a high degree of biotinylation might increase the background or might destabilize the antibody. To obtain a degree of biotinylation of about 3–7 biotins/IgG, generally a molar ratio of 15 mol of amino biotinylating reagent/mol of protein is used. When the concentration of the antibody is <3 mg/mL, this ratio should be increased. The amount of increase should be determined experimentally, because the reactivity of the lysines available for conjugation varies for each antibody (Ab). This could become a significant factor, especially at low antibody concentrations.

The succinimidyl esters or hydrazides of biotin, biotin-*X*, and biotin-*XX* exhibit similar degrees of reactivity, and the choice is up to the researcher. In general, the longer spacer arm in biotin-*XX* should be advantageous (**Fig. 2**). The overall stability of biotinylated MAbs derivatized with a moderate number of biotin should be similar to the stability of the native antibody, and the storage conditions also should be the same.

4.2. Factors that Affect Antibodies

7. Most Abs can withstand biotinylation with minimal change in activity and stability, especially if the degree of biotinylation is about 3–6 biotins/mol.
8. Biotin or any of its longer chain derivatives do not contribute to the absorbance of the antibody at 280 nm. Consequently, the concentration of the antibody can be measured by using $A^{1\%}_{1\,cm} = 14$ at 280 nm.
9. It is essential that the entire procedure for biotinylation of antibodies at the carbohydrate site (**Subheading 3.2**) be performed in the dark, protected from light.
10. It should be noted that dry milk, serum, and other biological fluids contain biotin and, consequently, they should not be used as blocking agents in systems where blocking is required.

Preparation of Avidin Conjugates

Rosaria P. Haugland and Mahesh K. Bhalgat

1. Introduction

The high-affinity avidin–biotin system has found applications in different fields of biotechnology including immunoassays, histochemistry, affinity chromatography, and drug delivery, to name a few. A brief description of avidin and avidin-like molecules, streptavidin, deglycosylated avidin, and NeutrAvidin™ avidin, is presented in Chapter 69. With four biotin binding sites per molecule, the avidin family of proteins is capable of forming tight complexes with one or more biotinylated compounds ***(1)***. Typically, the avidin–biotin system is used to prepare signal-amplifying "sandwich" complexes between specificity reagents (e.g., antibodies) and detection reagents (e.g., fluorophores, enzymes, and so on). The specificity and detection reagents are independently conjugated, one with avidin and the other with biotin, or both with biotin, providing synthetic flexibility ***(2)***.

Avidin conjugates of a wide range of fluorophores, phycobiliproteins, secondary antibodies, microspheres, ferritin, and enzymes commonly used in immunochemistry are available at reasonable prices, making their small scale preparation impractical and not cost effective (*see* **Note 1**). However, conjugations of avidin to specific antibodies, to uncommon enzymes, and to other proteins and peptides are often performed onsite. A general protocol for the conjugation of avidin to enzymes, antibodies, and other proteins is described in this chapter.

Avidin conjugates of oligodeoxynucleotides are hybrid molecules that not only provide multiple biotin binding sites, but can also be targeted to complementary DNA or RNA sequences, by annealing interactions. Such conjugates are useful for the construction of macromolecular assemblies with a wide variety of

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

constituents ***(3)***. The protocol outlined in **Subheading 3.1** can be modified (*see* **Note 2**) for the conjugation of oligonucleotides to avidin.

Streptavidin conjugates are also being evaluated for use in drug delivery systems. A two-step imaging and treatment protocol has been developed that involves injection of a suitably prepared tumor-specific monoclonal antibody, followed by a second reagent that carries an imaging or therapeutic agent, capable of binding to the tumor-targeted antibody ***(4)***. Owing to complications associated with the injection of radiolabeled biotin ***(5)***, conjugation of the imaging or therapeutic agent to streptavidin is being considered, instead. A protocol for radioiodination of streptavidin using IODO-BEADS® ***(6)*** is described in **Subheading 3.2**. Some other methods that have been developed include the iodogen method ***(7,8)***, (*see* Chapter 176), the Bolton–Hunter reagent method (*see* Chapter 177) ***(9)***, and a few that do not involve direct iodination of tyrosine residues ***(10–13)***. Streptavidin–drug conjugates are also candidates for therapeutic agents. Synthesis of a Streptavidin-drug conjugate involves making a chemically reactive form of the drug followed by its conjugation to streptavidin. The synthetic methodology thus depends on the structure of the specific drug to be conjugated ***(14–16)***.

The avidin-biotin interaction can also be exploited for affinity chromatography; however, there are limitations to this application, because a biotinylated protein captured on an avidin affinity matrix would likely be denatured by the severe conditions required to separate the high-affinity avidin–biotin complex. On the other hand, an avidin affinity matrix may find utility in the removal of undesired biotinylated moieties from a mixture or for the purification of compounds derivatized with 2-iminobiotin. The biotin derivative 2-iminobiotin has reduced affinity for avidin, and its moderate binding to avidin at pH 9.0 is greatly diminished at pH 4.5 ***(17)***. Another approach to reducing the affinity of the interaction is to denature avidin to its monomeric subunits. The monomeric subunits have greatly reduced affinity for biotin ***(18)***. We describe here a protocol for preparing native ***(19)*** and monomeric avidin matrices ***(20)***. Modified streptavidins, hybrids of native and engineered subunits with lower binding constants, have been prepared that may also be suitable for affinity matrices ***(21)***. A new form of monovalent avidin, nitrated at the tyrosine located at three of the four biotin binding sites, has recently been available from Molecular Probes. The binding affinity of this modified avidin ***(22)***, called CaptAvidin™ biotin-binding protein, is lower than for the native protein. At pH 4 CaptAvidin biotin-binding protein associates with biotin with a K_a of $10^9\ M^{-1}$; if needed, the complex can be completely dissociated at pH ~10.0. This property makes CaptAvidin biotin-binding protein the ideal ligand for affinity matrices suitable for isolation and purification of biotinylated compounds. A nitration protocol is described in Chapter 87.

2. Materials

2.1. Conjugation to Antibodies, Enzymes or Oligonucleotides

1. Avidin (mol wt = 66,000).
2. Antibody, enzyme, peptide, protein, or thiolated oligonucleotide to be conjugated to avidin.
3. Succinimidyl 3-(2-pyridyldithio)propionate (SPDP; mol wt = 312.36) (*see* **Note 3**).
4. Succinimidyl *trans*-4-(*N*-maleimidylmethyl)cyclohexane-1-carboxylate (SMCC; mol wt = 334.33).
5. Dithiothreitol (DTT; mol wt = 154.24).
6. Tris-(2-carboxyethyl) phosphine (TCEP; mol wt = 286.7).
7. *N*-ethylmaleimide (NEM; mol wt = 125.13)
8. Anhydrous dimethyl sulfoxide (DMSO) or anhydrous dimethylformamide (DMF).
9. 0.1 *M* Phosphate buffer: Contains 0.1 *M* sodium phosphate, 0.1 *M* NaCl at pH 7.5. Dissolve 92 g of Na_2HPO_4, 21 g of $NaH_2PO_4 \cdot H_2O$, and 46.7 g of NaCl in approx 3.5 L of distilled water and adjust the pH to 7.5 with 5 *M* NaOH. Dilute to 8 L. Store refrigerated.
10. 1 *M* Sodium bicarbonate (*see* **Note 4**). Dissolve 8.4 g in 90 mL of distilled water and adjust the volume to 100 mL. A freshly prepared solution has a pH of 8.3–8.5.
11. Molecular exclusion matrix with properties suitable for purification of the specific conjugate. Sephadex G-200 (Pharmacia Biotech, Uppsala, Sweden), Bio-Gel® A-0.5 m or Bio-Gel® A-1.5 m (Bio-Rad Laboratories, Hercules, CA) are useful for relatively small to large conjugates, respectively.
12. Sephadex G-25 (Pharmacia Biotech) or other equivalent matrix

2.2. Radioiodination Using IODO-BEADS

1. Streptavidin (mol wt = 60,000).
2. $Na^{131}I$ or $Na^{125}I$, as desired.
3. IODO-BEADS (Pierce Chemical, Rockford, IL).
4. Phosphate-buffered saline (PBS), pH 7.2 : Dissolve 1.19 g of K_2HPO_4, 0.43 g of KH_2PO_4, and 9 g of NaCl in 900 mL of distilled water. Adjust the pH to 7.2 and dilute to 1 L with distilled water.
5. Saline solution: 9 g of NaCl dissolved in 1 L of distilled water.
6. 0.1% Bovine serum albumin (BSA) solution in saline: 0.1 g of bovine serum albumin dissolved in 100 mL of saline solution.
7. Trichloroacetic acid (TCA), 10% w/v solution in saline: Dissolve 1 g of TCA in 10 mL of saline solution.
8. Bio-Gel® P-6DG Gel (Bio-Rad Laboratories).

2.3. Avidin Affinity Matrix

1. 50–100 mg of avidin.
2. Sodium borohydride.
3. 1,4-Butanediol-diglycidyl ether.
4. Succinic anhydride.

5. 6 *M* Guanidine HCl in 0.2 *M* KCl/HCl, pH 1.5: Dissolve 1.5 g of KCl in 50 mL of distilled water. Add 57.3 g of guanidine HCl with stirring. Adjust the pH to 1.5 with 1 *M* HCl. Adjust the volume to 100 mL with distilled water.
6. 0.2 *M* Glycine HCl pH 2.0: Dissolve 22.3 g of glycine HCl in 900 mL of distilled water. Adjust the pH to 2.0 with 6 *M* HCl and the volume to 1 L with distilled water.
7. PBS: *See* **Subheading 2.2.4.**
8. 0.2 *M* Sodium carbonate, pH 9.5: Dissolve 1.7 g of sodium bicarbonate in 80 mL of distilled water. Adjust the pH to 9.5 with 1 *M* NaOH and the volume to 100 mL with distilled water.
9. 0.2 *M* Sodium phosphate, pH 7.5: Weigh 12 g of Na_2HPO_4 and 2.5 g of $NaH_2PO_4 \cdot H_2O$ and dissolve in 900 mL of distilled water. Adjust the pH to 7.5 with 5 *M* NaOH and the volume to 1 L with distilled water.
10. 20 m*M* Sodium phosphate, 0.5 *M* NaCl, 0.02% sodium azide pH 7.5: Dilute 100 mL of the buffer described in **Subheading 2.3., item 9**) to 900 mL with distilled water. Add 28 g of NaCl and 200 mg of sodium azide. Adjust pH if necessary, and dilute to 1 L with distilled water.
11. Sepharose 6B (Pharmacia Biotech) or other 6% crosslinked agarose gel.

3. Methods

3.1. Conjugation to Antibodies or to Enzymes

3.1.1. Avidin Thiolation

An easy-to-use, protein-to-protein crosslinking kit is now commercially available (Molecular Probes, Eugene, OR). This kit allows predominantly 1:1 conjugate formation between two proteins (0.2–3 mg) through the formation of a stable thioether bond ***(23)***, with minimal generation of aggregates. A similar protocol is described here for conjugation of 5 mg of avidin to antibodies or enzymes. Modifications of the procedure for conjugation of avidin to thiolated oligonucleotides and peptides are described in **Notes 2** and **5**, respectively. Although the protocol described in this section uses avidin for conjugation, it can be applied for the preparation of conjugates using either avidin, streptavidin, deglycosylated avidin, or NeutrAvidin avidin.

1. Dissolve 5 mg of avidin (76 nanomol) in 0.5 mL of 0.1 *M* phosphate buffer to obtain a concentration of 10 mg/mL.
2. Weigh 3 mg of SPDP and dissolve it in 0.3 mL of DMSO to obtain a 10 mg/mL solution. This solution must be prepared **fresh** immediately before using. Vortex-mix or sonicate to ensure that the reagent is completely dissolved.
3. Slowly add 12 µL (380 nanomoles) of the SPDP solution (*see* **Note 3**) to the stirred solution of avidin. Stir for 1 h at room temperature.
4. Purify the thiolated avidin on a 7 × 250 mm size exclusion column, such as Sephadex G-25 equilibrated in 0.1 *M* phosphate buffer.
5. Determine the degree of thiolation (optional):

Table 1
Molar Extinction Coefficients at 280 nm and Molecular Weights of Avidin and Avidin-Like Proteins

Protein	Molecular weight	$E_{Avidin}{}^{M}$/cm/M
Avidin	66,000	101,640
Deglycosylated avidin/NeutrAvidin	60,000	101,640
CaptAvidin biotin-binding protein	66,000	118,800
Streptavidin	60,000	180,000

a. Prepare a 100 m*M* solution of DTT by dissolving 7.7 mg of the reagent in 0.5 mL of distilled water.
b. Transfer the equivalent of 0.3–0.4 mg of thiolated avidin (absorbance at 280 nm of a 1.0 mg/mL avidin solution = 1.54) and dilute to 1.0 mL using 0.1 *M* phosphate buffer. Record the absorbance at 280 nm and at 343 nm.
c. Add 50 mL of DTT solution. Mix well, incubate for 3–5 min at room temperature and record the absorbance at 343 nm.
d. Using the extinction coefficient at 343 nm of 8.08×10^3/cm/M ***(24)***, calculate the amount of pyridine-2-thione liberated during the reduction, which is equivalent to the number of thiols introduced on avidin, using the following equation along with the appropriate extinction coefficient shown in **Table 1**:

$$\text{Number of thiols/avidin} = [\mathrm{r}\ \ A_{343}/(8.08 \times 10^3)] \times (A_{280} - 0.63\mathrm{r}\ \ A_{343})] \quad (1)$$

where ΔA_{343} = change in absorbance at 343 nm; E^{M}_{avidin} = molar extinction coefficient; and $0.63\Delta A_{343}$ = correction for the absorbance of pyridyldithiopropionate at 280 nm ***(24)***.

6. **Equation 1** allows the determination of the average number of moles of enzyme or antibody that can be conjugated with each mole of avidin (*see* **Note 6**). For a 1:1 proteinavidin conjugate, avidin should be modified with 1.2–1.5 thiols/mol. Thiolated avidin prepared by the above procedure can be stored in the presence of 2 m*M* sodium azide at 4°C for 4–6 wk.

3.1.2. Maleimide Derivatization of the Antibody or Enzyme

In this step, which should be completed prior to the deprotection of thiolated avidin, some of the amino groups from the antibody or enzyme are transformed into maleimide groups by reacting with the bifunctional crosslinker, SMCC. (*see* **Note 7**).

1. Dissolve or, if already in solution, dialyze the protein in 0.1 *M* phosphate buffer to obtain a concentration of 2–10 mg/mL. If the protein is an antibody, 11 mg are required to obtain an amount equimolar to 5 mg of avidin (*see* **Note 6**).

2. Prepare a **fresh** solution of SMCC by dissolving 5 mg in 0.5 mL of dry DMSO to obtain a 10 mg/mL solution. Vorte-mix or sonicate to assure that the reagent is completely dissolved.
3. While stirring, add an appropriate amount of SMCC solution to the protein solution to obtain a molar ratio of SMCC to protein of approx 10. (If 11 mg of an antibody is the protein used, 30 µL of SMCC solution is required.)
4. Continue stirring at room temperature for 1 h.
5. Dialyze the solution in 2 L of 0.1 *M* phosphate buffer at 4°C for 24 h, with four buffer changes using a membrane with a suitable molecular weight cutoff.

3.1.3. Deprotection of the Avidin Thiol Groups

This procedure is carried out immediately before reacting thiolated avidin with the maleimide derivative of the antibody or enzyme prepared in **Subheading 3.1.2.**

1. Dissolve 3 mg of TCEP in 0.3 mL of 0.1 *M* phosphate buffer.
2. Add 11 µL of TCEP solution to the thiolated avidin solution. Incubate for 15 min at room temperature.

3.1.4. Formation and Purification of the Conjugate

1. Add the thiolated avidin–TCEP mixture dropwise to the dialyzed maleimide derivatized protein solution with stirring. Continue stirring for 1 h at room temperature, followed by stirring overnight at 4°C.
2. Stop the conjugation reaction by capping residual sulfhydryls with the addition of NEM at a final concentration of 50 µ*M*. Dissolve 6 mg of NEM in 1 mL of DMSO and dilute 1:1000 in the conjugate reaction mixture. Incubate for 30 min at room temperature or overnight at 4°C (*see* **Note 8**). The conjugate is now ready for final purification.
3. Concentrate the avidin–protein conjugate mixture to 1–2 mL in a Centricon®-30 (Amicon, Beverly, MA) or equivalent centrifuge tube concentrator.
4. Pack appropriate size columns (e.g., 10 × 60 mm for approx 15 mg of final conjugate) with a degassed matrix suitable for the isolation of the conjugate from unconjugated reagents. If the protein conjugated is an antibody, a matrix such as Bio-Gel A-0.5 m is suitable. For other proteins, Sephadex G-200 or a similar column support may be appropriate, depending on the size of the protein–avidin conjugate.
5. Collect 0.5–1-mL fractions. The first protein peak to elute contains the conjugate, however the first or second fraction may contain some aggregates. Analyze each fraction absorbing at 280 nm for biotin binding and assay it for the antibody or enzyme activity. High-performance liquid chromatography (HPLC) may be also be performed for further purification, if necessary.

3.2. Radioiodination Using IODO-BEADS

The radioiodination procedure (*see* **Note 9**) described here uses IODO-BEADS, which contain the sodium salt of *N*-chlorobenzenesulfonamide immobilized on nonporous, polystyrene beads. Immobilization of the oxidizing agent

allows for easy separation of the latter from the reaction mixture. This method also avoids the use of reducing agents.

1. Wash six to eight IODO-BEADS twice with 5 mL of PBS. Dry the beads by rolling them on a clean filter paper.
2. Add 500 µL of PBS to the supplier's vial containing 8–10 mCi of carrier-free $Na^{125}I$ or $Na^{131}I$. Place the beads in the same vial and gently mix the contents by swirling. Allow the mixture to sit for 5 min at room temperature with the vial capped.
3. Dissolve or dilute streptavidin in PBS to obtain a final concentration of 1 mg/mL. Add 500 µL of streptavidin solution to the vial containing sodium iodide. Cap the vial immediately and mix the contents thoroughly. Incubate for 20–25 min at room temperature, with occasional swirling (*see* **Note 10**).
4. Carefully remove and save the liquid from the reaction vessel; this is the radioiodinated streptavidin solution. Wash the beads by adding 500 µL of PBS to the reaction vial. Remove the wash solution and add it to the radioiodinated streptavidin.
5. For purification, load the reaction mixture onto a 9 × 200 mm Bio-Gel P-6DG column packed in PBS (0.1% BSA may be added as a carrier to the PBS to reduce loss of streptavidin by adsorption to the column). Elute the column with PBS and collect 0.5-mL fractions. The first set of radioactive fractions (as determined by counting in a γ-ray counter) contain radioiodinated streptavidin, while the unreacted radioiodine elutes in the later fractions. Pool the radioiodinated streptavidin fractions.
6. Assessment of protein-associated activity with TCA acid precipitation:
   a. Dilute a small volume of the pooled radiolabeled streptavidin with saline solution such that 50 µL of the diluted solution has 10^4–10^6 cpm.
   b. Add 50 µL of the diluted streptavidin solution to a 12 mm × 75 mm glass tube, followed by 500 µL of a 0.1% BSA solution in saline.
   c. For precipitating the proteins, add 500 µL of 10% (w/v) TCA solution in saline.
   d. Incubate the solution for 30 min at room temperature and count the radioactivity of the solution for 10 min ("Total Counts").
   e. Centrifuge the tube at 500 g for 10 min and carefully discard the supernatant in a radioactive waste container.
   f. Resuspend the pellet in 1 mL of saline and count its radioactivity for 10 min ("Bound Counts").
   g. The percentage of radioactivity bound to streptavidin is determined using the following equation:

$$[(\text{Bound counts})/(\text{Total counts})] \times 100 = \% \text{ of radioactivity bound to streptavidin} \quad (2)$$

3.3. Avidin Affinity Matrices

3.3.1. CaptAvidin Biotin-Binding Protein Affinity Matrix

CaptAvidin agarose is available from Molecular Probes. For the preparation of this column avidin has been nitrated at the tyrosine sites involved with biotin binding. Nitration is performed to the extent that three of the four active sites

of avidin are modified and loose their binding activity for biotin. The fourth site allows binding of biotin at pH 4 with a K_a of 10^9 M^{-1} as reported by Morag et al. *(22)*. This monovalent form of modified avidin had been covalently attached to agarose to generate an affinity matrix that does not need the harsh eluting conditions necessary for the avidin or even the iminobiotin affinity columns. The biotinylated compounds are easily dissociated from the CaptAvidin, biotin-binding protein matrix by elution at pH 10.0.

3.3.2. Native Avidin Affinity Matrix

1. Wash 10 mL of sedimented 6% crosslinked agarose with distilled water on a glass or Buchner filter and remove excess water by suction.
2. Dissolve 14 mg of $NaBH_4$ in 7 mL of 1 *M* NaOH. Add this solution along with 7 mL of 1,4-butanediol-diglycidyl ether to the washed agarose, with mixing. Allow the reaction to proceed for 10 h or more at room temperature with gentle stirring.
3. Extensively wash the activated gel with distilled water on a supporting filter. The washed gel can be stored in water at 4°C, for up to 10 d.
4. Dissolve 50–100 mg of avidin in 10–20 mL of 0.2 *M* sodium carbonate, pH 9.5, and suspend the sedimented activated agarose gel in the same buffer to obtain a workable slurry.
5. Slowly drip the agarose slurry into the stirred protein solution and allow the binding to take place at room temperature for 2 d with continuous gentle mixing.
6. Wash the avidin–agarose mixture in PBS until the filtrate shows no absorbance at 280 nm. Store at 4°C in the presence of 0.02% sodium azide.

3.3.3. Monomeric Avidin Affinity Matrix

1. Filter the avidin–agarose matrix (from **Subheading 3.3.1., step 6**) on a glass or Buchner filter (or pack in a column) and wash 4× with two volumes of 6 *M* guanidine HCl in 0.2 *M* KCl, pH 1.5, to dissociate the tetrameric avidin.
2. Thoroughly wash the gel with 0.2 *M* potassium phosphate, pH 7.5, and suspend in 10 mL of the same buffer.
3. Add 3 mg of solid succinic anhydride to succinylate the monomeric avidin and incubate for 1 h at room temperature with gentle stirring.
4. Wash the gel with 0.2 *M* potassium phosphate, pH 7.5, pack in a column, and saturate the binding sites by running through three volumes of 1 m*M* biotin dissolved in the same buffer.
5. Remove biotin from the low-affinity binding sites by washing the column with 0.2 *M* glycine HCl, pH 2.0.
6. Store the column equilibrated in 20 m*M* sodium phosphate, 0.5 *M* NaCl, 0.02% sodium azide, pH 7.5. The column is now ready to use.
7. Load the column with the mixture to be purified. Elute any unbound protein by adding 20 m*M* sodium phosphate, 0.5 *M* NaCl, pH 7.5. Add biotin to the same buffer to obtain a final concentration of 0.8 m*M* to elute the biotinylated compound.
8. Regenerate the column after each run by washing with 0.2 *M* glycine HCl, pH 2.0.

4. Notes

1. A detailed procedure for the conjugation of fluorophores to antibodies has been recently published ***(25)***. This protocol can be modified for conjugation of fluorophores to avidin or avidin-related proteins by using a dye to avidin molar ratio of 5–8:1.
2. The conjugation reaction for oligonucleotides synthesized with a disulfide containing a protecting group, should be performed under nitrogen or argon. Deprotect the disulfide of the oligonucleotide using DTT. Add 1 mg of DTT to 140 µL of a 6 µ*M* oligonucleotide (21–33 mer) solution in 0.1 *M* phosphate buffer containing 5 m*M* ethylenediami–netetraacetic acid. Stir the solution at 37°C for 0.5 h. Purify the reaction mixture using a disposable desalting column. Combine the oligonucleotide-containing fractions with thiolated avidin prepared as described in **Subheading 3.1.1**. It should be noted that, in this case, conjugation occurs through the formation of a disulfide bond instead of a thioether bond. Disulfides are sensitive to reducing agents; however, they make reasonably stable conjugates, useful in most applications ***(26)***. Purify the conjugate as outlined in **Subheading 3.1.4**.
3. Using a molar ratio of SPDP to avidin of 5 yields one or two protected sulfhydryls per molecule of avidin. This range of thiols per mole is found to produce the best yield of a 1:1 conjugate.
4. Buffer and pH: The entire procedure for preparation of conjugates through thioether bonds can be performed at pH 7.5. (**Note:** Organic buffers containing amines, such as Tris, are unsuitable.) Antibodies or enzymes in PBS can be prepared for reaction with SMCC by adding 1/10 volume of 1 *M* sodium bicarbonate solution. This step eliminates dialysis and consequent dilution of the protein. The presence of azide at concentrations above 0.1% may interfere with the reaction of the protein with SMCC or of avidin with SPDP. Some gM antibodies denature above pH 7.2. They can, however, be conjugated in PBS at pH 7.0 by increasing the molar ratio of maleimide to antibody.
5. Peptides (20–25 amino acids) containing a single cysteine can also be conjugated to thiolated avidin by modifying the procedure described in **Subheading 3.1** and performing the reaction under argon or nitrogen ***(26)***. Peptide–avidin conjugate formation described here also involves the formation of a disulfide bond. For conjugation with 5 mg of avidin, dissolve 1.6 mg of a lyophilized cysteine-containing peptide in 900 µL of water–methanol (2:1 v/v) using 50 m*M* NaOH (a few microliters at a time) to improve solubility. Immediately prior to use, cleave any cystine-bridged homodimer that may be present by the addition of TCEP solution (10 mg/mL in 0.1 *M* phosphate buffer) to obtain a TCEP to peptide ratio of 3. Incubate for 15 min at room temperature. Purify the peptide–TCEP mixture using a disposable desalting column. Combine the peptide-containing

fractions with thiolated avidin prepared as described in **Subheading 3.1.1**. Purify the conjugate as described in **Subheading 3.1.4**.

6. Avidin and antibody or enzyme concentration: The concentration of avidin as well as that of the protein to be conjugated should be 2–10 mg/mL. The crosslinking efficiency and, consequently, the yield of the conjugate decreases at lower concentrations of the thiolated avidin and maleimide-derivatized protein. To obtain 1:1 conjugates, equimolar concentrations of avidin and the protein are desirable. However, most methods of conjug'ation will generate conjugates of different sizes, following the Poisson distribution. The size range obtained with the method described here is much narrower because the number of proteins reacting with each mole of avidin can be regulated by the degree of thiolation of avidin.
7. It is essential that the procedure described in **Subheading 3.1.2** be performed approx 24 h before the procedure described in **Subheading 3.1.3**, because the deprotected thiolated avidin and the maleimide derivative of the protein are unstable. Purification of the maleimide-derivatized protein by size exclusion chromatography can be performed more rapidly than dialysis; however, the former leads to dilution of the protein and a decrease in the yield of the conjugate.
8. If the molecule being conjugated to avidin is β-galactosidase or other free thiol-containing oligonucleotide or protein, NEM treatment is not performed.
9. Radioiodination of streptavidin uses procedures similar to those used for stable nuclides. However, some distinct differences remain, since radioiodinations are performed in dilute solutions. Also, the radioiodination mixture contains minor impurities formed during the preparation and purification of the radionuclide. Thus, optimization of reaction parameters is essential for performing radioiodination. This reaction is carried out in small volumes; it is therefore essential to ensure adequate mixing at the outset of the reaction. Inadequate mixing is often responsible for poor radioiodination yield.
10. Specific activity using the method described in **Subheading 3.2** is usually in the range of 10–50 mCi/mg and the protein-bound radioactivity obtained is >95%. Higher specific activity can be achieved by increasing the reaction time of **step 3** in **Subheading 3.2** by using more beads or by increasing the amount of radioiodine. However, one must bear in mind that at longer incubation times, the risk of damage to streptavidin or avidin is greater.
11. Storage and stability of avidin conjugates: Most avidin conjugates can be stored at 4°C or –20°C after lyophilization. Because of the variation in antibody structure, there is no general rule on the best method to store avidin–antibody conjugates, and the best conditions are determined experimentally.

Aliquoting in small amounts and freezing is generally satisfactory. Radiolabeled streptavidin is aliquoted (100 µL/tube) and stored at 4°C or −20°C until use.

MDPF Staining of Proteins on Western Blots

F. Javier Alba and Joan-Ramon Daban

1. Introduction

We describe a method for the detection of total protein patterns on polyvinylidene difluoride (PVDF) membranes using the fluorogenic dye 2-methoxy-2,4-diphenyl-3(2*H*)-furanone (MDPF) ***(1)***. This method is based on the fluorescent properties of this dye ***(2)***. As can be seen in **Fig. 1**, MDPF (**A**) and the hydrolysis product (**C**) are nonfluorescent; only the adduct **B** formed with the proteins is fluorescent. This makes unnecessary the destaining of the PVDF membrane after protein labeling. The whole process of staining with MDPF is completed in about 20 min. Wet membranes are translucent, allowing the visualization of MDPF labeled protein bands by transillumination with UV light (*see* **Fig. 2A**). Electrophoretic bands containing less than 10 ng of protein transferred to PVDF membranes can be detected after the reaction with MDPF.

This staining method is compatible with previous visualization of protein bands on the sodium dodecyl sulfate (SDS)-polyacrylamide gel with the noncovalent fluorescent dye Nile red (*see* Chapter 45). Thus, Nile red and MDPF staining can be performed sequentially. This allows the rapid monitoring of total protein patterns on both the electrophoretic gel and Western blot. In addition, MDPF staining allows further immunodetection of specific bands with polyclonal antibodies (*see* **Fig. 2B**). Finally, using the adequate conditions described in the Materials section, MDPF staining does not preclude the N-terminal sequence analysis of proteins in selected bands. A review about the psychochemical basis of MDPF staining has been published elsewhere ***(3)***.

2. Materials

All solutions should be prepared using electrophoresis-grade reagents and deionized water and stored at room temperature. Wear gloves to handle all

From: *The Protein Protocols Handbook, Third Edition*

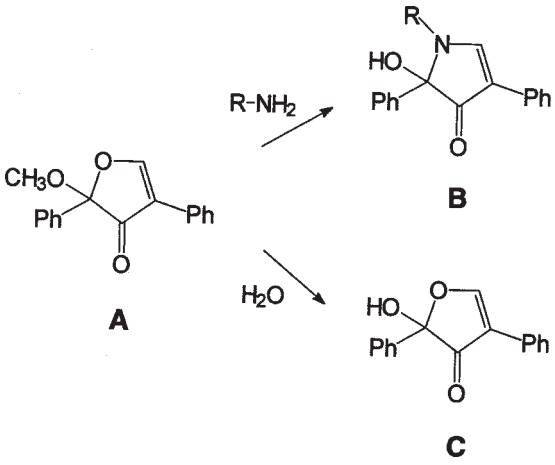

Fig. 1. According to Weigele et al. *(2)*, the reaction of MDPF **(A)** with primary amino groups of proteins produces the fluorescent adduct **(B)**; the excess reagent is hydrolyzed forming the nonfluorescent product **(C)**.

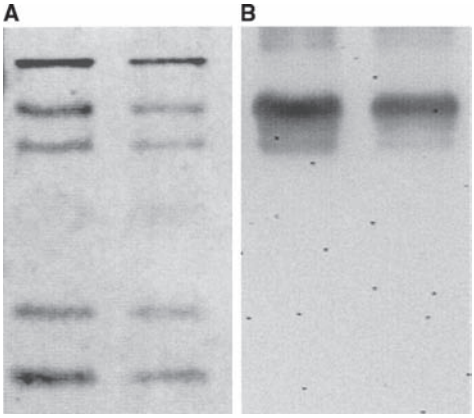

Fig. 2. **(A)** Example of MDPF staining of different proteins on PVDF membranes. The blot was equilibrated twice (5 min each time) in borate buffer and stained for 10 min with MDPF (*see* **Subheading 3.**). Proteins, from top to bottom, are: BSA, ovalbumin, glyceraldehyde-3-phosphate dehydrogenase, β-lactoglobulin, and α-lactalbumin; the amount of each protein loaded initially onto the SDS gel before electroblotting was 100 *(left lane)* and 50 *(right lane)* ng. (**B**) After staining with MDPF ovalbumin was immunodetected with the ECL system (Amersham).

reagents and solutions and do not pipet by mouth. Collect and dispose all waste according to good laboratory practice and waste disposal regulations.

1. MDPF: Concentrated stock (35 m*M*) in dimethyl sulfoxide (DMSO). This solution is stable for 1 wk at room temperature in a glass bottle wrapped in aluminum foil. **Handle this solution with care, DMSO is flammable and, in addition, this solvent may facilitate the passage of hazardous chemicals such MDPF through the skin.** MDPF can be obtained from Fluka (Bunch, Switzerland).
2. PVDF membranes (Bio-Rad Laboratories [Hercules, CA]).
3. Transfer apparatus (e.g., Mini-Trans-Blot Cell [Bio-Rad]).
4. Opaque plastic box for membrane equilibration and staining.
5. Orbital shaker.
6. Transilluminator equipped with midrange ultraviolet (UV) bulbs (~300 nm) to excite MDPF labeled proteins on blots (e.g., Foto UV 300 [Fotodyne Inc., Harland, WI] or the transilluminator included in the Gel Doc 1000 system from Bio-Rad). *See* Chapter 45 for details about protection from UV during transillumination.
7. Photography: We have used the Polaroid (Cambridge, MA) MP-4 camera with Polaroid instant film 667 and the CCD camera of the Gel Doc 1000 system (Bio-Rad). With both cameras use the Wratten (Kodak [Rochester, NY]) filters numbers 3 (yellow) and 47 (blue). Place filter 47 on top of filter 3. Store the filters in the dark and protect them from heat, intense light sources, and humidity. Store the Polaroid film at 4°C.
8. Immunodetection: Ovalbumin antiserum developed in rabbit (Sigma [St. Louis, MO]); ECL detection kit, including horseradish peroxirase-labeled antirabbit antibodies (Amersham [Buckinghamshire, UK]).
9. Transfer buffer: 25 m*M* Tris, 192 m*M* glycine, pH 8.3.
10. Borate buffer: 10 m*M* sodium borate, pH 9.5.
11. Phosphate-buffered saline: 80 m*M* Na_2HPO_4, 20 m*M* NaH_2PO_4, 100 m*M* NaCl, pH 7.4.

3. Method

After SDS-polyacrylamide gel electrophoresis (SDS-PAGE), the gels were stained with Nile red (*see* Chapter 45). Protein bands stained with Nile red can be transferred to PVDF membranes without being necessary to perform the destaining of the gel ***(1)***. The method described in this part gives all the details for the staining of the blotted proteins with MDPF. All operations are performed at room temperature. Handle blots by their edges using stainless steel forceps.

1. After electrophoresis and Nile red staining, equilibrate the gel (8 × 6 × 0.075 cm) in 100 mL of transfer buffer for 15 min. Immerse sequentially the PVDF membrane in 20 mL of methanol for 5 s, in 100 mL of water for 2–3 min, and finally in 100 mL of transfer buffer for 10 min.
2. Assemble the gel and the membrane in the blotting apparatus and fill the tank with transfer buffer. Perform electroblotting at 100 V for 1 h.
3. Following transfer, equilibrate the blot twice (for 5 min each time) in 100 mL of borate buffer. Use an orbital shaker at about 75 rpm.

4. Incubate the blots for 10 min in a staining solution containing 40 mL of borate buffer and 0.2 mL of the concentrated stock (35 m*M*) of MDPF in DMSO (*see* **Note 1**); use an orbital shaker (~75 rpm). The plastic box containing the blot should be covered with aluminum foil during staining. The staining conditions compatible with N-terminal sequencing of selected bands are indicated in **Note 2**.
5. After staining, rinse the blot briefly (for about 10 s) with borate buffer.
6. Place the wet membrane (*see* **Note 3**) on the UV transilluminator. Focus the camera (Polaroid or charge coupled device [CCD]) with the help of lateral illumination with a white lamp, place the optical filters indicated in **Subheading 2.7.** (*see* **Note 4**) in front of the camera lens and, in the dark, turn on the transilluminator and photograph the blot (*see* **Note 5**). Finally, turn off the transilluminator.
7. Develop the Polaroid film for the time indicated by the manufacturer (*see* **Note 6**). The images obtained with the CCD camera are stored directly in the computer and can be printed afterwards (*see* **Note 7**).
8. After photography, if specific bands have to be immunodetected (*see* **Note 8**), equilibrate the stained blot for 15 min in phosphate buffered saline containing 0.1% Tween 20, and then perform the ECL immunodetection according to the manufacturer's instructions. An example of immunodetection with the ECL system (*see* **Subheading 2.8.**) after MDPF staining is presented in **Fig. 2B.**
9. Mark with a soft pencil the stained protein bands (*see* **Note 2**) to be sequenced (*see* **Note 9**). Use a UV transilluminator to visualize the fluorescent bands. Cut out of the membrane the selected bands and apply them to the sequencer (we have used an LF3000 Automatic Sequencer [Beckman, Palo Alto, CA], *see* **Ref. *1***).

4. Notes

1. The reaction of MDPF with different proteins in solutions containing 10 m*M* sodium borate, pH 9.5, is completed in <10 min ***(4)***.
2. When the protein bands have to be used for sequencing (*see* **Note 9**), use a lower concentration of MDPF (0.1 mL of the concentrated solution of MDPF in 100 mL of borate buffer) and reduce the incubation time to 2 min. The sensitivity obtained under these conditions is lower than that obtained using the normal staining conditions (*see* **Note 5**), but it is high enough to detect bands containing protein amounts suitable for microsequencing by Edman degradation.
3. Membranes must be wet during visualization and imaging. Wet membranes are highly translucent, but dry membranes are opaque and reduce dramatically the sensitivity ***(1)***.
4. Wratten filters nos. 3 and 47 allow the visualization of the blue fluorescence emission from MDPF-labeled bands. In addition, these filters eliminate the light coming from the transilluminator and the background fluorescence produced by Nile red adsorbed on the surface of the PVDF membrane during the electrotransfer.

5. Electrophoretic bands containing 5–10 ng of protein can be seen in the images obtained with Polaroid film and the CCD system. However, considering that the yield of protein transfer from the gel to the membrane is relatively low, the actual sensitivity is presumably higher. In fact, we have observed that when proteins are transferred directly to the membrane using a slot-blotting device, 0.5 ng of protein per slot can be detected ***(1)***.
6. The development time of Polaroid film is dependent on the film temperature. Store the film at 4°C (*see* **Subheading 2.7.**), but allow them to equilibrate at room temperature before use.
7. Ink jet printers with glossy paper yield images with photographic quality (*see* e.g., **Fig. 2A**).
8. Our results ***(1)*** have shown that the covalent modification of blotted proteins produced by the reaction with MDPF does not alter the antigenic properties that allow the binding of polyclonal antibodies.
9. Our results ***(1)*** have shown that the staining conditions indicated in **Note 2** do not preclude further sequencing reactions with a high yield. Since MDPF reacts with primary amino groups of proteins (*see* **Fig. 1**), probably including N-teminal groups, these results indicate that under these staining conditions the reaction with MDPF is not complete.

Copper Iodide Staining of Proteins and Its Silver Enhancement

Douglas D. Root and Kuan Wang

1. Introduction

Copper iodide staining and silver-enhancement is designed to quantify proteins adsorbed to solid surfaces such as nitrocellulose, nylon, polyvinylidene difluoride (PVDF), silica, cellulose, and polystyrene ***(1–5)*** and has important applications in Western blotting and thin layer chromatography ***(3,6)***. The binding of cupric ions to the backbone of proteins under alkaline conditions and their reduction to the cuprous state is the basis of several protein assays in solution including the biuret, Lowry, and bicinchoninic acid methods (***1–3,7*** and *see* Chapters 2–4). In the case of copper iodide staining, the protein binds copper iodide under highly alkaline conditions. This protein assay demonstrates sensitivity, speed, reversibility, low cost, and the lack of known interfering substances (including nucleic acid; **refs.** ***4,5***). Copper iodide staining is sufficiently sensitive to permit the quantification of proteins adsorbed to microtiter plates ***(5)***. The information is particularly useful for the quantitative interpretation of enzyme-linked immunosorbent assay (ELISA) and protein binding experiments. The precision of the determination of protein adsorbed to the microtiter plate by copper iodide staining is typically about 10–15%. The high sensitivity of copper iodide staining (about 40 pg/μL) may be increased several fold by a silver-enhancement procedure that allows the detection of protein down to about 10 pg/μL, which is more sensitive than common solution-based assays ***(7)***. The sensitivity of the assay can be increased by repeated applications of the protein on a membrane to concentrate it. Protein concentrations may be estimated from copper iodide staining from very dilute protein solutions or when only small amounts of a precious protein are available such as for the analysis of chromatography fractions.

2. Materials

2.1. Copper Iodide Staining

1. Prepare the copper iodide staining reagent by mixing 12 g of $CuSO_4 \cdot 5H_2O$, 20 g of KI, and 36 g of potassium sodium tartrate with 80 mL of distilled water in a glass beaker (*see* **Note 1**). As the slurry is vigorously stirred, 10 g of solid NaOH is slowly added. The suspension becomes warmer and changes color from brown to green to dark blue. After the NaOH is completely dissolved, the beaker is allowed to cool at room temperature for 30 min without stirring to allow the brownish-red precipitate to settle. Then 70 mL of solution is aspirated from the top to leave approx 50 mL of reagent with precipitate. The reagent is stable and may be stored in a sealed bottle at room temperature for at least 1 mo or at 4°C for at least 1 yr (*see* **Note 2**).
2. Prepare the copper iodide stain remover solution with 0.19 g of Na_4EDTA H_2O, 0.28 g of $NaH_2PO_4 \cdot H_2O$, and 2.14 g of $Na_2HPO_4 \cdot 7H_2O$ in 100 mL of deionized water.
3. Nitrocellulose (e.g., BA85, Schleicher & Schuell, Keene, NH), PVDF (e.g., PVDF, Millipore Corporation, Bedford, MA), or nylon blotting paper (e.g., Zeta probe, Bio-Rad Laboratories, Richmond, CA; *see* **Note 3**).

2.2. Silver-Enhanced Copper Staining (SECS)

1. Prepare the silver enhancing reagent just prior to use by dissolving 0.1 g of $AgNO_3$, 0.1 g of NH_4NO_3, and 7 µL of 5% (v/v in water) β-mercaptoethanol in 100 mL of distilled water. After the other components are dissolved and immediately before use add 2.5 g of Na_2CO_3.
2. Prepare the SECS stain remover by dissolving 33.2 g of KI in 100 mL of distilled water (final concentration, 2 *M* KI).

2.3. Copper Iodide Microtiter Plate Assay

1. Polystyrene 96-well microtiter plates (e.g., Nunc Immuno-Plate, Denmark; Titertek 76-381-04, McLean, VA; or Immulon 1 and 2, Dynatech Laboratories, Chantilly, VA).
2. Nitrocellulose membranes (e.g., BA85, Schleicher & Schuell, Keene, NH).
3. Household 3-in-one lubricating oil (Boyle-Midway, New York, NY).
4. A standard single hole puncher (6 mm diameter).
5. Some form of densitometer is required such as a flatbed scanner or video camera and framegrabber with image analysis software (*see* **Note 4**).

3. Methods

3.1. Copper Iodide Staining

1. Stir the copper iodide staining reagent vigorously at room temperature immediately prior to use. The reagent should be a fine slurry.
2. Rock the copper iodide staining reagent over the dried protein blot (or Western blot) for at least 2 min (but not more than 5 min; *see* **Note 5**) as the reddish-brown bands appear on the blot.

3. Gently dip the stained blot up and down in three beakers of deionized water and then allow the blot to dry (*see* **Note 6**).
4. The stained blot then may be quantified by densitometry (*see* **Note 7**) and photographed for documentation.
5. The staining pattern is stable at room temperature for at least 1 yr.
6. If greater sensitivity is desired, the blot may be used directly in the silver-enhanced copper staining procedure (*see* **Subheading 3.2**).
7. If subsequent immunostaining on the same blot is required, destain for 15 min with gentle agitation in the copper iodide stain remover prior to immunostaining.

3.2. Silver-Enhanced Copper Staining (SECS)

1. Rock a nitrocellulose protein blot stained with copper iodide (*see* **Subheading 3.1**) for 5 min in freshly prepared silver-enhancing reagent until the bands become dark black.
2. Dip the blot in a 1-L beaker of deionized water and stored in the dark to dry (to prevent background development).
3. The blot then may be quantified by densitometry and photographed for documentation.
4. If subsequent immunostaining on the same blot is required, destain for 30 min with gentle agitation in the SECS stain remover prior to immunostaining (*see* **Note 8**).

3.3. Copper Iodide Microtiter Plate Assay

1. Adsorb the protein of interest to duplicate microtiter plates and note the volume (*V*) that was used to adsorb the protein in each well (*see* **Note 9**). One of the microtiter plates is for copper iodide staining and the other is for quantitative ELISA or binding experiments. The microtiter plate for copper iodide staining contains protein adsorbed to only a few of the wells (e.g., 4–16 wells; see the schematic diagram and **Note 10**).
2. Create a standard curve by dot blotting approx 5–100 ng of the protein of interest per 5-µL drop onto nitrocellulose paper and allow to air dry. Blanks are dotted with equal volumes of buffers.
3. Stain both the nitrocellulose paper and the microtiter plate with adsorbed protein by the copper iodide staining procedure (*see* **Subheading 3.1**).
4. Use the hole puncher to excise stained dots from the nitrocellulose membrane and place them stained side down into blank wells on the microtiter plate (*see* **Note 11**).
5. Use the hole puncher to excise blank nitrocellulose circles and place them in microtiter plate wells containing copper iodide-stained protein and also in some blank wells to determine the background density (*see* **Fig. 1**).
6. For transmittance densitometry, first add 5 µL per well of Household 3-in-one oil to make the nitrocellulose translucent, thus reducing the background. For reflectance densitometry, the bottom of the microtiter plate may be scanned directly (the stained sides of the nitrocellulose must all be face down in the wells).

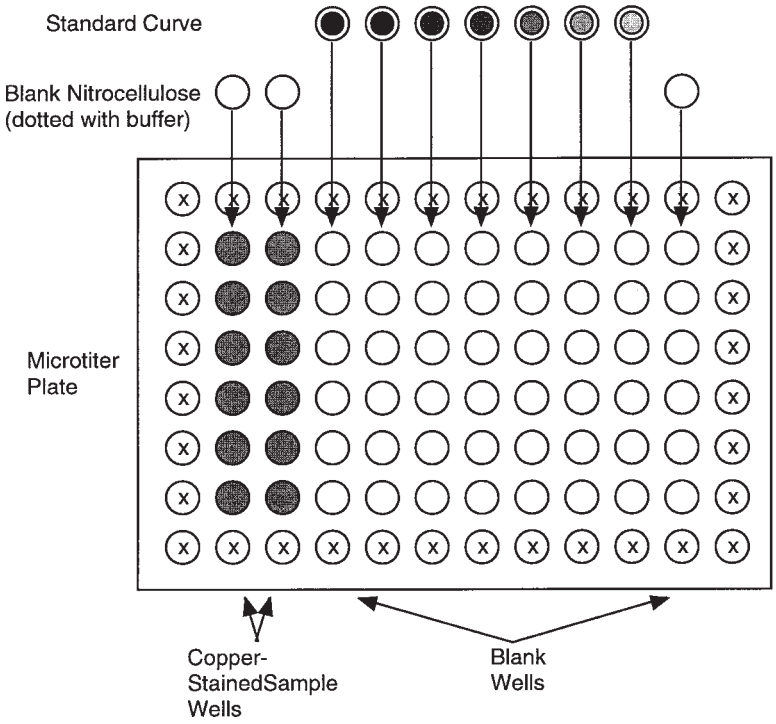

Fig. 1. Schematic diagram of the assembly of a microtiter plate for the copper iodide staining assay. Avoid wells marked with "x" due to possible distortions from edge effects.

7. Measure the mean optical density and total area of the known amounts of stained protein (adsorbed to nitrocellulose) and construct a standard curve of mean optical density vs ng/mm^2 of protein (*see* **Note 12**).
8. Measure the mean optical density of stained sample protein (adsorbed to microtiter plate) and compare to the standard curve to determine the concentration of protein (in ng/mm^2) on the microtiter plate well.
9. Calculate the total area of the stained sample protein (adsorbed to microtiter plate) on the microtiter plate well from the equation:

$$\text{Total Area} = 3.14r^2 + (2v/r)$$

in which r (in mm) is the radius of the cylindrical flat-bottom well, and V (in µL) is the volume that was used to adsorb protein to the well. The Total Area (typically 94.7 mm^2 for a 100-µL volume applied to a plate with a 3.25-mm well radius) multiplied by the surface density (in ng/mm^2) of the sample protein yields the amount of protein (in nonograms) adsorbed to each microtiter plate well.

4. Notes

1. Proportions of sodium and potassium ions in the copper iodide staining reagent are important. Thus potassium sodium tartrate (sodium potassium tartrate) should not be substituted with, for instance, sodium tartrate.
2. The copper iodide staining reagent can generally be reused two or three times but will eventually become less sensitive.
3. Copper iodide staining reagent stains proteins adsorbed on most solid phase adsorbents including nitrocellulose, nylon, PVDF, silica, cellulose, and polystyrene. PVDF requires that the blot be prewetted in 50% methanol immediately prior to staining, and some smearing of bands can occur at high loads of protein with PVDF. Copper iodide staining of silica leaves an uncharacteristic bluish background. Comparisons of the sensitivities of copper iodide staining and SECS with other stains on a variety of common supports are illustrated in **Table 1**.
4. Microtiter plate readers are to be avoided for quantitative measurements, because they are usually not sensitive enough (copper iodide staining yields OD ≤ 0.1) and do not sample a large enough area of the stained surface to detect any nonuniformity in the staining density.
5. Exceeding a staining time of 5 min can both damage nitrocellulose membranes and lead to solubilization of adsorbed protein. A staining time of 2 min is optimal.
6. Washing of microtiter plates should be handled gently by dipping in beakers of deionized water. Vigorous washing procedures often lead to nonuniform protein distribution and consequent uneven staining of microtiter plates.

Table 1
Comparison of the Detection Limits (in ng/1μL) of Protein Stains[a]

Stain	Nitrocellulose	PVDF	Nylon	Silica	Cellulose
SECS	0.01	0.071	1	5	0.02
Copper iodide	0.04	0.014	5	20	0.04
Kinetic silver staining[b]	40	None	300	70	0.01
Coomassie[c]	9	150	None	40	300
Eu metal chelate[d]	9	150	2000	70	150

[a]Two-fold serial dilutions of bovine albumin were dotted in 1-μL spots on the indicated support, then dried, stained, and evaluated visually.

[b]Performed as described in Chapter 8.

[c]Performed as described in **ref. *8***.

[d]Performed as described in **ref. *9***. The Eu metal chelate stain was visualized over a UVP (Upland, CA) 302 nm UV transilluminator. When spots were excised and quantified by time-resolved fluorescence in an SLM Aminco Bowman II spectrometer, a detection limit of 3 ng/1 μL was observed on nitrocellulose consistent with reported values ***(9)***.

7. An example of a low cost densitometer is a desktop flatbed scanner, color Apple Macintosh computer, and NIH Image software (public domain, by Wayne Rasband; further details are available by personal communication).
8. SECS may be removed by concentrations of KI that are less than 2 *M* but will require longer incubations (e.g., 90 min for 0.5 *M* KI).
9. The wells on the edge of microtiter plates should be avoided for quantitative measurements because they tend to yield less accurate numbers.
10. Nitrocellulose quantitatively binds most proteins that are dot blotted onto it and retains them well throughout copper iodide staining.
11. If there is a problem with static repulsion and transmission densitometry will be used, the Household 3-in-one oil (**Subheading 3.3., step 6**) may be first applied to the microtiter plate well to release the static charge.
12. Quantitative measurements of copper iodide staining should be done at least in triplicate because of the relatively high (10–15%) standard deviation of the results.

Detection of Proteins on Blots Using Direct Blue 71

Wei-Tao Cong, Sun-Young Hwang, Li-Tai Jin, Jung-Kap Choi

1. Introduction

The visualization of proteins blotted onto transfer membranes has important applications for the localization of bands prior to further steps and for the comparison of individual proteins detected by immunostaining with total proteins ***(1,2)***. Consequently, sensitive, convenient, and quantitative total protein stained on membranes is required ***(3,4)***. Among transfer membranes available (NC, PVDF, and nylon), NC appears to be the material of choice because it is relatively inexpensive and requires a fast and simple step for blocking from nonspecific binding ***(5)***. The widely used methods for staining of NC membranes are Amido Black ***(2,6)***, Coomassie Blue ***(7,8)***, India ink ***(9,10)***, and Ponceau S ***(11,12)*** staining (*see* **Note 1**). However, none of them is as sensitive as silver stain on gels ***(4)***. Metal stains (colloidal gold stain, silver stain) of membranes can provide the highest sensitivity, but they have certain disadvantages: long incubations, troublesome preparation, an expensive metal, or irreversible protein staining ***(4,13)***. Copper iodide staining is also sensitive, but complicated steps are required to prepare reagents. Furthermore, this method employs strongly alkaline solution of pH 13.8, resulting in membrane impairment after incubation for more than 5 min ***(14)***. Recently, reversible metal complex stains were introduced, which are compatible with subsequent evaluation ***(15-17)***.

We have attempted to develop a dye-based staining method with sensitivity, convenience, and economy. DB71 (C.I. 34140) produces blue color in water with an absorption maximum at 594 nm and possesses excellent light fastness (Product Information of Organic Dyestuffs Co., East Providence, RI). No hazard has been connected with the use of the dye under normal conditions. The structure of the dye consists of four biphenyls with a hydroxyl, a primary amine, three azo, and four sulfonate groups (*see* **Fig. 1**). The relatively strong hydrophobicity

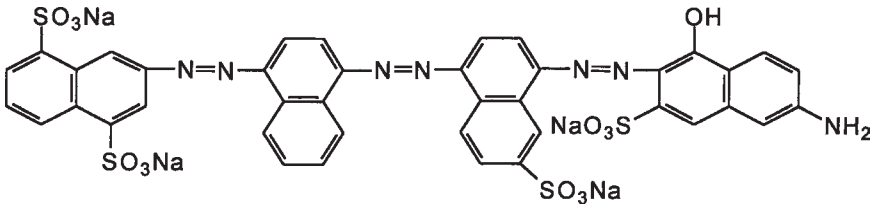

Fig. 1. Chemical structure of DB71.

Table 1
Comparison of Staining Procedures for Protein Blots[a]

Dyes	Conditions	Approx. detection limits (ng)
0.05% Coomassie Blue R-250	S: 50% MeOH–7% HAc (10 min) D: 10% MeOH–14% HAc (overnight at 65°C)	100[d]
0.1% Amido Black 10B	S: 45% MeOH–10% HAc (10 min) D: 10% HAc (15 min)	50[d]
0.1% Ponceau S	S: 5% HAc (3 min) W: Water[b]	100[d]
0.05% CPTS	S: 12 m*M* HCl (~1min) W: 12 m*M* HCl[b]	10[d]
0.008% DB71	S: 40% EtOH–10% HAc (5 min) W: 40% EtOH–10% HAc[c]	5–10 (our work)

[a]The staining procedures of Coomassie Blue ***(9)***, Amido Black ***(6)***, and CPTS ***(21)*** were performed as in references cited. Ponceau S staining followed the product information of Sigma Chemical Co.
[b]Membranes were briefly washed in several changes of the solutions to remove excess dye.
[c]Membranes were washed once in the solution, since background was almost clear.
[d]Approximate detection limits are from the references cited, where they were determined by comparing protein slot blots stained by these methods.
S, staining; D, destaining; W, washing.

imparted by four biphenyl rings of DB71 is expected to improve the low sensitivity observed in Ponceau S staining (*see* **Notes 2** and **3**; **Table 1**). On the basis of this reasoning, DB71 appears to be a satisfactory candidate for protein staining on membranes (*see* **Notes 4** and **5**; **ref. *18***).

2. Materials

1. Stock dye solution: 0.1% [w/v] DB71. Dissolve 0.1 g of DB71 (dye content, 50%; from Aldrich) in 100 mL of distilled water. The stock solution is stable for months at room temperature.
2. Working dye solution: 0.008% [w/v] DB71. Dilute 4 mL of stock dye solution to 50 mL of washing solution (*see* **Note 6**). The working solution is stable for weeks at room temperature.
3. Washing solution: For 1 L of solution, mix 500 mL of distilled water with 400 mL of absolute ethanol (EtOH) and 100 mL of acetic acid (HAc) (*see* **Notes 7–9**).
4. Destaining solution: For 1 L of solution, mix 350 mL of distilled water with 500 mL of absolute EtOH and 150 mL of 1 *M* sodium bicarbonate (*see* **Note 10**).

3. Methods

3.1. Membrane Staining

1. Prior to staining, wet protein transferred membranes, if the membranes had been dried: wet NC membranes for a minute in distilled water, and wet PVDF membranes first in MeOH, then rinse them in distilled water.
2. Immerse membranes gently in working solution for 5 min (*see* **Note 11**).
3. Rinse membranes briefly with washing solution for seconds.
4. Allow membranes to be air-dry or wrap them up with Saran Wrap to stay wet (*see* **Note 12**).
5. Keep membranes in a refrigerator for further uses.

3.2. Dye Removal

1. After staining, if necessary, incubate membranes for 5–10 min in destaining solution (*see* **Note 13**).
2. Rinse membranes briefly with distilled water.
3. Proceed to next steps (*see* **Note 14**).

4. Notes

1. Both Coomassie Blue and Amido Black are inferior to DB71 stain in terms of requiring destaining solution and lengthy time (*see* **Table 1**), and giving lower sensitivity on PVDF. While DB71 staining is based on dye binding to proteins under acidic conditions similar to that in Amido Black ***(2,6)***, Coomassie Blue ***(7,8)***, and Ponceau S ***(11,12)*** staining methods.
2. The detection limits of DB71 staining for slot blot and electroblot are 5–10 ng of protein on NC, which is 10-fold more sensitive than Ponceau S staining that detected down to 50–100 ng. DB71 can also stain proteins bound to PVDF; however, background is colored a little, possibly due to the relatively increased hydrophobicity in PVDF, comparing with NC. DB71 staining detects down to 10–20 ng of protein on PVDF, whereas Ponceau S staining does to 100 ng of protein.

3. DB71 is comparable with copper phthaloryanine-3,4' ,4",4 "'-tetrasulfonic acid (CPTS) (*see* **Figs. 2C** and **G**) reported as the highest sensitive dye-binding staining method ***(19)***, in its sensitivity, rapidity, and reversibility. The bluish violet color of DB71 stained proteins gives better band contrast than the turquoise blue CPTS stained ones, allowing easy photography without any filter system; moreover, DB71 is much cheaper than CPTS.
4. DB71 possesses the properties of an ideal protein stain, including high and nonspecific affinity for protein; rapid staining; convenient application conditions compatible with matrix material and protein; large molar absorptivity with the absorption maximum in blue region; and safe to use ***(19)***.
5. It is noticeable that among the methods tested, DB71 staining allows the highest band contrast on PVDF with a similar staining intensity as on NC (*see* **Figs. 2D** and **H**).
6. At concentrations < 0.002%, the staining intensity of protein bands is weak; at concentrations > 0.01%, unwanted background coloration is obtained.
7. The binding of DB71 to proteins is favored under acidic condition: It is quite probable that in DB71 staining solution most carboxyl groups of proteins

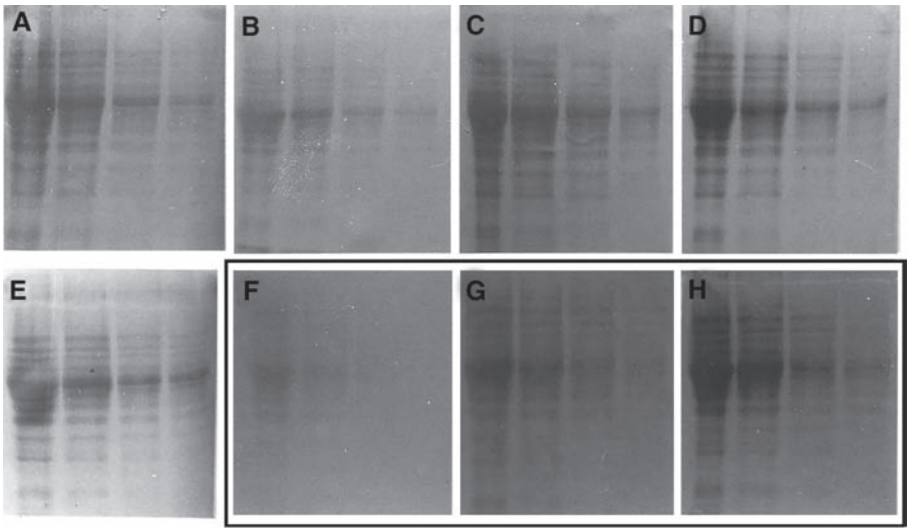

Fig. 2. Comparison of DB71 staining with various dye-based staining methods. Blots contained a whole cell lysate of HL-60, a human promyelocytic leukemia cell line, that 2×10^6 cells were lysed in 150 µL of lysis buffer. Four serial half dilutions of the lysates were separated on 10% SDS-PAGE and transferred onto two types of membranes (**A–E**, NC, **F–H**, PVDF). Transferred proteins were visualized by Coomassie Blue **(A)**, Ponceau S **(B** and **F)**, CPTS **(C** and **G)**, DB71 **(D** and **H)**, and Amido Black **(E)**. All staining procedures were as described in **Table 1**.

are protonated and thus there is no electrostatic repulsion between proteins and the dye molecule containing four sulfonate groups. In the acidic solutions, ionic interactions between maximally protonated amino moieties of proteins and anionic functional groups of the dye might primarily contribute to the stain. Additional forces for the staining could involve hydrophobic interaction, hydrogen bond, and Van der Waals forces which have been reported to be the binding mode of proteins to most anionic dyes ***(20)***.

8. For the visualization of proteins in gels and membranes, most of dye-based protein staining methods have generally employed MeOH as a component of staining/destaining solution ***(2,6-9)***, despite its toxicity. DB71 can use EtOH instead of MeOH, without any loss of staining intensity by the dye.
9. DB71 staining is influenced by the concentration of EtOH. Less than 20% EtOH causes background coloration; more than 60% EtOH not only reduces band intensity, but also causes distortion of the membranes.
10. The removal of DB71 from stained bands requires incubating membranes in ethanol–1 *M* sodium bicarbonate–water (10:3:7) for a few minutes. Complete destaining, however, may take up to an hour or more, depending on the amount or nature of proteins of interest. The membranes can be repeatedly stained and destained, with no apparent loss of sensitivity.

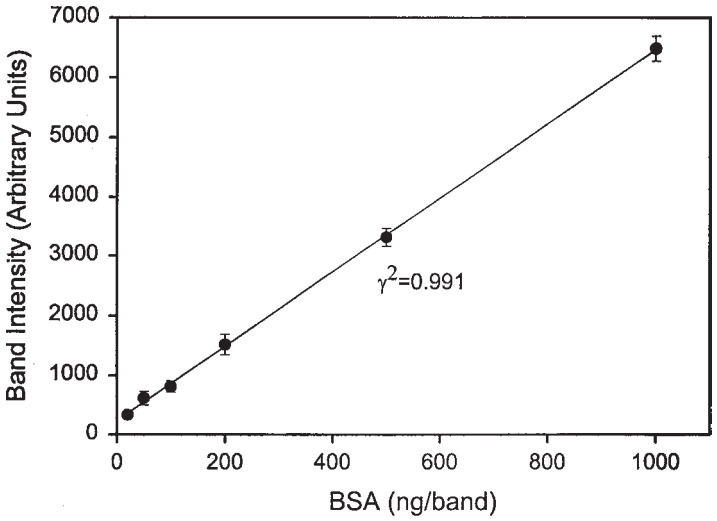

Fig. 3. Standard assay of BSA after DB71 staining. The peak areas of the densitometric measurements of BSA representing the relative band intensities were used to obtain a response curve (*see* **Note 17**). Electroblotted BSA was stained for 5 min in 0.008% DB71 solution and washed briefly with 40% EtOH–10% HAc, and quantified by using a TINA 2.09 software program. Data are expressed as the means ± SEM of the mean of triplicate of the experiments.

11. In DB71 staining solution containing 0.008% DB71 in 40% EtOH–10% HAc, major protein bands appear in usually 1–2 min, with minor protein bands being detected within 5 min.
12. A higher band contrast for photography is obtained when the stained membrane keeps wet rather than dry. The stain remains stable for several months in a refrigerator.
13. DB71 staining is applicable to a subsequent immunostaining without removing the dye from developed bands. However, we recommend the dye removal, prior to the immunodetection of small amounts of a particular protein.
14. DB71 staining can also be applied for quantification purposes with simplicity and convenience over the conventional spectrophotometric procedures. The relationships between peak area representing band intensity after DB71 staining and the protein amounts hold a linearity between 20 and 1000 ng, with a correlation coefficient of 0.991 (*see* **Fig. 3**).

Detection of Proteins on Western Blots Using Colorimetric and Radiometric Visualization of Secondary Ligands

Nicholas J. Kruger

1. Introduction

Western blotting (immunoblotting) provides a simple and effective method for identifying specific antigens in a complex mixture of proteins. Initially, the constituent polypeptides are separated by SDS-polyacrylamide gel electrophoresis, or a similar technique, and are then transferred either electrophoretically or by diffusion onto a nitrocellulose filter. Once immobilized onto the membrane, specific polypeptides can be identified by probing with antibodies that bind to antigens retained on the filter and subsequently visualizing the resulting antibody-antigen complex. This chapter describes conditions suitable for binding antibodies to immobilized proteins and methods for locating these antibody-antigen complexes using appropriately labelled ligands. These methods are based on those of Blake et al. ***(1)***, Burnette ***(2)*** and Towbin et al. ***(3)***.

Although there are many techniques for visualizing antibodies bound to nitrocellulose, most exploit only two different types of ligand; one is protein A and the other is an antibody raised against immunoglobulin G (or other class of immunoglobulin) from the species used to generate the primary antibody. Protein A, from the cell wall of *Staphalococcus aureus*, specifically binds the Fc region of immunoglobulin G (IgG) from many mammals ***(4)***. Thus, this compound provides a general reagent for detecting antibodies from several sources. With this ligand, as little as 0.1 ng of protein may be detected using the simple techniques described here, though the precise amount will vary with the specific antibody titer ***(5)***. The principal disadvantage of protein A is that it fails to bind effectively to major IgG sub-classes from several experimentally

Table 1
Variation in species specificity of various immunogobulin-binding proteins

Species	Immunoglobulin class	Affinity of binding by			
		Protein A	Protein G	Protein A/G	Protein L
Human	IgG1*	+++	+++	+++	+++
	IgG2	+++	+++	+++	+++
	IgG3	–	+++	+++	+++
	IgG4	+++	+++	+++	+++
	IgM	–	–	–	+++
	IgA	–	–	–	+++
	IgE	–	–	–	+++
	IgD	–	–	–	+++
Mouse	IgG1*	+	++	++	+++
	IgG2a	+++	+++	+++	+++
	IgG2b	++	++	+++	+++
	IgG3	+	++	+++	+++
Rat	IgG1	–	++	++	+++
	IgG2a	–	+++	+++	+++
	IgG2b	–	+	+	+++
	IgG2c	+	+++	+++	+++
Cow	IgG	++	+++	+++	–
Cat	IgG	+++	–	+++	n.d.
Chicken	IgG	–	+	+	++
Dog	IgG	+++	+	+++	+
Goat	IgG	+/–	++	+++	–
Guinea pig	IgG	+++	+	+++	++
Hamster	IgG	+	++	++	+++
Horse	IgG	+/–	–/+++	+++	+/–
Pig	IgG	+++	+	+++	+++
Rabbit	IgG	+++	++	+++	+
Sheep	IgG	+/–	+++	+++	–

The binding affinities for immunoglobins from different sources is indicated as follows: –, no binding; +, low; ++, moderate; +++, high; n.d., not determined. * Denotes major sub-class of IgG. Complied from information provided by Pierce Co. (technical resource TR0034.1) and data in references ***4, 9-11*** and references therein.

important sources, such as rat, mouse, goat and sheep (*see* **Table 1**). For antibodies raised in such animals a similar method using derivatives of other bacterial immunoglobulin-binding proteins may be suitable (*see* **Note 1**). Alternatively, antibody-antigen complex bound to the nitrocellulose filter may be detected using a secondary antibody raised against IgG from the species used

to generate the primary antibody. An advantage of such secondary antibody systems is that they bind only to antibodies from an individual species, and this specificity may be exploited to identify multiple polypeptides on a single nitrocellulose membrane (***6,7***).

Strategies for visualizing the ligand bound to the antibody-antigen complex on the membrane generally fall into three broad categories. One is direct detection, in which the ligand itself is tagged with some readily detectable marker, typically a radioactive label such as ^{125}I, or gold particles or a fluorescent dye. The second is indirect detection, in which the ligand is linked to a marker enzyme and visualization is dependent on localizing a product of the reaction catalysed by the enzyme activity. The third is a hybrid strategy in which the ligand is conjugated to biotin and this, in turn, is detected using a marker enzyme linked to avidin (or streptavidin).

The marker enzymes most commonly used for detection are alkaline phosphatase and horseradish peroxidase. Both can be linked efficiently to other proteins, such as antibodies, protein A and avidin, without interfering with the function of the latter proteins or inactivating the enzyme. Moreover, a broad range of synthetic substrates have been developed for each of these enzymes. Enzyme activity is normally visualised by incubating the membrane with an appropriate chromogenic substrate which is converted to a colored, insoluble product. The latter precipitates onto the membrane in the area of enzyme activity, thus identifying the site of the antibody-antigen complex (*see* **Note 2**).

Both antigens and antisera can be screened efficiently by western blotting. Probing of a crude extract after fractionation by SDS-polyacrylamide gel electrophoresis can be used to assess the specificity of an antiserum. The identity of the antigen can be confirmed using a complementary technique, such as immunoprecipitation of enzyme activity. This information is essential if the antibodies are to be used reliably. Once characterized, an antiserum may be used to identify antigenically related proteins in other extracts using the same technique. Examples of the utility and application of western blotting have been reviewed by Kurien and Scofield ***(8)***.

2. Materials

1. Electrophoretic blotting system, such as Trans-Blot or Mini Trans-Blot supplied by Bio-Rad.
2. Nitrocellulose paper: 0.45 µm pore size (*see* **Note 3**).
3. Protein A derivatives.
   a) Alkaline phosphatase-conjugated protein A obtained from Sigma-Aldrich Co. Dissolve 0.1 mg in 1 mL of 50% (v/v) glycerol in water. Store at −20°C.
   b) Horseradish peroxidase-conjugated protein A obtained from Sigma-Aldrich Co. Dissolve 0.1 mg in 1 mL of 50% (v/v) glycerol in water. Store at −20°C.
   c) ^{125}I-labelled protein A, specific activity 30 mCi/mg. Affinity-purified protein A, suitable for blotting, is available commercially (*see* **Note 4**). **^{125}I emits**

γ-radiation. Be sure that you are familiar with local procedures for safe handling and disposal of this radioisotope.

4. Secondary antibody: A wide range of both alkaline phosphatase and horseradish peroxidase conjugated antibodies are available commercially. They are usually supplied as an aqueous solution containing protein stabilizers. The solution should be stored under the conditions recommended by the supplier. *Ensure that the enzyme-linked antibody is against IgG of the species in which the primary antibody was raised.*
5. Washing solutions: Phosphate buffered saline (PBS). Make 2 L containing 10 m*M* NaH_2PO_4, 150 m*M* NaCl adjusted to pH 7.2 using NaOH. This solution is stable and may be stored at 4°C. It is susceptible to microbial contamination, however, and is usually made as required. The other washing solutions are made by dissolving the appropriate weight of bovine serum albumin or Triton X-100 in PBS. Dissolve Bovine serum albumin by rocking the mixture gently in a large, sealed bottle to avoid excessive foaming. The "blocking" and "antibody" solutions containing 8% albumin may be stored at −20°C and reused several times. Microbial contamination can be limited by filter-sterilizing these solutions after use or by adding 0.05% (w/v) NaN_3 (*but see* **Note 5**). Other solutions are made as required and discarded after use.
6. Alkaline phosphatase substrate mixture:
   a) Diethanolamine buffer. Make up 100 m*M* diethanolamine and adjust to pH 9.8 using HCl. This buffer is usually made up as required, but may be stored at 4°C if care is taken to avoid microbial contamination.
   b) 1 *M* $MgCl_2$. This can be stored at 4°C.
   Combine 200 µL of 1 *M* $MgCl_2$, 5 mg nitroblue tetrazolium, 2.5 mg 5-bromo-4-chloroindolyl phosphate (disodium salt, *see* **Note 6**). Adjust the volume to 50 mL using 100 m*M* diethanolamine buffer. Make up this reaction mixture as required and protect from the light before use.
7. Horseradish peroxidase substrate mixture:
   a) Make up 50 m*M* acetic acid and adjust to pH 5.0 using NaOH. This buffer is usually made up as required, but may be stored at 4°C if care is taken to avoid microbial contamination.
   b) Diaminobenzidine stock solution of 1 mg/mL^{-1} dissolved in acetone. Store in the dark at −20°C. **Caution: Diaminobenzidine is a potential carcinogen; handle with care.**
   c) Hydrogen peroxide at a concentration of 30% (v/v). This compound decomposes, even when stored at 4°C. The precise concentration of the stock solution can be determined by measuring its absorbance at 240 nm. The molar extinction coefficient for H_2O_2 is 43.6 $M^{-1}.cm^{-1}$ at this wavelength (*see* **Note 7**).
   Combine 50 mL of acetate buffer, 2 mL of diaminobenzidine stock solution and 30 µL of hydrogen peroxide immediately before use. Mix gently and avoid vigorous shaking to prevent unwanted oxidation of the substrate. Protect the solution from the light.
8. Protein staining solutions: These are stable at room temperature for several weeks and the stains may be reused.

a) Amido black stain (100mL): 0.1% (w/v) amido black in 25% (v/v) propan-2-ol, 10% (v/v) acetic acid.
b) Amido black destain (400 mL): 25% (v/v) propan-2-ol, 10% (v/v) acetic acid.
c) Ponceau S stain (100 mL): 0.2% (w/v) Ponceau S, 10% (w/v) acetic acid.
d) Ponceau S destain (400 mL): distilled water.

3. Methods

3.1. Immunodetection of Polypeptides

1. Following SDS-polyacrylamide gel electrophoresis, electroblot the polypeptides from the gel onto nitrocellulose at 50 V for 3 h using a Bio-Rad Trans-Blot apparatus, or at 100 V for 1 h using a Bio-Rad Mini Trans-Blot system (*see* **Note 8**).
2. After blotting, transfer the nitrocellulose filters individually to plastic trays for the subsequent incubations. Ensure that the nitrocellulose surface that was closest to the gel is uppermost. Do not allow the filter to dry out, since this often increases non-specific binding and results in heavy, uneven background staining. The nitrocellulose filter should be handled sparingly to prevent contamination by grease or foreign proteins. Always wear disposable powder-free examination gloves, and only touch the edges of the filter.
3. If desired, stain the blot for total protein using Ponceau S as described in **Subheading 3.3.2** (*see* **Note 9**).
4. Rinse the nitrocellulose briefly with 100 mL of PBS. Then incubate the blot at room temperature with the following solutions, shaking gently (*see* **Note 10**).
   a) 50 mL of PBS/8% bovine serum albumin for 30 min. This blocks the remaining protein-binding sites on the nitrocellulose (*see* **Note 11**).
   b) 50 mL of PBS/8% bovine serum albumin containing 50–500 µL of antiserum for 2–16 h (*see* **Note 12**).
   c) Wash the nitrocellulose at least five times, each time using 100 mL of PBS for 15 min, to remove unbound antibodies.
   d) 50 mL of PBS/4% bovine serum albumin containing an appropriate ligand for 2 h (*see* **Note 13**). This is likely to be one of the following:
      (i) enzyme-conjugated secondary antibody at the manufactures recommended dilution (normally between 1:1000 and 1:10,000)
      (ii) 5 µg enzyme-conjugated protein A
      (iii) 1 µCi ^{125}I-labelled protein A
   e) Wash the nitrocellulose at least five times, each time using 100 mL PBS/1% Triton X-100 for 5 min, to remove unbound protein A or secondary antibody. To ensure effective washing of the filter, pour off the solution from the same corner of the tray each time and replace the lid in the same orientation.

3.2. Visualization of Antigen-Antibody Complex

3.2.1. Alkaline phosphatase-conjugated ligand

In this method the enzyme hydrolyzes 5-bromo-4-chloroindolyl phosphate to the corresponding indoxyl compound. The product tautomerizes to a ketone, oxidizes, and then dimerizes to form an insoluble blue indigo that is deposited

on the filter. Hydrogen ions released during the dimerization reduce nitroblue tetrazolium to the corresponding diformazan. The latter compound is an insoluble intense purple compound that is deposited alongside the indigo, enhancing the initial signal.

1. Briefly rinse the filter twice, each time using 50 mL of diethanolamine buffer.
2. Incubate the filter with 50 mL of alkaline phosphatase substrate mixture until the blue-purple products appear, usually after 5–30 min.
3. Prevent further color development by removing the substrate mixture and washing the filter thrice, each time in 100 mL of distilled water. Finally, dry the filter thoroughly before storing (*see* **Note 14**).

3.2.2. Horseradish peroxidase-conjugated ligand

Peroxidase catalyses the transfer of hydrogen from a wide range of hydrogen donors to H_2O_2, and it is usually measured indirectly by the oxidation of the second substrate. In this method, soluble 3,3´-diaminobenzidine is converted to a red-brown insoluble complex that is deposited on the filter. The sensitivity of this technique may be increased up to 100-fold by intensifying the diaminobenzidine-based products using a combination of cobalt and nickel salts that produce a dense black precipitate (*see* **Note 15**).

1. Briefly rinse the filter twice, each time using 50 mL of sodium acetate buffer.
2. Incubate the filter with 50 mL of horseradish peroxidase substrate mixture until the red-brown insoluble products accumulate. Reaction times longer than about 30 min are unlikely to be effective due to substrate-inactivation of peroxidase (*see* **Note 7**).
3. When sufficient color has developed, remove the substrate mixture and wash the filter three times with 100 mL of distilled water. Then dry the filter and store it in the dark (*see* **Note 14**).

3.2.3. ^{125}I-labelled protein A

1. If desired, stain the blot for total protein as described in **Subheading 3.3.**
2. Allow the filter to dry. Do not use excessive heat since nitrocellulose is potentially explosive when dry.
3. Mark the nitrocellulose with radioactive ink to allow alignment with exposed and developed X-ray film (*see* **Note 16**).
4. Fluorograph the blot using suitable X-ray film and intensifying screens. Expose the film at –70°C for 6–72 h, depending on the intensity of the signal.

3.3. Staining of Total Protein

Either of the following stains is suitable for visualizing polypeptides after transfer onto nitrocellulose. Each can detect bands containing about 1 µg of protein. Coomassie brilliant blue is unsuitable for nitrocellulose membranes, since generally it produces heavy background staining (*see* **Note 17**).

3.3.1. Amido Black

Incubate the filter for 2–5 s in 100 mL of stain solution. Transfer immediately to 100 mL of destain solution, and wash with several changes to remove excess dye. Unacceptably dark backgrounds are produced by longer incubation times in the stain solution.

3.3.2. Ponceau S

Incubate the filter with 100 mL of Ponceau S stain solution for 30 min. Wash excess dye off the filter by rinsing in several changes of distilled water. The proteins may be destained by washing the filter in PBS (*see* **Note 9**).

4. Notes

1. Protein G, a cell wall component of group C and group G streptococci, binds to the Fc region of IgG from a wider range of species than that recognised by protein A ***(9)***. Therefore antibodies that react poorly with protein A, particularly those from rat, mouse, goat and sheep, may be detected by a similar method using protein G derivatives. Natural protein G also contains albumin binding sites and membrane binding regions which can lead to non-specific staining. However, these problems can be avoided by using protein G', a recombinant, truncated form of the protein which lacks both albumin and membrane binding sites and is thus more specific for IgG than the native form of the protein. This is the form of protein G provided by suppliers such as Sigma-Aldrich Co.

   An alternative is protein A/G which is a recombinant fusion protein that contains four Fc binding domains from protein A and two from protein G ***(10)***. Protein A/G therefore combines the IgG binding characteristics of protein A and protein G, and as a consequence individual IgG subclasses of mouse monoclonal antibodies are likely to have a stronger affinity for the chimeric protein A/G than for either protein A or protein G ***(10)***. Protein A/G has the additional advantage of being less dependent upon pH than protein A.

   Another useful ligand is protein L from *Peptostreptococcus magus* which has affinity for kappa light chains from various species, and will bind to IgG, IgA and IgM as well as Fab, $F(ab')_2$ and recombinant scFv fragments that contain kappa light chains. It will also bind chicken IgG. However, species such as cow, goat, sheep and horse whose immunoglobulins contain predominantly lambda chains will not bind well, if at all, to protein L ***(11)***. This selectivity may be useful in some detection strategies involving mixtures of antibodies (*see* **Note 21**).

Currently, alkaline phosphatase- and horseradish peroxidase-conjugated and ^{125}I-labelled protein G are commercially available, while only the peroxidase-conjugate of protein A/G and protein L appear to be produced.

2. Several colorimetric visualization systems have been developed for both alkaline phosphatase and horseradish peroxidase. Other assay systems for these enzymes are described by Tijssen ***(4)***.
3. Nitrocellulose is the most commonly used blotting membrane but suffers from the disadvantage that it has a relatively low protein-binding capacity and is brittle when dry. The issue of mechanical strength can be avoided by using a supported nitrocellulose, such as Hybond-C Extra (GE Healthcare, formerly Amersham Biosciences) in which a polyester web has been incorporated into the membrane, making it easier to handle. Alternatively, proteins can be transferred onto a polyvinylidene difluoride (PVDF) membrane which has a higher protein-binding capacity, better physical strength and greater chemical stability. The latter property is particularly useful in allowing the membrane to be compatible with a broader range of protein analytical techniques, ranging from standard N-terminal sequencing by Edman degradation to direct determination of peptide fragments using MALDI-QIT-TOF tandem MS ***(12)***.
4. Iodination of protein A using Bolton and Hunter reagent labels the ε-NH_2 group of lysine, which apparently is not involved directly in the binding of protein A to the Fc region of IgG. This method is preferable to others, such as those using chloramine T or iodogen, which label tyrosine. The only tyrosine residues in protein A are associated with Fc binding sites, and their iodination may reduce the affinity of protein A for IgG ***(13)***.
5. Some workers include up to 0.05% (w/v) sodium azide in the antibody and washing buffers to prevent microbial contamination. However, azide inhibits horseradish peroxidase. Therefore, do not use buffers containing azide when using this enzyme.
6. In the original description of this protocol 5-bromo-4-chloroindolyl phosphate was made up as a stock solution in dimethylformamide. However, this is not necessary if the disodium salt is used since this compound dissolves readily in aqueous buffers.
7. Urea peroxide (carbamide peroxide) may be used instead of hydrogen peroxide as a substrate for peroxidase. The problems of instability, enzyme inactivation and possibility of caustic burns associated with hydrogen peroxide are reduced by using urea peroxide, which is a hydrogen peroxide-urea adduct, obtainable as a powder or tablets. A 10% (w/v) stock solution of urea peroxide is stable for several months and is used at a final concentration of 0.1% in the peroxidase substrate mixture.

8. Extra care should be taken when working with small proteins and peptide fragments below about 15 kDa. These tend to move through nitrocellulose (and PVDF) membranes during the electro-transfer step (a phenomenon often referred to as "blow-through") and their weak binding to the membrane can result in further loss during the subsequent washing steps in the blotting procedure. The losses during the processing of blots can be partly avoided by treating the membrane with glutaraldehyde prior to blocking and detection, but this is not particularly effective for peptides smaller than 6–10 kDa and does not overcome the problem of blow-through during transfer from the gel. The retention of such small proteins and peptides may be significantly improved by transfer onto metal nanoparticle-coated PVDF membranes that are generated by soaking the membrane in a solution of gold or silver nanoparticles prior to blotting ***(14)***. This approach exploits the high affinity binding of both gold and silver to protein and facilitates the effective retention of peptides as small as 2 kDa on the membrane allowing their detection at the same level of sensitivity as that of higher molecular weight proteins in the 30–60 kDa range.
9. If desired, the nitrocellulose filter may be stained with Ponceau S immediately after electroblotting. This staining apparently does not affect the subsequent immunodetection of polypeptides, if the filter is thoroughly destained using PBS before incubation with the antiserum. In addition to confirming that the polypeptides have been transferred successfully onto the filter, initial staining allows tracks from gels to be separated precisely and probed individually. This is useful when screening several antisera.
10. High background signals arising from non-specific binding of antibodies and ligands is a common problem in immunoblotting. Several factors are important in reducing the resulting background, and even relatively minor modifications to the procedure can have marked effects (***15,16***)

    First, the filter is washed in the presence of an "inert" protein to block the unoccupied binding sites. Bovine serum albumin is a commonly used protein, but others such as fetal calf serum, haemoglobin, gelatin, and non-fat dried milk have been used successfully. Economically, the latter two alternatives are particularly attractive, and in many circumstances we now use 5% (w/v) dried milk instead of bovine serum albumin.

    The quality of protein used for blocking is important, since minor contaminants may interfere with either antigen-antibody interactions or the binding of protein A to IgG. These contaminants may vary between preparations and can be sufficient to inhibit completely the detection of specific polypeptides. In this context it should be noted that milk contains varying amounts of phosphoproteins that may interfere with immunodetection

using anti-phosphoserine or anti-phosphotyrosine antibodies. Milk also contains variable amounts of biotin so it should not be used with avidin/biotin-based detection systems.

For routine analysis we use bovine serum albumin (Cohn fraction V) from Sigma-Aldrich (product number A4503) or "Marvel" non-fat dried milk produced by Premier Brands UK. It is likely that similar products from other sources are equally effective. However, the suitability of individual batches of protein as a blocking agent should be checked using antisera known to react well on immunoblots.

Secondly, the background may be reduced further by including non-ionic detergents in the appropriate solutions. These presumably decrease the hydrophobic interactions between antibodies and the nitrocellulose filter. Tween 20, Triton X-100, and Nonidet P-40 at concentrations of 0.1–1.0% have been used. In my experience, such detergents may supplement the blocking agents described above, but cannot substitute for these proteins. In addition, these detergents sometimes remove proteins from nitrocellulose (*see* **Note 11**).

Thirdly, the nitrocellulose must be washed effectively to limit non-specific binding. For this, the volumes of the washing solutions should be sufficient to flow gently over the surface of the filter during shaking. The method described in this chapter is suitable for 12 × 7 cm filters incubated in 14 × 9 cm trays. If the size of the filter is significantly different, the volumes of the washing solutions should be adjusted accordingly.

Finally, decreasing the incubation temperature to 4°C may greatly decrease the extent of non-specific background binding ***(17)***.

11. Protein desorption from the membrane during the blocking step and subsequent incubations can result in the loss of antigen and decrease the sensitivity of detection ***(18)***. In some instances, this problem may be reduced by incubating the membrane in 0.1 *M* phosphate buffer (pH 2.0) for 30 min and then rinsing in PBS prior to treatment with the blocking agent. Such acid treatment is particularly effective when using non-denaturing gel blots, or SDS-PAGE blots transferred onto PVDF rather than nitrocellulose membrane ***(19)***.

    Alternatively, polyvinyl alcohol may be used as a blocking agent ***(20)***. In comparative tests, PBS containing 1 µg/mL polyvinyl alcohol produced lower background staining than other commonly used blocking agents. Moreover, the blocking effect of polyvinyl alcohol is virtually instantaneous allowing the incubation time to be reduced to 1 min and decreasing the opportunity for loss of protein from the membrane ***(20)***.
12. The exact amount of antibody to use will depend largely on its titer. Generally it is better to begin by using a small amount of antiserum. Excessive

quantities of serum tend to increase the background rather than improve the sensitivity of the technique. Non-specific binding can often be reduced by decreasing the amount of antibody used to probe the filter. Also, *see* **Notes 18** and **19**.

13. The decision as to which secondary ligand to use will be influenced by the nature of the primary antibody, the preferred visualization strategy and the availability of the relevant conjugated or tagged ligand. For most general purposes colorimetric visualization of enzyme activity provides a simple, rapid and robust technique that is equally applicable to protein A and secondary antibody conjugates. A range of colorimetric assay systems are available for both alkaline phosphatase and horseradish peroxidase ***(4)***. However, comparison between the two enzymes is difficult because the reported sensitivity limits of the assays vary considerably and most studies use different antigens, different primary antibodies and different protocols. Despite these uncertainties, alkaline phosphatase is generally considered more sensitive than horseradish peroxidase when visualized using the standard colorimetric detection systems described in this chapter. For routine work I prefer to use alkaline phosphatase-conjugated protein A.

    The disadvantage of these colorimetric assay systems is that they are relatively insensitive and are difficult to use to quantify the amount of antigen (*see* **Note 20**). However, chemiluminescent detection systems based on light emission arising from the enzyme-catalyzed degradation of synthetic substrates are available for both alkaline phosphatase and peroxidase. These permit detection using X-ray film similar to radiolabeled probes and are not only more sensitive, but also allow quantitation of antigen by densometric scanning of the exposed X-ray film (but *see* **Note 20**). The major disadvantage of this approach is that the systems are more sensitive to interference from contaminants and place greater demands on the purity of the assay components. However, quality-control detection kits are available from several manufactures such as GE Healthcare, Pierce and Bio-Rad. More recently, chemifluorescent detection systems in which enzyme activity results in the generation of a fluorescent product have been developed commercially for both marker enzymes. These are reported to improve sensitivity of detection relative to standard chemiluminescent systems, but again they are sensitive to interference and demand greater technical care. In addition, this detection system requires an appropriate fluorescence imaging system or a CCD camera coupled with a suitable excitation light source to capture the light output. However, this obviates the need for the film output to be digitized since the fluorescence emission is recorded directly.

    Despite improvements in the sensitivity of analysis of enzyme-conjugated ligands, direct detection using ^{125}I-labelled protein A remains competitive in

terms of sensitivity, robustness and ease of application, and the method outlined in this article continues to be the technique of choice in critical studies. Nevertheless, many researchers would prefer to use non-radioactive methods and continuing effort is being focused on the development of fluorescence-based direct detection systems. These involve the conjugation of secondary antibodies to fluorescent organic dyes ***(21)*** or quantum dots (***22,23***). The latter are semiconductor nanoparticles (2–10 nm diameter) that absorb light over a broad spectral range and fluoresce at defined tunable wavelengths determined by their physical size ***(24)***. They are particularly attractive because of their high fluorescence yield, resistance to photobleaching, and superior dynamic range of detection. The defined emission spectra of these fluorophores enable precise visualization of specific ligands and offer the potential for simultaneous quantitation of two or more signals on a single western blot (*see* **Note 21**). However, as with chemifluorescent systems, visualization requires an appropriate fluorescence imaging system and because of the sensitivity of the detection technique care is needed to avoid interference from fluorescence artifacts. Antibodies linked directly to cyanine or other dyes are currently available from GE Healthcare and Pierce, while a range of antibodies conjugated to quantum dots as original described by QDot Corp ***(7)*** are produced by Invitrogen and Evident Technologies. Several of these ligands are marketed in kits that are designed to be "plug-and-play" substitutes for colorimetric or chemiluminescent detection systems.

14. The products of the peroxidase reaction are susceptible to photobleaching and fading. Consequently, the developed filters should be stored in the dark, and the results photographed as soon as possible. The products of the phosphatase reaction are reportedly stable in the light. However, I treat such filters in the same way - just in case!
15. To increase sensitivity of the diaminobenzidine-based staining protocol replace the standard substrate mixture with the following intensifying solution ***(25)***. Dissolve 100 mg diaminobenzidine in 100 ml of 200 mM phosphate buffer (pH 7.3). To this solution add, dropwise and with constant stirring, 5 mL of 1% (w/v) cobalt chloride followed by 4 mL of 1% (w/v) nickel ammonium sulfate. Finally add 60 µL of 30% (v/v) hydrogen peroxide just before use.
16. Alternatively, luminescent markers, such as Glogos II supplied by Stratagene, can be used for accurately marking and aligning an autoradiograph. These luminescent peel-off stickers are easily affixed to plastic wrap or paper, and emit low-level luminescence rather than radioactivity, making them a non-hazardous substitute for radioactive ink. Exposure of the marker to ambient room light for 1 minute provides sufficient luminescence to be readily detected in autoradiograph exposures lasting 45

minutes. Because most light decay occurs within the first hour, the signal produced by the marker is similar irrespective of whether the autoradiograph is exposed for 1 hour or for several days. The use of an intensifying screen increases the intensity of the image by two- to threefold, although it also decreases the resolution of the image slightly.

17. Coomassie brilliant blue R-250 should be used in preference to Ponceau S to stain proteins blotted onto PVDF since it is more sensitive and does not bind to this membrane, whereas Ponceau S appears to interact only weakly with polypeptides attached to this matrix. If greater sensitivity is required, as little as 2 ng of a polypeptide can be detected using Sypro Ruby, a metal chelate stain containing ruthenium as part of an organic complex (developed by Molecular Probes), which works well on both nitrocellulose and PVDF membranes ***(26)***. The dual-excitation maxima displayed by the ruthenium complex means that this dye exhibits luminescence upon excitation with either UV or visible light and is therefore easily visualized using a range of instruments. The main disadvantage of this dye is that the protein staining is not reversible and while it is compatible with colorimetric immunodetection of proteins on blots it may interfere with their subsequent visualization. Sypro Rose Plus, an europium-based metal chealate stain, has a similar sensitivity to Sypro Ruby and has the added advantage of being fully reversible ***(27)***. However, the stain has a single excitation maximum at 350 nm which precludes it from being visualized using visible-wavelength excitation sources. [Note that Sypro Red and Orange, which have been developed to stain proteins within polyacrylamide gels, react relatively poorly with polypeptides attached to PVDF.] An attractive alternative is MemCode, a copper-containing stain (developed by Pierce). Although slightly less sensitive than the Sypro dyes with a reported detection limit of about 25 ng, MemCode is fully reversible, compatible with both nitrocellulose and PVDF membranes, and is easily visualized as a turquoise blue stain under visible light ***(28)***.
18. Particular care should be taken when attempting to detect antigens on nitrocellulose using monoclonal antibodies. Certain cell lines may produce antibodies that recognize epitopes that are denatured by detergent. Such "conformational" antibodies may not bind to the antigen after SDS-polyacrylamide gel electrophoresis.
19. Even before immunization, serum may contain antibodies, particularly against bacterial proteins. These antibodies may recognize proteins in an extract bound to the nitrocellulose filter. Therefore, when characterizing an antiserum, control filters should be incubated with an equal amount of pre-immune serum to check whether such pre-existing antibodies interfere in the immunodetection of specific proteins.

20. Quantitation of specific antigens using this technique is difficult and must be accompanied by adequate evidence that the amount of reporting ligand (protein A or secondary antibody) bound to the filter is directly related to the amount of antigen in the initial extract. This is important, since polypeptides may vary in the extent to which they are eluted from the gel and retained by the nitrocellulose (*see* **Notes 8** and **11**). Additionally, in some tissues proteins may interfere with the binding of antigen to the filter or their subsequent detection ***(29)***. Therefore, the reliability of the technique should be checked for each extract, although it is rare for this issue to be addressed.

    Perhaps the best evidence is provided by determining the recovery of a known amount of pure antigen. For this, duplicate samples are prepared, and to one is added a known amount of antigen comparable to that already present in the extract. Ideally the pure antigen should be identical to that in the extract. The recovery is calculated by comparing the antigen measured in the original and supplemented samples. Such evidence is preferable to that obtained from only measuring known amounts of pure antigen. The latter indicates the detection limits of the assay, but does not test for possible interference by other components in the extract.

    The other major problem derives from the technical difficulties associated with quantifying the measured signal and relating this to the amount of antibody bound to the filter. In this regard it is important to recognise that the colorimetric detection systems described in this chapter cannot be quantified reliably and to resist the temptation to use this technique to obtain anything other than the very crudest indication of relative amounts of antigen in different samples on the same blot.

    In principle, images generated on X-ray film after probing a blot with ^{125}I-labelled protein A or using a chemiluminescent detection system may be quantified by digitization on a densitometer. However, film-based detection suffers several drawbacks. First, although the film itself has a dynamic range of 5×10^2, in practice the linear range of detection for chemiluminescent systems is typically only about 10^1. In addition, film exhibits reciprocity failure. At low signal levels a threshold level of signal is required before an image is generated, and pre-flashing of the film is required to overcome this effect ***(30)***. At the other extreme, high signal levels saturate the response meaning that the darkening of the film is again not accurately recording the signal that is generated, and this can only be overcome by shortening the exposure time. Therefore when using X-ray film it is important that either different amounts of sample are analysed or several exposures are taken to ensure the signal from the blot is within the linear detection range of the film. Alternatively, many of these issues may be circumvented by using a PhosphorImager to

quantify the signal ***(31)***. Similarly, quantification of signals generated by fluorescence-based visualization systems is relatively easy using a CCD camera or flat bed laser scanner which capture the image as a directly quantifiable digital signal. The wide dynamic range (10^3–10^5) of these detection systems ensure that the range over which samples can be quantified is greater than that using film. Although, in practise, the binding capacity of the membrane and steric hindrance in antibody-antigen binding usually restrict the signal detection range to 10^2–10^3, this is sufficient for the majority of biochemical studies.

21. The amount of a specific protein in a sample is usually quantified by expressing the signal intensity relative to that obtained from the same protein in a reference sample (which might be a control extract or a known amount of the pure protein). However, care must be taken if measuring the signals by autoradiography because the density of the image is not necessarily linearly related to the amount of light or radioactivity (*see* **Note 20**), and this is likely to underestimate any differences between samples ***(32)***. A refinement of this approach is to quantify the amount of the antigen of interest by measuring its signal intensity relative to that of a reference protein (typically a constitutively expressed polypeptide) in the same sample. This approach normally requires that the two (or more) proteins can be visualized separately using antibodies raised in different hosts. This is greatly facilitated by the availability of different fluorescently tagged antibodies that allow the identification of several proteins independently in a single sample in a process known as "multiplexing." This approach has the added advantage of compensating for variation between samples in the amounts of protein that are transferred to the blot.

Identification of Glycoproteins on Nitrocellulose Membranes Using Lectin Blotting

Patricia Gravel

1. Introduction

Glycoproteins result from the covalent association of carbohydrate moieties (glycans) with proteins. The enzymatic glycosylation of proteins is a common and complex form of post-translational modification. It has been established that glycans perform important biological roles including: stabilisation of the protein structure, protection from degradation, control of protein solubility, of protein transport in cells and of protein half-life in blood. They also mediate the interactions with other macromolecules and the recognition and association with viruses, enzymes and lectins ***(1-6)***.

Carbohydrate moieties are known to play a part in several pathological processes. Alterations in protein glycosylation have been observed, for example, with the membrane glycoproteins of cancer cells, with the plasma glycoproteins of alcoholic patients and patients with liver disease, with the glycoproteins in human brains from patients with Alzeimer disease, inflammation and infection. These changes provide the basis for more sensitive and more discriminative clinical tests ***(2, 7-11)***.

Lectins are carbohydrate-binding proteins and can be used to discriminate and analyze the glycan structures of glycoproteins. The lectin-blotting technique detects glycoproteins separated by electrophoresis (SDS-PAGE or two-dimensional polyacrylamide gel electrophoresis 2-D PAGE) and transferred to membranes. This chapter describes the protocol for the detection of glycoproteins on nitrocellulose membrane using biotinylated lectins and avidin conjugated with horseradish peroxidase (HRP) or with alkaline phosphatase (AP) (*see* **Note 1**). These complexes are subsequently revealed either by a chemiluminescent or a colorimetric reaction. To illustrate this method, human plasma glycoprotein patterns, obtained after the separation of proteins by 2-D PAGE and different lectin

incubations, are presented in **Figs. 1** to **4** (*see* **Note 2**). The principal merits of this separation technique are the high resolution and reproducibility of the separation and the high loading capacity. Using the lectin blotting technique after 2-D PAGE separation, the modification of glyproteins that affect the global charge (e.g. alteration of the sugar sialic acid) and/or the molecular weight result in multiple isoforms. Different protein alterations associated to alcohol-related disease has been identify and confirmed using this lectin blotting technique coupled to 2-D PAGE ***(12)***.

1.1. Classification of Glycoproteins

A useful classification of glycoproteins is based on the type of glycosidic linkage involved in the attachment of the carbohydrate to the peptide backbone. Three types of glycan-protein linkage have been described:

1. N-glycosidic linkage of N-acetyl glucosamine to the amide group of asparagine:

   GlcNAc (β-1,N) Asn

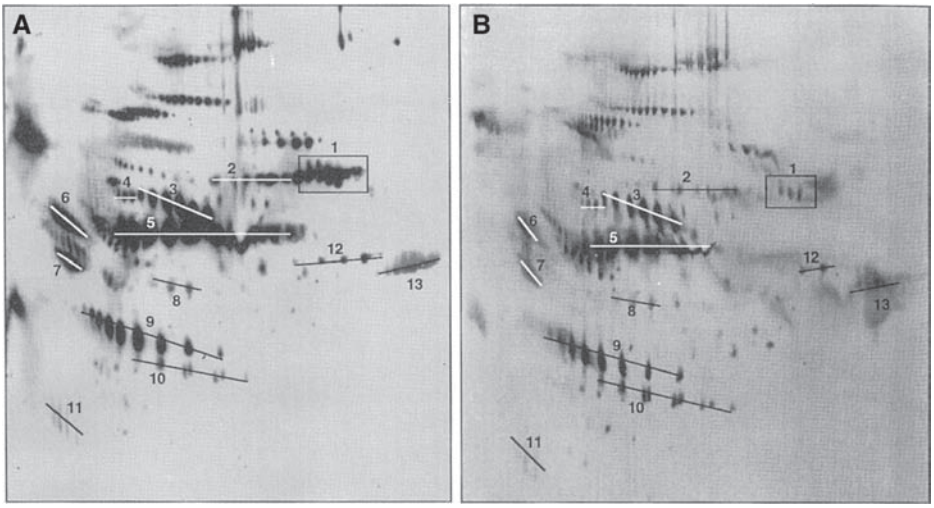

Fig. 1. Glycoprotein blot pattern of 2-D PAGE separation of plasma proteins (120 µg) probed with WGA (specific for N-acetylglucosamine and neuraminic acid) and **(A)** revealed with chemiluminesence (15 s film exposure) and **(B)** with NBT/BCIP (20 min for the development of the color reaction). Since most of the glycoproteins in plasma contain one or more N-linked glycans with at least two N-acetylglucosamine residues, the use of WGA allows a general staining of N-linked glycoproteins. 1) transferrin, 2) IgM µ-chain, 3) hemopexin, 4) α1-β-glycoprotein, 5) IgA α-chain, 6) α1-antichymotrypsin, 7) α2-HS-glycoprotein, 8) fibrinogen γ-chain, 9) haptoglobin β-chain, 10) haptoglobin cleaved β-chain, 11) apolipoprotein D, 12) fibrinogen β-chain, 13) IgG γ-chain.

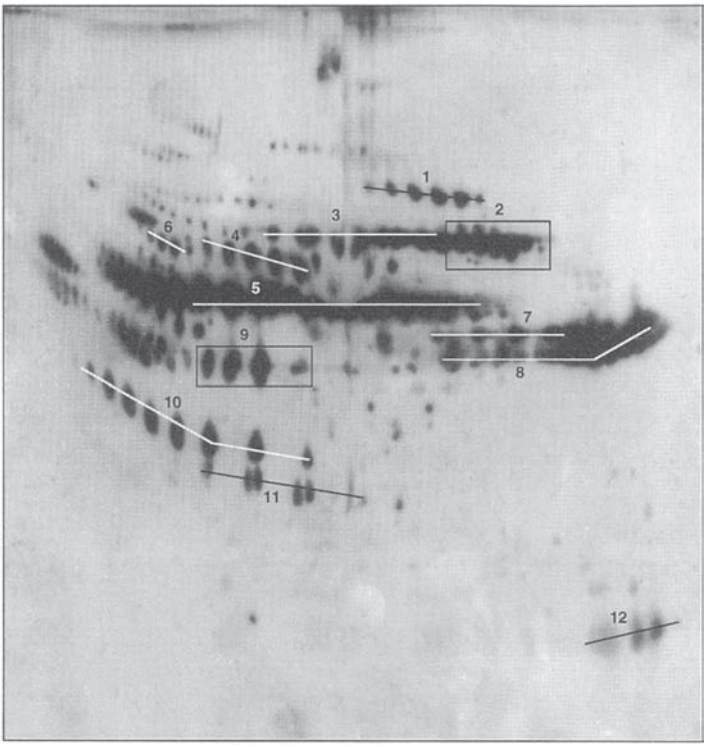

Fig. 2. Glycoprotein blot pattern of 2-D PAGE separation of plasma proteins (120 µg) probed with RCA (specific for galactose) and revealed using chemiluminescence reaction (5 s film exposure). 1) complement 3 α-chain, 2) transferrin, 3) IgM µ-chain, 4) hemopexin, 5) IgA α-chain, 6) α1-β-glycoprotein, 7) fibrinogen β-chain, 8) IgG γ-chain, 9) fibrinogen γ-chain, 10) haptoglobin β-chain, 11) haptoglobin cleaved β-chain, 12) Ig light chain.

2. O-glycosidic linkage of N-acetylgalactosamine to either the hydroxyl group of serine or threonine:

   GalNAc (α-1,3) Ser

   GalNAc (α-1,3) Thr

3. O-glycosidic linkage of galactose to 5-hydroxy-lysine:

   Gal (β-1,5) OH-Lys

Most plasma glycoproteins bear exclusively asparagine-linked oligosaccharides ***(13)*** and these N-glycosidic linkages are by far the most diverse. They can be subdivided into 3 groups according to structure and common oligosaccharide sequences (**Table 1**). They all have in common the inner-core structure presented

Table 1
Glycans *N*-Glycosidically Conjugated to Proteins

Type of *N*-glycosidic linkage	Examples of structures
High mannose type	Man(α-1,2) Man(α-1,3) Man(α-1,2)Man(α-1,6) → Man(α-1,6) → Man(β-1,4)GlcNAc(β-1,4)GlcNAc(β-1,N)Asn Man(α-1,2)Man(α-1,2) → Man(α-1,3) → Man(β-1,4)GlcNAc(β-1,4)GlcNAc(β-1,N)Asn
Complex type	NeuAc(α-2,6)Gal(β-1,4)GlcNAc(β-1,2)Man(α-1,6) NeuAc(α-2,6)Gal(β-1,4)GlcNAc(β-1,2)Man(α-1,3) → Man(β-1,4)GlcNAc(β-1,4)GlcNAc(β-1,N)Asn
Hybrid type	Gal(β-1,4)GlcNAc(β-1,4) GlcNAc(β-1,2) → Man(α-1,3) Man(α-1,3) Man(α-1,6) → Man(α-1,6) GlcNAc(β-1,4) → Man(β-1,4)GlcNAc(β-1-4)GlcNAc(β-1,N)Asn

Man, mannose; GlcNAc, *N*-acetylglucosamine; NeuAc, neuraminic acid; Gal, galactose.

NeuAc located at the terminal position of oligosaccharide side chains are *N*-acetylated (NeuAcNAc) and are often referred to as sialic acid. Sialic acid is in fact the generic term given to a family of acetylated derivatives of neuraminic acid.

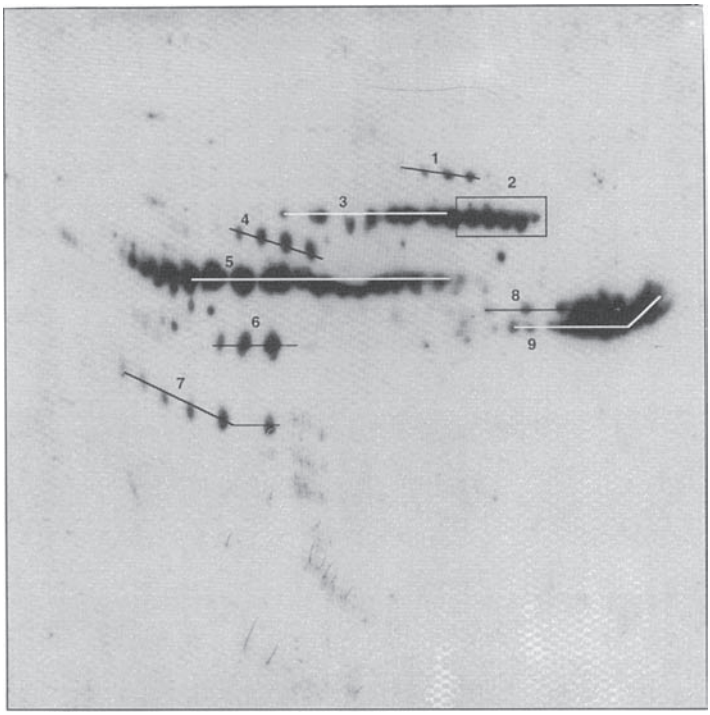

Fig. 3. Glycoprotein blot pattern of 2-D PAGE separation of plasma proteins (120 µg) probed with AAA (specific for fucose) and revealed using chemiluminescence reaction (5 s film exposure). 1) complement 3 α-chain, 2) transferrin, 3) IgM µ-chain, 4) hemopexin, 5) IgA α-chain, 6) fibrinogen γ-chain, 7) haptoglobin β-chain, 8) fibrinogen β-chain, 9) IgG γ-chain.

in **Fig. 5**. The presence of this common core structure reflects the fact that all these asparagine-linked oligosaccharides originate from the same precursor.

O-glycans are found frequently in mucins, but rarely in plasma glycoproteins. **Table 2** illustrates the 3 different groups of O-glycosyl protein glycans.

1.2. Lectins as a Tool for Glycoprotein Detection

Lectins are a class of carbohydrate-binding proteins, commonly detected by their ability to precipitate glycoconjugates or to agglutinate cells (some lectins react selectively with erythrocytes of different blood types). Lectins are present in plants, animals and microorganisms ***(14)***.

Each lectin binds specifically and non-covalently to a certain sugar sequence in oligosaccharides and glycoconjugates. Lectins are traditionally classified into specificity groups (mannose, galactose, N-acetylglucosamine, N-acetylgalactos-

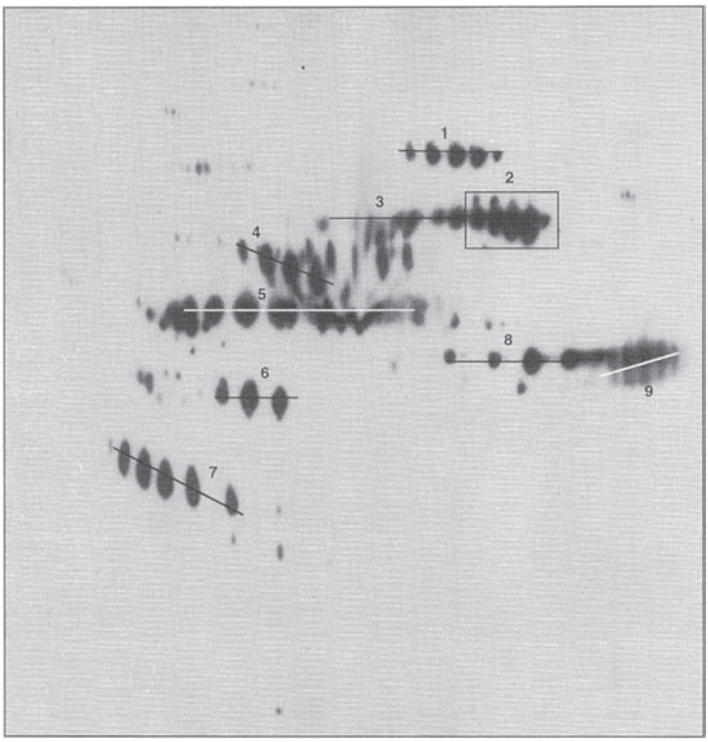

Fig. 4. Glycoprotein blot pattern of 2-D PAGE separation of plasma proteins (120 μg) probed with SNA (specific for neuraminic acid linked α-2,6 to galactose) and revealed using chemiluminescence reaction (30 s film exposure). 1) complement 3 α-chain, 2) transferrin, 3) IgM μ-chain, 4) hemopexin, 5) IgA α-chain, 6) fibrinogen γ-chain, 7) haptoglobin β-chain, 8) fibrinogen β-chain, 9) IgG γ-chain.

Table 2
Glycans *O*-Glycosidically Conjugated to Proteins

Type of *O*-glycosidic linkage	Examples of structures
Mucin type	NeuAc(α-2,6)GalNAc(α-1,3) Ser (or) Thr Gal(β-1,3)GalNAc(α-1,3) Ser (or) Thr The presence of such *O*-glycosidically linked moieties has been established for a number of plasma proteins (IgA, IgD, hemopexin, plasminogen, apoE)
Proteoglycan type	[GalNAc(β-1,4)GlcUA(β-1,3)]*n*GalNAc(β-1,4)GlcUA(β-1,3) Gal(β-1,3)Gal(β-1,4) Xyl(β-1,3)Ser They are generally linear polymers made up from repeating disaccharide units
Collagen type	Glc(β-1,2)Gal(β-1,5)OH-Lys

NeuAc, neuraminic acid; GalNAc, *N*-acetylgalactosamine; Gal, galactose; GlcUA, Glucuronic acid; Glc, glucose; Xyl, xylose.

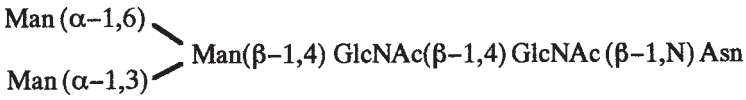

Fig. 5. Oligosaccharide inner core common to all N-glycosylproteins.

amine, fucose, neuraminic acid) according to the monosaccharide which is the most effective inhibitor of the agglutination of erythrocytes or precipitation of polysaccharides or glycoproteins by the lectin (fixation-site saturation method). Another method to determine the carbohydrate specificity of a given lectin consists in the determination of the association constant, by equilibrium analysis.

In most cases, lectins bind more strongly to oligosaccharides (di, tri and tetra saccharides) than to monosaccharides ***(15, 16)***. Therefore, the concept of "lectin monosaccharide specificity" should advantageously be replaced by that of "lectin oligosaccharide specificity." **Table 3** summarizes the carbohydrate specificity of lectins commonly used in biochemical/biological research, both in terms of the best monosaccharide inhibitor of the precipitation of polysaccharides or glycoproteins and in terms of the structure of oligosaccharides recognized by immobilized lectins. The interactions of lectins with glycans are complex and not fully understood. Many lectins recognize terminal nonreducing saccharides, while others also recognize internal sugar sequences. Moreover, lectins within each group may differ markedly in their affinity for the monosaccharides or their derivatives. They do not have an absolute specificity and therefore can bind with different affinities to a number of similar carbohydrate groups. Because lectin binding can also be affected by structural changes unrelated to the primary binding site, the results obtained with lectin-based methods must be interpreted with caution ***(2)***.

Despite these limitations, lectin probes do provide some information as to the nature and composition of oligosaccharide substituents on glycoproteins. Their use together with blotting technique provides a convenient method of screening complex protein samples for abnormalities in the glycosylation of the component proteins. Lectin blotting requires low amounts of proteins, is easy to perform and therefore is particularly indicated to analyze biological samples.

When the lectin-blotting method described hereafter is combined with the high resolution and reproducibility of 2-D PAGE and with the sensitivity of enhanced chemiluminescence, it is possible to identify rapidly the glycoproteins of interest by comparison with a reference 2-D PAGE protein map and to obtain reliable and reproducible results ***(30-32)***.

Table 3
Specificity of Lectins for Glycan Linked to Asparagine (*N*-Linked Oligosaccharide Chains)

Lectin	Monosaccharide specificity	Oligosaccharide specificity[a]
Wheat germ (WGA)	GlcNAc NeuAc	NeuAc(α-2,6)Gal(β-1,4)GlcNAc(β-1,2)Man(α-1,6) GlcNac(β-1,4) — Man(β-1,4)GlcNAc(β-1,4)GlcNAc(β-1,N)Asn NeuAc(α-2,6)Gal(β-1,4)GlcNAc(β-1,2)Man(α-1,3)
		Note: The GlcNAc (β-1,4) Man (β-1,4) GlcNAc (β-1,4) GlcNAc (β-1,N) Asn structure is important for tight binding of glycopeptides to a WGA agarose column ***(17)***. Neuraminic acids (NeuAc) are implicated as important factors in WGA interactions but the inhibitory effect of NeuAc is weaker than that of GlcNAc. The presence of clustering sialyl residues may be necessary for the stronginteraction of sialoglycoconjugates with WGA ***(18)***.
Ricinus communis (RCA1, RCA120)	Gal	Gal(β-1,4)GlcNAc(β-1,6) Gal(β-1,4)GlcNAc(β-1,2) — Man(α-1,6) Gal(β-1,4)GlcNAc(β-1,4) Gal(β-1,4)GlcNAc(β-1,2) — Man(α-1,3) Man(α-1,6) / Man(α-1,3) — Man(β-1-4)GlcNAc(β-1,4)GlcNAc(β-1,N)Asn
		Note: RCA is specific for terminal β-galactosyl residues ***(19)***. It binds primarily to the terminal Gal (β-1,4) GlcNAc sugar sequence and much more weakly to the Gal (β-1,3) GalNAc sugar sequence ***(20)***. As galactose is the subterminal sugar in fully formed *N*-linked oligosaccharides, RCA provides a means of identifying the asialo forms of glycoproteins.
Concanavalin A (Con A)	Man	GlcNAc(β-1,2)Man(α-1,6) GlcNAc(β-1,2)Man(α-1,3) — Man(β-1,4)GlcNAc(β-1,4)GlcNAc(β-1,N)Asn
		Note: Con A interacts with glycoconjugates that have at least two nonsubstituted or 2-*O*-substituted α-mannosyl residues. It detects the core portion of *N*-linked oligosaccharide chains. The most potent hapten is illustrated here ***(17)***.

Lens culinaris (LCA)	Man	GlcNAc(β-1,2)Man(α-1,6) / GlcNAc(β-1,2)Man(α-1,3) → Man(β-1,4)GlcNAc(β-1,4)GlcNAc(β-1,N)Asn; Fuc(α-1,6) → GlcNAc Note: LCA is specific of mannose (α-1,3) or (α-1,6). Fucose (α-1,6) linked to GlcNAc is required for the reaction ***(3)***.
Galanthus nivalis (GNA)	Terminal Man	Man(α-1,2)(α-1,3) or (α-1,6)Man Note: GNA is particularly useful for identifying high mannose or hybrid type oligosaccharide structure because it does not react (unlike ConA) with biantennary complex type chains ***(21,22)***.
Datura stramonium (DSA)	GlcNAc	[Gal(β-1,4)GlcNAc(β-1,3)]nGal(β-1,4)GlcNAc(β-1,2) / [Gal(β-1,4)GlcNAc(β-1,3)]$_n$Gal(β-1,4)GlcNAc(β-1,6) → Man(α-1,6); Man(α-1,6) / [Gal(β-1,4)GlcNAc(β-1,3)]$_n$Gal(β-1,4)GlcNAc(β-1,2) Man(α-1,3) → Man(β-1,m4)GlcNAc(β-1,4)GlcNAc(β-1,N)Asn Note: Datura lectin is specific for Gal-GlcNAc termini of complex oligosaccharides ***(22)***.
Peanut agglutinin (PNA)	Gal	Gal(β-1,3)GalNAc **refs.** ***22*** and ***23***
Phaseolus vulgaris (E-PHA) erythroagglutinating phytohemagglutinin	GlcNAc	Gal(β-1,4)GlcNAc(β-1,2)Man(α-1,6) / GlcNAc(β-1,4) / Gal(β-1,4)GlcNAc(β-1,2)Man(α-1,3) → Man(β-1,4)GlcNAc(β-1,4)GlcNAc(β-1,N)Asn Note: A bisecting GlcNAc residue that links (β-1,4) to the β-linked mannose residue in the core is an essential and specific determinant for high-affinity binding to E-PHA-agarose column. Without this bisecting GlcNAc residue, a complex-type glycopeptide is not retained by E-PHA-agarose ***(24)***.

(continued)

Table 3
Specificity of Lectins for Glycan Linked to Asparagine (*N*-Linked Oligosaccharide Chains) *(continued)*

Lectin	Monosaccharide specificity	Oligosaccharide specificity[a]
Phaseolus vulgaris (L-PHA) leukoagglutinating phytohemagglutinin	GlcNAc	Gal(β-1,4)GlcNAc(B-1,2) \ Man (α-1,6) \ Gal(β-1,4)GlcNAc(β-1,6) / Man(β-1,4)GlcNAc(β-1,4)GlcNAc(β-1,N)Asn Gal(β-1,4)GlcNAc(β-1,4) \ Man(α-1,3) / Gal(β-1,4)GlcNAc(β-1,2) Note: The Gal (β-1,4) GlcNAc Man sugar sequence is essential for the binding of L-PHA (and E-PHA), as the interaction is completely abolished by the removal of the β-galactosyl residue in the peripheral portion ***(24)***.
Ulex europeus 1 (UEA1)	Fuc	Fuc(α-1,6) | GlcNAc(β-1,N)Asn **ref. *3***
Lotus tetragonolobus (LTA)	Fuc	Fuc(α-1,6) — GlcNAc(β-1,N)Asn; Fuc(α-1,3) — Gal(β-1,4)GlcNAc; Fuc(α-1,2) — Gal(β-1,4)GlcNAc **refs. *3*** and ***25***
Aleuria aurantia (AAA)	Fuc	Fuc(α-1,6) — GlcNAc(β-1,N)Asn; Fuc(α-1,2) — Gal(β-1,4)GlcNAc; Fuc(α-1,3) — Gal(β-1,4)GlcNAc Note: The AAA lectin is particularly useful for identifying fucose bound (α-1,6) to GlcNAc. Fucose bound (α-1,6) to GlcNAc in the core region is necessary for strong binding of AAA. Fucose (α-1,3) linked to GlcNAc and fucose (α-1,2) linked to Gal (β-1,4) GlcNAc in the outer chain react only very weakly with AAA. However, fucose (α-1,3) or (α-1,2), in addition to a fucose-linked (α-1,6) to the proximal core GlcNAc enhances the binding ***(17,26)***.

Sambucus nigra (SNA)	NeuAc	NeuAc(α-2,6)Gal Note: SNA binds specifically to glycoconjugates containing the (α-2,6)-linked NeuAc while isomeric structures containing terminal NeuAc in (α-2,3)- linkage are very weakly bound ***(27)***.
Maackia amurensis (MAA)	NeuAc	NeuAc(α-2,3)Gal Note: Immobilized MAA interacts with high affinity with complex-type tri- and tetraantennary Asn-linked oligosaccharides containing outer NeuAc linked (α-2,3) to penultimate Gal residues. Glycopeptide containing NeuAc linked only (α-2,6) to Gal do not interact with MAA ***(28)***.
Limulus polyphemus (LPA)	NeuAc	Terminal NeuAc **ref. *29***

Man, mannose; GlcNAc, *N*-acetylglucosamine; NeuAc, neuraminic acid; Gal, galactose; GalNAc: *N*-acetylgalactosamine; Fuc, fucose.
*a*Examples of carbohydrate structures recognized by the lectins commonly used in biochemical/biological research are presented in this table.

2. Materials

1. The transfer buffer for protein blotting by semi-dry method (see Chapter 59) or by tank method (*see* Chapter 58) is the Towbin buffer diluted 1:2 with distilled water: 12.5 m*M* Tris, 96 m*M* glycine and 10% (v/v) methanol ***(33)***.
2. PVDF membranes (0.2 mm, 200 × 200 mm) are supplied by Bio-Rad, the filter papers (chromatography paper grade 3 mm CHr) by Whatman and the nitrocellulose membranes (0.45 mm) by Schleicher & Shuell.
3. Blocking solution: 0.5% (w/v) Tween 20 in Phosphate buffered saline (PBS) ***(34).*** All further incubations and washing steps are carried out in the same blocking solution.
4. Phosphate buffered saline (PBS): 137 m*M* NaCl, 27 m*M* KCl, 10 m*M* Na_2HPO_4, 1.8 m*M* KH_2PO_4, pH 7.4. A 10 fold concentrated PBS solution is prepared, sterilized by autoclaving and stored at room temperature for many weeks (PBS 10 X: 80 g NaCl, 2 g KCl, 14.4 g Na_2HPO_4, 2.4 g KH_2PO_4. Add H_2O to 1 liter).
5. Biotinylated lectins are obtained from Boehringer-Mannheim. Sigma supply horseradish peroxidase (HRP) labelled Extravidin (a modified form of affinity-purified avidin) and alkaline phosphatase (AP) labelled Extravidin.
6. Two different detection methods are described: the chemiluminescent detection of horseradish peroxidase (HRP) activity using the luminol reagent (ECL Kit, Amersham International) and the conventional colorimetric reaction of alkaline phosphatase (AP) revealed by nitroblue tetrazolium/ bromochloro-indolyl phosphate (NBT/BCIP).

   a) Stock solutions of NBT and BCIP (Fluka): solubilize 50 mg NBT in 1 ml of 70% (v/v) dimethylformamide and 50 mg BCIP disodium salt in 1 ml dimethylformamide. These two solutions are stable when stored in closed containers at room temperature.
   b) Alkaline phosphatase buffer: 100 m*M* NaCl, 5 m*M* $MgCl_2$ and 100 m*M* Tris-HCl, pH 9.5 is prepared just before the colorimetric detection.
7. For the chemiluminescent detection of HRP activity, X-ray films (X-OMAT S, 18 × 24 cm) and a cassette (X-OMATIC cassette, regular screens) are available from Kodak.
8. For the development of X-ray film, an automatic developer machine is used (Kodak RP X-OMAT Processor, Model M6B). Manual development can also be done using the developer for autoradiography films (reference number P-7042, Sigma) and the fixer (reference number P-7167, Sigma).

3. Method

The use of gloves is strongly recommended to prevent blot contamination.

1. After electrophoresis and protein blotting procedures, the membrane is first washed with distilled water (3 × 5 min) and then treated for 1 hour at room temperature and under gentle agitation with 100 ml blocking solution (PBS containing 0.5% (w/v) Tween 20 (*see* **Note 3**).
2. The blot is then incubated for 2 h in biotinylated lectin, at a concentration of 1 µg/ml in the blocking solution, under agitation, in a glass dish and at room temperature. Twenty-five ml of lectin solution is used for the incubation of a membrane of 16.5 cm × 21 cm (*see* **Note 4**).
3. A washing step is then performed for 1 h with 6 changes of 200 ml of PBS-Tween 20.

4. Extravidin-HRP or Extravidin-AP diluted 1:2000 in the blocking solution is added for 1 h at room temperature under agitation. The membrane is then washed for 1 h with 6 changes of PBS-Tween 20.
5. The colorimetric reaction with alkaline phosphatase is carried out under gentle agitation by incubating the blot in the following solution: 156 µl BCIP stock solution, 312 µl NBT stock solution in 50 ml alkaline phosphatase buffer. The colorimetric reaction is normally completed within 10 to 20 min. The blotted proteins are colored in blue.
6. The chemiluminescence detection of peroxidase activity is performed according to the manufacturer's instructions (Amersham). The enhanced chemiluminescent assay involves reacting peroxidase with a mixture of luminol, peroxide and an enhancer such as phenol.

Five ml of detection solution 1 are mixed with 5 ml of detection solution 2 (supplied with the ECL Kit). The washed blot is placed in a glass plate and the 10 ml of chemiluminescent reagents are added directly to the blot with a 10 ml pipette, in order to cover all the surface carrying the proteins. The blot is incubated for 1 min at room temperature without agitation.

The excess chemiluminescent solution is drained off by holding the blot vertically. The blot is then wrapped in plastic sheet (Saran Wrap™), without introducing air bubbles and exposed (protein side up) to X-ray film in a dark room, using red safelights. The exposure time of the film depends on the amount of target proteins on the blot (*see* **Note 5**).

The development of the X-ray films can be done with an automatic developer or manually with the following protocol:

- The developer and fixer solutions are prepared according to the manufacturer's instructions (dilution 1:4 with distilled water).
- In a dark room, the film is attached to the film hanger and immersed in the developer solution until the bands (or spots) appear (the maximum incubation time is 4 min). The film should not be agitated during development.
- The hanger is immersed into water and the film is rinsed for 30 s to 1 min.
- The hanger is then placed in the fixer solution for 4 to 6 min. Intermittent agitation should be used throughout the fixing procedure.
- The film is washed in clean running water for 5 to 30 min.
- Finally, the film is dried at room temperature. All previous incubations are also undertaken at room temperature.

4. Notes

1. Instead of nitrocellulose, PVDF membrane can be used for lectin blotting.
2. **Fig. 1A** shows the plasma glycoprotein signals detected with WGA and generated on a film after chemiluminescence detection. **Fig. 1B** shows an identical blot stained with NBT/BCIP. As already reported ***(32)***, the same pattern of glycoproteins or glycoprotein subunits are revealed by both methods but the chemiluminescent detection system shows higher sensitivity (about 10

fold) than NBT/BCIP staining. The spots in the former case are more intense and the detection with enhanced chemiluminescence is more reliable and easier to control than the colorimetric reaction.

Albumin which does not contain any carbohydrate moiety represents a negative protein control in all blots.

Lectin blotting of plasma proteins with RCA, with AAA and with SNA are presented in **Figs. 2, 3,** and **4** respectively.

3. Generally, bovine serum albumin (BSA) or nonfat dry milk is used to block membranes. For lectin blotting, we have tested BSA, which has produced a very high background, probably due to glycoprotein contamination in the commercial preparations of this protein. When low fat dried milk was used, no glycoprotein signals were obtained on the blot after the chemiluminescent reaction. This could be attributed to the presence of biotin, that competed with biotinylated lectin and avoided its binding to the sugar moieties of glycoproteins ***(35)***. The PBS-Tween 20 blocking solution gave a very low background both for colorimetric and chemiluminescence detections.
4. The blot should be immersed in a sufficient volume of solution to allow a good exchange of fluid over its entire surface. The use of plastic bags to incubate protein-blots is not recommended because it often leads to uneven background and may cause areas without signal.
5. Most of the proteins in plasma are glycosylated. Therefore, a very short exposure time of the blot to X-ray film is needed. In general, when 120 µg of plasma proteins are loaded onto 2-D PAGE, the blot is exposed for a period of 3 to 30 s. The difference in the exposure time depends on the lectin used. For example, WGA lectin detects most of the N-linked glycoproteins and an exposure of only 3 s is sufficient ***(32)***. In this case, a longer exposure time leads to a very high background with no additional spot signal.

   For an unknown sample, the blot can be exposed for 1 and 5 min as a first attempt. The enhanced chemiluminescence using luminol (ECL Kit, Amersham) leads to a "flash" of light due to the addition of enhancers. The light emission on membrane peaks at 5–10 min after the addition of substrate and lasts for 2–3 h ***(36)***. Therefore longer exposure times (10 min – 3 h) may allow the detection of weak signals.

A Sensitive Method to Quantitatively Detect Total Protein on Membranes after Electrophoretic Transfer Using Avidin- or Streptavidin-Biotin

William J. LaRochelle

1. Introduction

Since the initial publication by Towbin and coworkers ***(1)*** on the preparation of sodium dodecyl sulfate-polyacrylamide gel replicas, commonly referred to as protein blots, the transfer of proteins from inaccessible gel matrices to readily accessible solid supports such as nitrocellulose or nylon membranes has become widely accepted ***(2-4)***.

The detection of electrophoretically transferred or blotted proteins has ranged from the selective identification of an individual protein of interest to the general staining of total protein ***(5)***. Specific proteins are detected with probes such as antibodies that are either directly radiolabeled or conjugated to an enzyme ***(6,7)***. Alternatively, bound and unlabeled antibodies are amplified by a secondary antibody or affinity probe similarly conjugated. The use of biotinylated antibodies followed by avidin or streptavidin enzyme conjugates has become well accepted ***(8).*** Indeed, the high affinity interaction between biotin and streptavidin has been further popularized in such diverse methods as generating cRNA (riboprobes) for *in situ* detection of low-quantity expressed mRNA ***(9)***, immunohistochemical analysis of proteins, and high-throughput screening of aptamer microarrays ***(10)***.

Total protein detection is usually based on chemical affinity staining methods such as Coomassie blue ***(11)***, amido black ***(12)***, India ink ***(13)***, oxidation/derivatization of carbohydrate moieties ***(14,15)***, silver enhanced copper detection ***(16)***, or ponceau S ***(17)***. Other approaches often require the chemical modification of the polypeptide with hapten followed by detection with anti-hapten antibody and labeled/conjugated secondary antibody, protein A, or protein G ***(18)***. Fluorescent

stains that improve on Sypro Ruby ***(19)*** such as LavaPurple or Deep Purple have been developed that improve the sensitivity for protein detection to as little as 1 ng per electrophoretically transferred band, but require fluorescent excitation capture by either a transilluminator or a fluorescent imager ***(19,20)***.

Here, we exploit the high affinity and well characterized interaction of biotin with either avidin or streptavidin ***(21-25)***. Briefly, proteins are resolved by SDS-PAGE, transferred to nitrocellulose membrane and the amino groups covalently derivatized ***(23,26)*** with sulfosuccinimidobiotin. Depending on the sensitivity

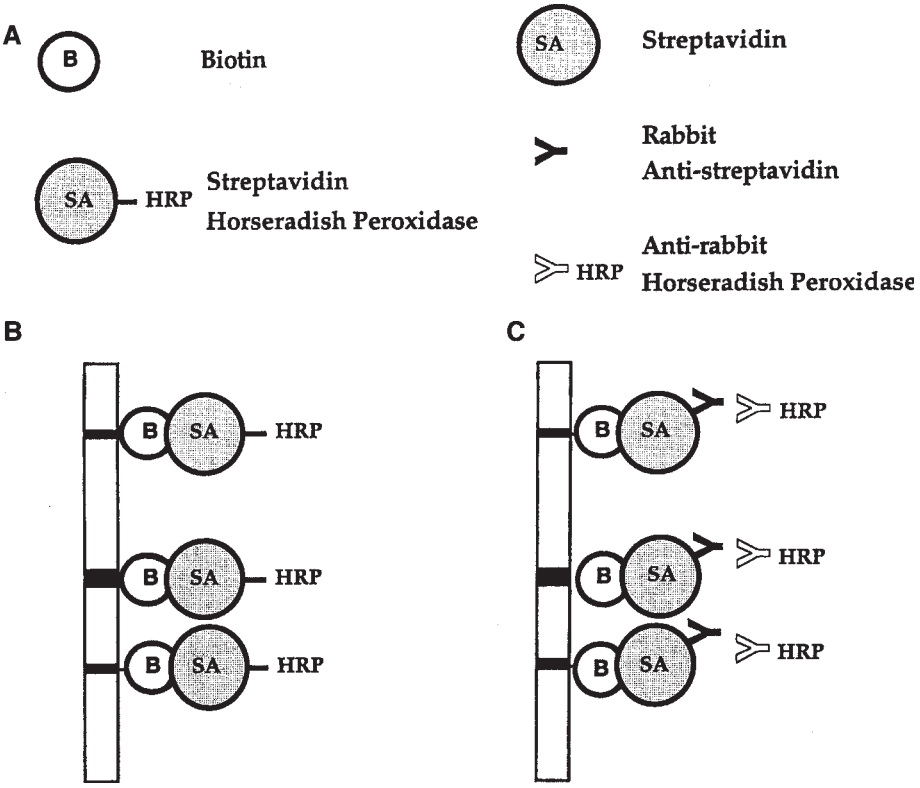

Fig. 1. Schematic diagram of streptavidin or amplified anti-streptavidin staining of nitrocellulose replicas. Electrophoretically transferred proteins were biotinylated on a nitrocellulose replica depicted here as a strip blot (elongated rectangle). Panel A: Legend. Biotin, B; streptavidin, SA; horseradish peroxidase, HRP. Panel B: Schematic diagram of streptavidin staining method (**Subheading 3.1**). Total protein, shown as individual dark bands, was biotinylated and detected with streptavidin conjugated to horseradish peroxidase followed by the α-chloronaphthol color reaction. Panel C. Schematic diagram of amplified anti-streptavidin staining method (**Subheading 3.2**). After electrophoretic transfer and biotinylation, streptavidin binding to biotinylated proteins was detected with rabbit anti-streptavidin followed by goat anti-rabbit antibody conjugated to horseradish peroxidase as described in **Subheading 3.2**.

required, either of two techniques that are illustrated in **Fig. 1,** is used to stain the proteins that appear as dark bands against an essentially white background ***(26,27)***. The first method utilizes avidin or streptavidin conjugated to horseradish peroxidase and detects less than 25 ng of protein in a single band. The second technique, although slightly more lengthy, requires streptavidin amplification with anti-streptavidin antisera followed by a secondary antibody conjugated to horseradish peroxidase. The latter procedure detects less than 5 ng of protein per band.

The methods described here ***(26-30)*** permit the direct comparison of stained replicas with a duplicate blot that has been probed with for example, a specific antibody or ligand. The approach is rapid and possesses greater sensitivity than the commonly used dyes. The detection scheme is less costly and time consuming than the use of metal stains that in some instances possess greater sensitivity. Moreover, problems associated with gel shrinkage on drying or altered electrophoretic mobility of proteins caused by staining or derivatization prior to electrophoresis is avoided. Since our initial study (26), this approach has also proved useful in detection and labeling of DNA on membrane supports ***(31,32)***.

2. Materials

2.1. Avidin or Streptavidin Horseradish Peroxidase Staining

1. Distilled, deionized water.
2. Plastic trays rather than glass are preferred.
3. Nitrocellulose membranes, 0.45 µm (Bio-rad, Richmond, CA).
4. Sulfosuccinimidobiotin (Pierce Chemical Company, Rockford, IL) solution: 10 m*M* in 100 m*M* sodium bicarbonate, pH 8.0.
5. Avidin conjugated to horseradish peroxidase (Cappel Laboratories, Malvern, PA.
6. Streptavidin conjugated to horseradish peroxidase (Gibco-BRL, Gaithersburg, MD).
7. PBS: 10 m*M* sodium phosphate, 150 m*M* sodium chloride, pH 7.4.
8. Block solution: PBS containing 5% v/v newborn calf serum (Gibco-BRL, Gaithersburg, MD) and 3% w/v bovine serum albumin (BSA, Fraction V, 98–99%, Sigma Chemical Co., St. Louis, MO).
9. Wash solution: PBS containing 0.05% w/v Tween 80 (Sigma Chemical Co., St. Louis, MO).
10. PBS containing 0.05% w/v Tween 80 and 1.0% w/v BSA.
11. 1.0 *M* glycine-HCl pH 6.5.
12. α-chloronaphthol solution: PBS containing 0.6 mg/ml α-chloronaphthol (4-chloro-1-naphthol, Sigma) and 0.01% hydrogen peroxide.

2.2. Streptavidin/ Anti-Streptavidin Amplified Staining

1. Materials listed in **Subheading 2.1** excluding avidin or streptavidin-HRP.
2. Streptavidin (Gibco-BRL, Gaithersburg, MD).
3. Anti-streptavidin (Sigma Chemical Co., St. Louis, MO or Zymed Laboratories Inc., South San Francisco, CA).

4. Goat anti-rabbit immunoglobulin conjugated to horse radish peroxidase (Cappel Laboratories, Malvern, PA).

3. Method

3.1. Avidin or Streptavidin Horseradish Peroxidase Staining

1. After sodium dodecyl sulfate-polyacrylamide gel electrophoresis, electrophoretically transfer proteins to nitrocellulose membranes (*see* **Notes 1** and **2**). Rinse the nitrocellulose replicas three times and soak in 100 m*M* sodium bicarbonate pH 8.0 for 5 min (0.25 to 0.50 ml/cm^2 nitrocellulose). Typically, a 10 ml volume is used for a minigel replica. The solution volume should permit the filter to move freely upon agitation. Carry out all incubation and washing reactions using an orbital shaker or rocker platform at ambient temperature.
2. Transfer and submerge the replicas in the same volume of freshly prepared sulfosuccinimidobiotin solution for 45 min (*see* **Notes 3** and **4**).
3. Add 1 *M* glycine-HCl, pH 6.5 to a final concentration of 1 mM for approximately 5 min to quench the derivatization reaction.
4. Wash the filters 3 times (5 min each wash) with PBS to remove free sulfosuccinimidobiotin. Incubate filters 30 min with block solution.
5. Incubate the replicas for 1 h with either avidin conjugated to horseradish peroxidase (5 ug/ml) or streptavidin conjugated to horseradish peroxidase (1 ug/ml) diluted in PBS containing 1% BSA, 0.05% Tween 80 (*see* **Note 5**).
6. Wash filters 3 times for 15 min each time with the same volume of wash solution. Protein bands are visualized by immersing the replicas in α-chloronaphthol solution (*see* **Note 6**).
7. After allowing sufficient time for color development (usually 30 min), rinse the replicas with distilled water and dry between two sheets of dialysis membrane. The replicas may also be dried and stored in cellophane for future use.

3.2. Streptavidin/ Anti-Streptavidin Amplified Staining

1. If desired, an alternative procedure to amplify five-fold the detection method described above is utilized. First, biotinylate and block the nitrocellulose filters as described in **Subheading 3.1, Step 1** to **Step 4** of the avidin or streptavidin staining protocol.
2. Incubate blots with streptavidin (1 µg/ml) for 1 h in PBS containing 1% BSA, 0.05% Tween 80. Wash the replicas 3 times for 15 min each time with wash solution.
3. Next, dilute affinity purified rabbit anti-streptavidin IgG (0.5 µg/ml) in PBS containing 1% BSA, 0.05% Tween 80. Add solution to replica for 4 h or overnight if convenient. Wash replicas 3 times for 15 min each time with wash solution.
4. Incubate replicas with goat anti-rabbit immunoglobulin conjugated to horseradish peroxidase diluted (4 µg/ml) in PBS containing 1% BSA, 0.05% Tween 80 for 4 h. Wash replicas 3 times for 15 min each time with wash solution.
5. Protein bands are visualized by immersing the replicas in α-chloronaphthol solution for approximately 30 min (*see* **Note 6**). The replicas are rinsed with distilled water and dried between two sheets of dialysis membrane.

4. Notes

1. We found that this method is more sensitive for nitrocellulose membranes than for proteins transferred to Biodyne membranes by approximately ten-fold due to the higher background staining of Biodyne membranes.
2. Because of the sensitivity of the staining, care should be taken to avoid protein contamination of replicas with fingertips, and so on. Gloves or forceps should be used.
3. This method chemically modifies the free amino groups of proteins bound to filters. Amine containing compounds such as Tris or glycine buffers will compete for biotinylation with the sulfosuccinimidobiotin. Blot transfer buffers that contain free amino groups such as Tris or glycine may be used, but must be thoroughly removed by soaking and rinsing as indicated in **Subheading 3.1**.
4. The staining is highly dependent on the sulfosuccinimidobiotin concentration. Sulfosuccinimidobiotin concentrations of greater than 10 μM have resulted in a dramatic decrease of protein staining intensity ***(19)***. In some instances it may be necessary to empirically determine the optimal concentration of sulfosuccinimidobiotin to use for staining particular proteins.
5. Little or no differences were observed when avidin conjugated to horseradish peroxidase was substituted for streptavidin conjugated to horseradish peroxidase. However, for some applications streptavidin may present fewer problems due to a neutral isoelectric point and apparent lack of glycosylation.
6. Sodium azide will inhibit horseradish peroxidase and accordingly must be removed before addition of the α-chloronaphthol solution.
7. All reagent concentrations were determined empirically and were chosen to give maximum staining sensitivity. In principle, our procedure can be used in double-label experiments in which all proteins on the replica are biotinylated and the same blot is then probed with radiolabeled antibody or protein A.
8. Enhanced chemiluminscence has been shown to increase the sensitivity of horseradish peroxidase calorimetric or dye based assays 10-fold ***(33)***.

Detection and Quantification of Proteins on Immunoblots using Enhanced Chemiluminescence

Jennifer J. Young

1. Introduction

The technique of immunoblotting (Western blotting), following separation of proteins by gel electrophoresis, is widely used in molecular and cell biology ***(1,2).*** It enables the proteins under study to be fixed on a membrane that is much easier to handle and probe than a polyacrylamide or agarose gel. Proteins are then detected by incubation of the membrane with an appropriate primary antibody for the protein concerned, followed by incubation with a secondary antibody raised to recognise epitopes on the constant region of the primary antibody. This secondary antibody can be conjugated to a radio-label, a fluorophore or an enzyme ***(3).*** In the latter case an appropriate substrate is then used to generate a product which can be measured.

Early workers used radiolabels, particularly ^{125}I, to detect proteins on immunoblots ***(1).*** The sensitivity was good and the method gave a quantifiable permanent record in the form of an image on X-ray film. However long exposure times were needed and this, combined with the associated safety and disposal problems, has made the technique less popular. Fluorescently-labelled antibodies have also been employed using a fluorescent laser scanner for measurement ***(4).*** This system overcomes the problems of dealing with radio-active materials and has the advantage that the signal is read directly from the bound antibody but has limits in terms of sensitivity ***(5).*** Enzymes conjugated to secondary antibodies offer a detection system where many molecules of product are generated for each enzyme-linked molecule of antibody bound to protein. This achieves amplification of the signal, giving increased sensitivity, without the need for the special handling conditions associated with radioactive tracers.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

The first detection systems developed for enzyme-linked antibodies were colorimetric, using chromogenic substrates which generated a product that could be visualised. Whilst easy to use and effective, they have several drawbacks. There is no permanent record as colours fade over time, membranes are not easily re-probed and sensitivity is still limited. Enhanced chemiluminescence (ECL) overcomes many of these limitations and is now widely used as a detection system, in preference to colorimetric methods. ECL is based on an enzyme-substrate system in which the reduction of hydrogen peroxide in alkaline conditions, catalysed by horseradish peroxidase (HRP), is accompanied by the oxidation of the chemiluminescent compound luminol, with the concomitant production of light (*see* ***Fig. 1***). In the presence of phenolic enhancers, the intensity of the light is increased (or enhanced) a 1000-fold and the time of emission extended ***(6)***. The outcome is a strong signal which peaks within 10 min and then decays slowly, having a half-life of 1 h. There is an excellent signal-to-noise ratio and the output can be satisfactorily recorded on photographic film. Subsequent densitometric analysis of the images can be used to quantify the protein bands. A similar system with alkaline phosphatase (AP) as the enzyme has also been developed, although this can suffer from problems of high background due to bacterial alkaline phosphatase contamination of buffers.

The use of enhanced chemiluminescence as a detection system offers a number of advantages:

- High sensitivity: using standard reagents 1 pg of protein can be detected, making it at least 10x more sensitive than colorimetric systems and 2–5x more sensitive than radioactive methods. Using some of the more recently developed reagents this sensitivity can be increased up to 200-fold (*see* **Note 11**).
- High resolution: the signal-to-noise ratio is low and a high contrast, easily quantifiable signal is generated.
- Speed: a strong light signal is generated rapidly which can be recorded within min.

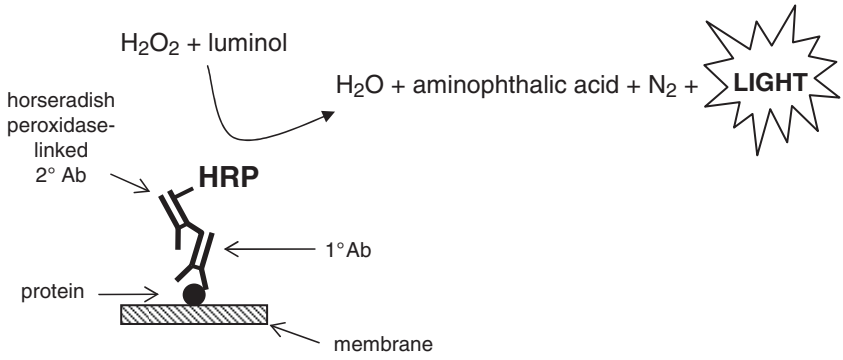

Fig. 1. Protein detection by chemiluminescence after immunoblotting.

- Permanent, quantifiable record: the film can be kept indefinitely and the amount of protein detected can be measured with a densitometer.
- Multiple images: the membrane can be repeatedly exposed to film, giving several copies of the image and an opportunity for optimisation.
- Conservative use of antibodies: the high sensitivity means a lower concentration of antibody is required.
- Versatility: agarose gels, in addition to one and two-dimensional polyacrylamide gels, can be probed.
- Nondestructive: the membrane can be reprobed many times with the same or different antibodies.

The technique of ECL is widely used as there are very many scenarios where proteins are studied both qualitatively and quantitatively. One example is the elucidation of signalling pathways within a cell under specific conditions when it is useful to monitor the induction, expression or phosphorylation of particular enzymes. Changes of proteins in different disease states can also be monitored. The example shown here is an immunoblot from an experiment that explored the possible contribution of lipopolysaccharide to the induction of the pro-inflammatory enzyme cyclo-oxygenase 2 at the site of a chronic wound (*see* **Fig. 2**).

2. Materials

2.1. Equipment

1. Electrophoresis equipment
2. Electroblotting equipment
3. Power pack
4. Forceps
5. Transfer membrane: for example nitrocellulose (Amersham Hybond™ ECL, GE Healthcare; WestClear™, GenScript; Immobilon P, Millipore), polyvinylidine difluoride (PVDF), (Amersham Hybond™ PAGE Healthcare)
6. Plastic cassette
7. SaranWrap™
8. X-ray film cassette
9. Autoradiography film: Amersham Hyperfilm™ ECL
10. Timer
11. Polaroid camera (Amersham, GE Healthcare) optional (*see* **Note 9**)
12. Software for densitometric analysis: Syngene GeneTools or Amersham ImageQuant™

2.2. Reagents

1. Acrylamide gels of the appropriate density prepared according to the method of Laemmli *(7)*.
2. Running buffer: 12 g Tris (0.05 *M*), 57.6 g glycine (0.384 *M*), 2.0 g SDS (0.1%) made up to 2 L in distilled water. No pH adjustment is necessary. It can be made up at x5 concentration and stored at room temperature for up to 3 months.

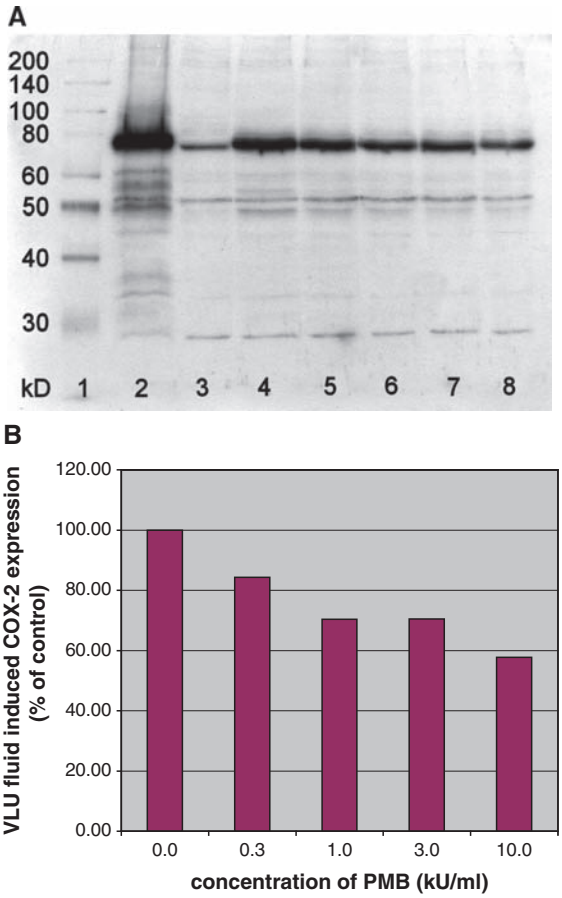

Fig. 2. Immunoblot and associated densitometry for the expression of cyclo-oxygenase 2 (COX-2) in J774 mouse macrophages treated for 18 hrs with venous leg ulcer (VLU) fluid. The VLU fluid had been pre-incubated with polymyxin B (PMB, which binds lipopolysaccharide), at a range of concentrations, for 1 hr prior to treatment of the cells. Depicted on the left of the immunoblot are the relative molecular masses of the standard proteins in the molecular weight marker (Biotinylated protein ladder detection pack, NE Biolabs). Lane 1 is the positive control for COX-2, lane 2 is lysate from untreated cells, lanes 4–8 are lysates from cells treated with VLU fluid which had been incubated with 0.0, 0.3, 1.0, 3.0, and 10.0 kU/ml of polymyxin B respectively. The graph shows the expression of enzyme as a percentage of that induced in cells dosed with untreated VLU fluid, The immunoblot was quantified using a document scanner and Syngene GeneTools software.

3. Sample buffer (*See* **Note 14**): 1 ml of 0.6M Tris-HCl, pH 6.8, 2 ml of 10% SDS solution, 1 ml glycerol, 0.1 ml of 2% bromophenol blue, can be stored at 2–8°C for 1 month. To use add the reducing agent 1*M* dithiothreitol (DTT) (0.1 ml DTT to 0.4 ml

stock). 1*M* DTT can be kept in one-use aliquots at −20°C. 2-mercaptoethanol can also be used as a reducing agent.
4. Samples
5. Positive control for the primary antibody (*see* **Note 1**).
6. Molecular weight marker (*see* **Note 2**).
7. Transfer buffer: Make up 15.14 g Tris (25 m*M*), 72.07 g glycine (192 m*M*) to 4L in distilled water and add 1L of methanol.
8. PBS-Tween: phosphate buffered saline with 0.05% Tween 20.
9. Blocking agent: for example 5% w/v nonfat dried milk, 1% w/v bovine serum albumin in PBS-Tween.
10. Primary antibody made up in PBS-Tween.
11. Secondary antibody conjugated to HRP or AP made up in PBS-Tween.
12. ECL reagents: Amersham ECL™ (GE Healthcare), Pierce ECL Western Blotting Substrate (Pierce), Immobilon™ Western HRP Substrate (Millipore), LumiSensor™ Chemiluminescent HRP Substrate Kit (GenScript) (*see* **Notes 10** and **11**)
13. Developer and fixer (Kodak GBX) diluted according to the manufacturer's instructions and stored in light-proof bottles. The prepared solutions can be kept at room temperature for at least 1 month provided the developer is not exposed to light other than the red light in the dark room.

3. Methods

3.1. Electrophoresis and Immunoblotting

The following is a brief summary of the protocols. These techniques are described in more detail in Chapters 58 and 59. The membrane should be handled using forceps and gloves at all times to avoid contamination.

1. Assemble the gel cassette and add running buffer.
2. Add the samples to an equal volume of sample buffer, heat to 95°C for 5 mins, centrifuge (10,000 g, 5 mins) and load onto the gel. Also load a sample of molecular weight marker and positive control for the primary antibody.
3. After separation by electrophoresis, transfer the proteins to a membrane (either nitrocellulose or PVDF) by immunoblotting. It is useful to cut one corner of the membrane before transfer to indicate the orientation of the blot. (*See* **Notes 6** and **12**)
4. The membrane can be probed immediately or air-dried and stored in a desiccator at 2–8°C for up to 3 months.

3.2. Probing the Membrane

The following is a recommended protocol but the solutions, times and temperatures can be varied to optimise conditions for the user's experimental system. All steps should be carried out on an orbital shaker.

1. Transfer the membrane to a plastic cassette containing blocking solution, with the surface that was touching the gel facing upwards. Incubate for 2 hrs at room temperature or overnight at 2–8°C (*see* **Note 4**)

2. Replace the blocking solution with primary antibody at the appropriate concentration and incubate for 2 hrs at room temperature or overnight at 2–8°C (*see* **Notes 4** and **13**)
3. Remove the primary antibody solution (*see* **Note 15**) and quickly rinse the membrane several times in PBS-Tween. Then wash the membrane more thoroughly by incubating 4x in PBS-Tween, placing the cassette on the shaker for 10 mins for each wash (*see* **Note 4**)
4. Add secondary antibody solution at the appropriate concentration and incubate at room temperature for 30 mins to 1 h. If using a molecular weight marker that requires a detection antibody add it to the solution at this stage (*see* **Notes 2** and **4**)
5. Remove the secondary antibody solution and wash the membrane in PBS-Tween, as described in step 4.

3.3. Detection by Enhanced Chemiluminescence

1. Remove excess buffer from the membrane by holding it vertically with forceps and touching the edge against a piece of paper towel. Further drying can be achieved by placing the membrane in a clean plastic cassette (protein side upwards) and then lifting it repeatedly, each time wiping the cassette beneath the membrane with a paper towel. Leave the membrane in the cassette (*see* **Note 4**)
2. Prepare the substrate according to the manufacturer's instructions. 1 ml of substrate will be sufficient for each membrane if it was cut to match the size of a minigel. Larger membranes will require more and the volume can be increased accordingly.
3. Using a Gilson pipette spread the substrate over the surface of the membrane, tilting the cassette gently to ensure it is evenly covered (*see* **Note 6**). Incubate for 1 min.
4. Using forceps dry the membrane by holding it vertically and touching the edge against a piece of paper towel. Further drying can be achieved as described above.
5. Place the membrane on a piece of SaranWrap™ and carefully fold over the wrap to cover the membrane, making sure there are no creases.
6. Place the membrane in the X-ray film cassette, protein side upwards. It can be taped in place if necessary.
7. Cut a piece of film slightly larger than the membrane and place it on top.
8. Close the cassette and expose the membrane for 5 min. This is a useful time for a first exposure but the time can be adjusted for subsequent images according to the result (*see* **Note 3**)
9. Remove the film using forceps and gently agitate in developer solution, watching for the appearance of bands (*see* **Notes 4** and **5**)
10. As soon as the bands appear transfer to a tray of water and wash off the developer by agitating gently.
11. Transfer to fixer and leave to fix. The background to the film will become clear when this stage is completed.
12. Thoroughly wash off fixer by holding the film under a running tap and leave to dry.
13. Further exposures can be carried out according to the results (*see* **Note 3**).
14. It is recommended that all images are labelled immediately with samples, date and antibody used.
15. If appropriate the membrane can be re-probed (*see* **Note 16**).

3.4. Densitometric Analysis of Immunoblot

The photographic film can be analysed semiquantitatively in one of several ways. Either the image can be captured on a gel documenter (SynGene Gene Genius) using SynGene software and then analysed using SynGene GeneTools. Alternatively the image can be scanned using a document scanner and then analysed by GeneTools software. Densitometric analysis is also possible in Photoshop but is more tedious done this way and is only useful for occasional images. Semi-quantitative analysis is useful when a comparison to a control is required, for instance when looking at the induction of an enzyme within a cell or for tracking the phosphorylation of a particular protein on a signalling pathway.

Several films exhibit a linear response to the light produced by ECL. It is therefore possible for a more rigorous quantification to be achieved. In addition the range can be extended to increase accuracy at the lower levels by pre-flashing the film prior to exposure (*see* **Note 17**). A range of standards containing known amounts of the protein under investigation should be loaded onto the gel, in addition to at least two dilutions of the unknown samples. The time of exposure to the film should then be optimised so that the lowest concentration of standard protein is just visible. After scanning and densitometric analysis a graph of peak area against protein concentration can be plotted and the concentration of the unknown samples determined.

A charge coupled device (CCD) camera can be used as an alternative system for capturing the light output. These convert the light emitted from the blot to an electrical signal which is then converted to a digital signal to give a quantifiable value ***(8)*****.** In some cases they can provide better sensitivity than film and they have a wider dynamic range, giving increased options for quantification.

4. Notes

The methods of electrophoresis and immunoblotting are addressed in Chapters 58 and 59 and the associated notes should also be read.

For detection by ECL please note the following.

1. A positive control for the primary antibody should always be included on the gel. This provides a way of ensuring that if no bands are seen in the experimental samples it is not due to lack of antibody binding.
2. Several types of molecular weight markers can be used and everybody has their favourites. Common ones are pre-stained markers which can be seen on the membrane. These have the advantage of showing whether the transfer has been successful prior to exposure to antibody. The position of the standard proteins can be noted on the image by lining it up with the membrane after development and recording their position with a permanent marker. Other types of molecular weight marker are sold as kits which include a labelled

secondary antibody for the standard proteins. This secondary antibody can be added at the same time as the secondary antibody for the protein under study. These markers usually require at least 3 mins exposure to the photographic film and are not always appropriate if a high affinity primary antibody is being used or if an abundant protein is being studied. However the primary antibody solution can always be used at a lower concentration and/or lower sample volumes applied to the gel to get round this.

3. Exposure times vary according to the relative abundance of the protein and the affinity of the primary antibody. If no bands are seen with a relatively short exposure time it is always worth leaving the membrane exposed to film for 20–30 mins.
4. A high background on the area of the photographic film that corresponds to the membrane can be caused by a variety of things. Firstly it should be noted that polyclonal primary antibodies, by their very nature, are likely to cause higher levels of nonspecific binding than monoclonal antibodies. However high background can be reduced by:
   - More thorough washing. Do not be afraid to spray directly onto the membrane with a squeezy bottle containing the PBS-Tween when carrying out the washes.
   - Better blocking. If blocking was carried out at room temperature, try an overnight incubation. This is particularly useful if using a detergent like Tween 80 rather than a protein as the blocking agent. Alternatively try a different blocking solution. It should be noted that not all nonfat milk is the same. The author has found that "own-label" products sometimes contain a low level of fat which seems to make them less efficient at blocking the empty sites on the membrane.
   - Reducing the concentration of the antibodies, particularly the secondary one.
   - Reducing the development time.
   - Checking that the secondary antibody is not too old. They do degrade over time and high background is a consequence of this.
   - More thorough drying of the membrane prior to application of ECL reagent. The presence of Tween 20 can cause increased background.
   - By including either nonfat milk (1–5%) or BSA (1%) in the primary and secondary antibody solutions.
5. High background across the entire film is usually caused by old developer and is rectified by preparing a fresh solution.
6. Bubbles can be seen on the image for several reasons. Either air or buffer was trapped between the membrane and the gel during transfer, the ECL reagent was unevenly applied to the membrane or the membrane was allowed to partially dry out at some stage.

7. White bands on the film are indicative of excess protein or antibody, leading to rapid substrate depletion.
8. If the bands on the image are very diffuse it may be because the membrane was inadvertently turned over during the procedure and the substrate applied to the side which was not in contact with the gel.
9. For initial experiments a Polaroid™ camera (Amersham, GE Healthcare) can be used to obtain an image from blots generated from mini-gels. Initial exposure time should be 1–2 mins. It is quick and easy and the resulting image gives a good first indication of the results of the experiment and can show whether it is worth using the conventional method to get a better quality image for possible publication.
10. Whilst there is a range of reagents commercially available, ECL reagent can also be prepared in the laboratory. The components are: 10 n*M* luminol in 20 m*M* Tris-HCl, pH 8.5; 5 n*M* 4-iodine-phenol in 20 m*M* Tris-HCl, pH 8.5; 20 n*M* aqueous H_2O_2 solution.
11. More sensitive ECL reagents have now been developed by some suppliers and are useful for visualising proteins at very low levels or when the primary antibody is in short supply. Examples are Amersham ECL Plus and Amersham ECL Advance™ (GE Healthcare). There are also chemifluorescent reagents such as Amersham ECL Plus™ Chemifluorescent (GE Healthcare).
12. If no image at all is seen this could indicate that the power pack was incorrectly connected or the gel membrane sandwich put in the cassette the wrong way around. The efficiency of the transfer can be checked before antibody application by incubation of the membrane in Ponceau S dye solution for a few minutes followed by washing with distilled water. Whilst the proteins under study may be of too low an abundance to be picked up, the standard proteins in the molecular weight marker should still be seen. In addition the gel can be stained with Coomassie Brilliant Blue dye (*see* Chapter 21).
13. Alternatively, if no image was seen, check that a primary antibody suitable for immunoblotting was used. The proteins in this procedure are denatured and antibodies raised to epitopes on native proteins may not bind to them.
14. For samples prepared from cell lysates, if the antibody affinity is low or the protein content of the sample low, a modified method of preparing the samples can be used to increase the protein content. By using a lysis buffer made up from the sample buffer without the dye and reducing agent to lyse the cells, only the latter two components need to be added to the samples to prepare them for electrophoresis. This reduces the overall volume, maximising the protein content of the sample.
15. Primary antibodies can be stored and reused. However care must be taken with the use of sodium azide to inhibit bacterial growth as it interferes with horse-

radish peroxidase. It can be used successfully but the amount must be kept to an absolute minimum and thorough washing prior to secondary antibody incubation adhered to.

16. Membranes can be re-probed. Sometimes, if the second protein under investigation is of a very different molecular weight, the membrane can just be thoroughly washed in PBS-Tween and reincubated with the appropriate primary antibody. Alternatively the membrane can be completely stripped of primary and secondary antibodies by submerging it in stripping buffer (62.5 m*M* Tris-HCl pH 6.7, 100 m*M* 2-mercaptoethanol, 2% SDS) and incubating at 50°C for 30 mins with occasional agitation. The membrane should then be washed in PBS-Tween (2 × 10 mins) and blocked by incubation in blocking solution for 1 hr at room temperature. It is also possible to buy stripping solution in kits, for example ReBlot plus™ Western Blot Recycling Kit (Millipore). Membranes can be probed 5–10 times and should be stored wet, wrapped in SaranWrap™, at 2–8°C between each immunodetection.
17. Preflashing can be carried out using a modified flash unit that has been calibrated (by adjusting its distance from the film) to raise the optical density of the film by 0.1–0.2 OD units above that of the standard film. The flash duration should be about 1 msec.

Reutilization of Western Blots After Chemiluminescent or Autoradiographic Detection

Scott H. Kaufmann

1. Introduction

Western blotting (also called immunoblotting) is a widely utilized laboratory procedure that involves formation and detection of antibody-antigen complexes between antibodies that are initially in solution and antigens that are immobilized on derivatized paper ***(1-3)*** This procedure is most commonly performed by sequentially subjecting a complex mixture of polypeptides to three manipulations: i) electrophoretic separation, usually through polyacrylamide gels in the presence of sodium dodecylsulfate (SDS); ii) electrophoretic transfer of the separated polypeptides to thin sheets of nitrocellulose or polyvinylidene fluoride (PVDF); and iii) reaction of the sheets sequentially with one or more antibody-containing solutions. Because these are laborious, low throughput procedures, there has been considerable interest over the past 15 years in increasing the information gained from immunoblots. Various approaches to this problem have included removal of bound antibodies so that immobilized polypeptides can be reprobed with additional antisera (last reviewed in ***(4)***), the sequential ***(5)*** or simultaneous ***(6)*** use of multiple antisera to detect different antigens, and the development of protein microarrays that can be used to simultaneously detect antibodies to a variety of immobilized antigens ***(7, 8)*** or quantitate binding of labeled polypeptides from complex mixtures to immobilized antibodies ***(9, 10)***. All of these approaches are variations on the basic immunoblotting procedure developed almost 30 years ago.

Because of their versatility, immunoblotting approaches are widely employed in biological studies. With a high quality antiserum or monoclonal antibody, this approach can determine whether an antigen of interest is present in a particular

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

biological sample, monitor the purification of the antigen, or assess the location of epitopes within the antigen after chemical or enzymatic degradation. If suitable immunological probes are available, blotting can likewise be utilized to search for polypeptides that bear a particular physiological or pathological posttranslational modification, e.g., phosphorylation ***(11)*** or nitrosylation of tyrosine ***(12)***, covalently attached glycosylphosphatidylinositol ***(13)***, or modification by D-penicillamine metabolites ***(14)***. Conversely, immunoblotting can also be utilized to determine whether antibodies that recognize a particular antigen are present in a sample of biological fluid. For example, western blotting has become a method of choice for confirming that antibodies to human immunodeficiency virus-1 ***(15)***, Herpes simplex virus-2 ***(16)*** or *B. burgdorferi* ***(17)*** are present in patients suspected of harboring these pathogens. Likewise, immunoblotting or variations on this procedure are utilized to detect autoantibodies present in the cerebrospinal fluid of patients with multiple sclerosis ***(18, 19),*** characterize antigens recognized by autoantibodies in various dermatological and rheumatological disorders ***(7, 20, 21)***, and identify allergens that plague atopic individuals ***(22)***.

There are certain circumstances in which it is convenient to be able to probe immunoblots for the presence of multiple antigens. If immunoblotting suggests an unexpected subcellular distribution for a polypeptide, for example, reprobing the blot with a reagent that recognizes a second polypeptide is essential in order to confirm that the samples have been properly prepared, loaded, and transferred. Likewise, if the polypeptides being analyzed are derived from a precious source (e.g. pathological tissue, biological fluid, or organism that is not readily available), it is sometimes important to reutilize the blots.

1.1. Reutilization of Blots Without Removal of Antibodies

When two antigens of interest can be readily distinguished by size, blots can be probed with two different immunological reagents simultaneously. Bound primary antibody is then visualized by probing with one or more enzyme-coupled or radiolabeled secondary antibodies as needed. Interpretation of results obtained in this manner can be difficult, however, if one or more of the immunological reagents cross-reacts with multiple polypeptides on the blot or one of the polypeptides of interest exists as multiple species, e.g., splice variants or posttranslationally modified forms. A recently described alternative to this procedure involves the use of primary antisera raised in several different species followed species-specific secondary antibodies coupled to fluorophores with distinguishable spectral properties ***(6).*** This approach has the advantage of allowing unequivocal detection of the species that react with each primary antibody. Its disadvantages, however, include the need for primary antisera raised in different species and the need for specialized imaging equipment, which some centers do not have.

An alternative to simultaneous probing involves sequential probing of blots with different reagents. Earlier studies demonstrated that sodium azide inactivates horseradish peroxidase ***(23, 24)***. Building on these observations, we demonstrated that blots can be sequentially reacted with multiple different peroxidase-coupled secondary antibodies without interference provided that the primary antibody solutions contain sufficient azide to inactive the enzyme bound to previously added secondary antibody ***(25)***. This process is illustrated in **Fig. 1,** where the same piece of nitrocellulose was sequentially reacted with

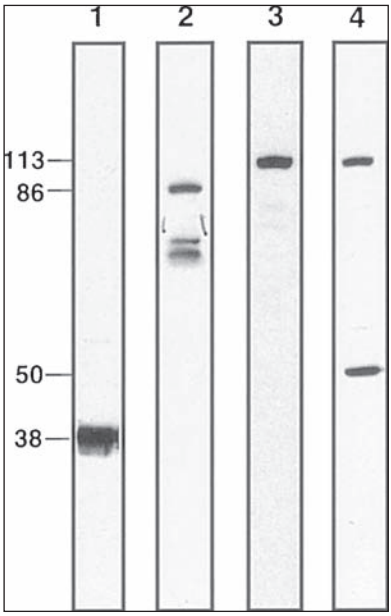

Fig. 1. Reutilization of immunoblots without intervening dissociation of antibodies. After staining with fast green FCF and coating with TSM (**Subheading 3.1, steps 8–11**), a single strip containing total cellular protein from 3×10^5 K562 human leukemia cells was sequentially subjected to immunoblotting using the following primary (secondary) reagents: chicken anti-B23 (peroxidase-coupled goat anti-chicken IgG), rabbit anti-protein kinase Cδ (peroxidase-coupled goat anti-rabbit IgG), mouse anti-poly(ADP-ribose) polymerase (peroxidase-coupled goat anti-mouse IgG), and mouse anti-procaspase-9 (peroxidase-coupled goat anti-mouse IgG). Bound secondary antibodies were detected using enhanced chemiluminescence reagents. At each step, the primary antibody solution contained 1 mM sodium azide. Note that the peroxidase bound to the blot at each step is not catalytically active at subsequent steps (cf. lanes 1–3), whereas the previously bound primary antibodies react with fresh secondary antibodies at subsequent steps (cf. lanes 3, 4). Numbers at left, molecular weights of the respective proteins in kDa.

immunological reagents raised in chickens, rabbits and mice. With successive use of reagents raised in different species, the signal obtained at each step is unaffected by the prior reactions (**Fig. 1,** lanes 1–3) even though the previously bound antibodies remain attached to the blot. It is important to stress, however, that each of these probings involves a different secondary antibody. When the same blot is subsequently probed with a second mouse IgG monoclonal antibody, the previously bound mouse IgG is detected by the peroxidase-coupled anti-mouse IgG (**Fig. 1,** lanes 3 and 4). Thus, sequential probing works well when multiple primary antibodies raised in different species are available or when antigens of different molecular weights can be unequivocally detected using antibodies from the same species. This approach can become problematic, however, if the antigens of interest migrate similarly or the immunological reagents cross-react with multiple species of different molecular weights. Under these circumstances, removal of antibodies from blots might be required between sequential probing.

1.2. Removal of Antibodies After Blotting

Methods for removing bound antibodies before probing with a new immunological reagent are patterned after methods for reutilizing Southern and Northern blots ***(26)***. In principle, the goal is to remove antibodies from the blot without removing the antigen of interest. The original methods developed with this purpose in mind (reviewed in **ref.** ***27***) involved the covalent binding of target polypeptides to derivatized paper so that subsequently bound antibodies could be solubilized under denaturing conditions without eluting the antigens of interest. Unfortunately, these techniques never gained widespread acceptance because of the fragility of derivatized paper.

Polypeptides are more commonly immobilized on nitrocellulose or PVDF, solid supports that are thought to bind macromolecules noncovalently. The critical issue then becomes the identification of conditions that solubilize antibodies without solubilizing the target polypeptides. Some reports have indicated that treatment of nitrocellulose blots with glycine (pH 2.2) at room temperature ***(28)*** or 8 M urea at 60°C ***(29)*** can remove antibodies and permit reutilization of blots. Other studies have indicated that these techniques disrupt low-affinity antibody-antigen interactions but not high-affinity interactions ***(28, 30)***

Subsequent observations allowed the development of a more widely applicable technique for the removal of antibodies from Western blots. In particular, treatment of nitrocellulose with acidic solutions of methanol was observed to "fix" transferred polypeptides to nitrocellulose ***(31, 32)***. Polypeptides treated in this fashion remain bound to nitrocellulose even during treatment with SDS at 70–100°C under reducing conditions ***(30, 31)***. These observations facilitated development of a simple procedure for removal of peroxidase-coupled antibodies after detection of antigens by enhanced chemiluminescence (*see* **Subheading 3.3**).

Because of the increased sensitivity of autoradiographic detection, merely solubilizing antibodies in SDS is sometimes not sufficient to permit reutilization of blots probed with radiolabeled antibodies. We previously observed that treatment of blots with a large excess of irrelevant protein immediately prior to drying and autoradiography facilitates subsequent removal of radiolabeled antibodies from nitrocellulose ***(30)***. Based on this observation, a stripping technique that allows the reutilization of Western blots after reaction with a wide variety of radiolabeled antibodies or lectins (**Subheadings 3.3** and **3.4**) was developed **(30)**.

2. Materials

1. Apparatus for transferring polypeptides from gel to solid support. (Design principles are reviewed in ***refs. 2*** and ***3***).
   a. Reservoir-type electrophoretic transfer apparatus (Hoefer Scientific, Holliston, MA) or equivalent.
   b. Polyblot semidry blotter (Amersham Biosciences) or equivalent.
2. Paper support for binding transferred polypeptides.
   a. Nitrocellulose.
   b. Nylon (e.g., Genescreen from New England Nuclear, Boston, MA, or Nytran from Schleicher and Schuell, Keene, NH).
   c. PVDF (e.g., Immobilon from Millipore, Bedford, MA).
3. Fast green FCF for staining polypeptides after transfer to solid support.
4. Penicillin 10,000 units/ml and streptomycin 10 mg/ml.
5. Reagents for electrophoresis (acrylamide, bisacrylamide, 2-mercaptoethanol, sodium dodecylsulfate) should be electrophoresis grade.
6. All other reagents (Tris, glycine, urea, methanol) are reagent grade.
7. Transfer buffer: 0.02% (w/v) sodium dodecylsulfate (SDS), 20% (v/v) methanol, 192 mM glycine, and 25 mM Tris base. Prepare enough buffer to fill the chamber of the transfer apparatus and a container for assembling cassette.
8. Fast green stain: 0.1% (w/v) Fast green FCF in 20% (v/v) methanol- 5% (v/v) acetic acid. This stain is reusable. Prepare 50–100 ml per blot.
9. Fast green destain: 20% (v/v) methanol in 5% (v/v) acetic acid.
10. TS buffer: 150 m*M* NaCl, 10 m*M* Tris-HCl, pH 7.4. This can be conveniently prepared as a 10X stock (1.5 *M* NaCl, 100 m*M* Tris-HCl, pH 7.4). The 10X stock can be stored indefinitely at 4°C and then used to prepare 1X TS buffer, TSM buffer, and the other buffers described below.
11. TSM buffer: TS buffer containing 10% (w/v) powdered milk, 100 units/ml penicillin, 100 µg/ml streptomycin, and 1 m*M* sodium azide. This buffer can be stored for several days at 4°C. Note that sodium azide is poisonous and can form explosive copper salts in drain pipes if not handled properly.
12. Phosphate-buffered saline (PBS): 137 m*M* NaCl, 2.7 m*M* KCl, 1.5 m*M* KH_2PO_4, 8 m*M* Na_2HPO_4, pH 7.4. This can be conveniently prepared as a 10-fold concentrated stock at pH 7.0 and stored at 4°C. Upon dilution the pH will be 7.4.
13. PBS containing 2 *M* urea and 0.05% (w/v) Nonidet P-40. Prepare 300 ml per blot by combining 0.15 gm of Nonidet P-40, 30 ml of 10X PBS buffer, 75 ml of 8 *M*

urea (freshly deionized over BioRad AG1X-8 mixed bed resin to remove traces of cyanate) and 195 ml of water.
14. PBS buffer containing 0.05% (w/v) Nonidet P-40. Prepare 300 ml per blot.
15. PBS buffer containing 3% (w/v) nonfat powdered milk. Prepare 25 ml per blot.
16. Blot erasure buffer: 2% (w/v) SDS, 62.5 m*M* Tris-HCl (pH 6.8 at 21°C), and 100 m*M* 2-mercaptoethanol. The SDS/Tris-HCl solution is stable indefinitely at 4°C. Immediately prior to use, 2-mercaptoethanol is added to a final concentration of 6 µl/ml.
17. Primary antibody.
18. Reagents for detection by chemiluminescence. This approach requires enzyme-coupled secondary antibody and a substrate that becomes chemiluminescent as a consequence of enzymatic modification, e.g., peroxidase-coupled secondary antibody and luminol (Supersignal® (Pierce, Rockford, IL) enhanced chemiluminescence kit or equivalent) (*see* Chapter 78).
19. In lieu of enzyme-coupled secondary antibody, (^{125}I)-labeled secondary antibody can be used. Secondary antibodies can be labeled as previously described (30) or purchased commercially. Radiolabeled antibodies should only be used by personnel trained to properly handle radioisotopes.

3. Methods

3.1. Transfer of Polypeptides to Nitrocellulose

The following description is appropriate for transfer in a transfer reservoir. If a semidry transfer apparatus is to be used, follow the manufacturer's instructions (*see* **Note 1**).

1. Perform SDS-polyacrylamide gel electrophoresis using standard techniques (*see* ***ref. 33*** for description of this method).
2. Wear disposable gloves while handling the gel and nitrocellulose at all steps. This avoids cytokeratin-containing fingerprints.
3. Cut nitrocellulose sheets to a size slightly larger than the polyacrylamide gel (*see* **Note 2**).
4. Fill the transfer apparatus with transfer buffer (*see* **Note 3**).
5. Fill a container large enough to accommodate the transfer cassettes with transfer buffer. Assemble the cassette under the buffer in the following order:
   a. Back of the cassette.
   b. Two layers of filter paper.
   c. The gel.
   d. One piece of nitrocellulose– gently work bubbles out from between the nitrocellulose and gel by rubbing a gloved finger or glass stirring rod over the surface of the nitrocellulose.
   e. Two layers of filter paper– again, gently remove bubbles.
   f. Sponge or flexible absorbent pad.
   g. Front of the cassette.

6. Place the cassette in the transfer apparatus so that the front is oriented toward the POSITIVE pole.
7. Transfer at 4°C in a cold room with the transfer apparatus partially immersed in an ice-water bath. Power settings: 90 V for 5–6 h or 60 V overnight.
8. Place the fast green stain in a container with a surface area slightly larger than one piece of nitrocellulose (*see* **Notes 4** and **5**). After the transfer is complete, place all the pieces of nitrocellulose in the stain and incubate for 2–3 min with gentle agitation. Decant the stain solution, which can be reused.
9. Destain the nitrocellulose by rinsing it for 3–5 min in fast green destain solution with gentle agitation. Decant the destain, which can also be reused. Rinse the nitrocellulose four times (1–2 min each) with TS buffer (200 ml/rinse).
10. Mark the locations of lanes, standards, and any other identifying features by writing on the blot with a standard ballpoint pen.
11. Coat the remaining protein binding sites on the nitrocellulose by incubating the blot in TSM buffer (50–100 ml per blot) for 6–12 h at room temperature (*see* **Note 6**). Remove the blot from the TSM buffer. Wash the blot four times in quick succession with TS buffer (25–50 ml per wash) and dry the blot on fresh paper towels.

Either before or after coating of the unoccupied protein binding sites, blots can be dried and stored indefinitely in an appropriate container, e.g. disposable resealable food storage bags (1–2 blots/bag).

3.2. Detection of Antibody-Antigen Complexes Using Peroxidase-Coupled Secondary Antibody

1. Place the nitrocellulose blot in a container appropriate for reaction with the antibody. A 15- or 20-lane sheet can be reacted with 15–20 ml of antibody solution in a resealable plastic bag or an open plastic dish of suitable size. A 1- or 2-lane strip can be reacted with 2–5 ml of antibody solution in a disposable 15 ml conical test tube.
2. If the nitrocellulose has been dried, rehydrate it by incubation for a few min in a small volume of TSM buffer.
3. Add an appropriate dilution of antibody to the TSM buffer and incubate overnight (10–15 h) at 4° C with gentle agitation (*see* **Notes 7** and **8**).
4. Remove the antibody solution and save for reuse (*see* **Note 9**).
5. Wash the nitrocellulose (100 ml/wash for each large blot or 15–50 ml/wash for each individual strip) with PBS containing 2 *M* urea and 0.05% NP-40 (three washes, 15 min each) followed by PBS buffer (two washes, 5 min each) (*see* **Note 10**).
6. Add freshly prepared PBS containing 3% milk to the nitrocellulose sheets or strips (*see* **Note 11**). For nitrocellulose sheets (or pooled strips) in resealable plastic bags it is convenient to use a 25 ml volume. Add peroxidase-labeled secondary antibody at a suitable dilution (*see* **Note 12**). Incubate for 90 min at room temperature.
7. Remove the secondary antibody and discard appropriately.

8. Wash the sheets (100 ml/wash for each large blot or each group of pooled strips) with PBS containing 0.05% NP-40 (two washes of 5 min each, two washes of 15 min each, and two washes of 5 min each).
9. Expose blots to enhanced chemiluminescent reagents according to the supplier's protocol.
   a. In the case of Supersignal®, combine equal volumes of the two solutions (e.g., 5 ml of each for a gel containing 20 lanes).
   b. Remove the last wash solution from the blot.
   c. Incubate the blot with the combined enhanced chemiluminescence reagents for 60 sec with gentle agitation.
   d. Remove enhanced chemiluminescence reagent from container (*see* **Note 13**). Remove excess reagent but do not dry the blot.
   e. Seal the bag containing the blot and a minimal amount of enhanced chemiluminescence reagent. Immediately expose to X-ray film (*see* **Notes 14** and **15**).
10. After exposure to X-ray film, rinse the blot three or four times with PBS (25 ml/wash) and store it dry at room temperature.

3.3. Dissociation of Bound Antibodies

1. Place the blot to be stripped in a resealable plastic bag.
2. Add 50 ml of erasure buffer, seal the bag, and incubate in a water bath at 65°C for 30 min with gentle agitation every 5–10 min (*see* **Notes 16-18**).
3. Decant and discard the erasure buffer. Rinse the blot three times with 50–100 ml of TS buffer to remove SDS.
4. To ensure that nonspecific binding sites on the blot are well coated, incubate with TSM buffer for at least 2 h at room temp. with gentle agitation.
5. The blot is ready to be dried and stored or to be incubated with a new antibody as described in **Subheading 3.2**.

3.4. Modification for Dissociation of Antibodies After Autoradiographic Detection

1. Perform steps 1–8 as described in **Subheading 3.2**, substituting 5–10 µCi (^{125}I)-labeled secondary antibody for peroxidase-coupled antibody.
2. Rather than exposing the blot to enhanced chemiluminescence reagents (**Subheading 3.2**, step 9), follow the last wash in PBS/Tween with a 5-min incubation with TSM buffer. This incubation facilitates subsequent removal of antibody and reuse of the blot (*see* **Notes 19** and **20**).
3. After incubating the blot with TSM buffer, immediately dry it between several layers of paper towels. After 5 min, move the blot to fresh paper towels to prevent the nitrocellulose from sticking to the paper towels. When the blot has dried thoroughly, tape it to a solid support (e.g. thin cardboard), wrap it with clear plastic wrap, and subject it to autoradiography. (For details, see ***ref. 34***.)
4. After autoradiography, remove antibodies as indicated in **Subheading 3.3, steps 1–5.**

4. Notes

4.1. Transfer of Polypeptides to Nitrocellulose

1. The method described is for transferring polypeptides after electrophoresis in SDS-containing polyacrylamide gels. Alternative methods have been described for transferring polypeptides after acid-urea gels and after isoelectric focusing (reviewed in ***refs. 2, 3*** and Chapter 61).
2. Choice of solid support for polypeptides: Various solid supports (nitrocellulose, nylon or PVDF) can be used for Western blotting, stripped and reprobed. Use of nitrocellulose and PVDF is illustrated in **Fig. 2**. Nitrocellulose is easy to use and is compatible with a wide variety of staining procedures. With multiple cycles of blotting and erasing, however, nitrocellulose becomes brittle. PVDF membranes are durable, are compatible with a variety of nonspecific protein stains, and are capable of being stripped and reprobed. PVDF membranes, however, require a pre-wetting step in methanol before protein can be transferred. Derivatized nylon has the advantage of greater protein binding capacity and greater durability, but avidly binds many nonspecific protein stains (reviewed in ***refs. 1-3***). The higher binding capacity of nylon is said to contribute to higher background binding despite the use of blocking solutions containing large amounts of protein (reviewed in ***ref. 3***). As illustrated below (see **Fig. 4** later in this chapter), however, antibodies can be more easily dissociated from nylon than from nitrocellulose.
3. Various compositions of transfer buffer have been described (reviewed in ***refs. 1–3***). Methanol is said to facilitate the binding of polypeptides to nitrocellulose, but to retard the electrophoretic migration of polypeptides out of the gel. In the absence of SDS, polypeptides with molecular weights above 116 kDa do not transfer efficiently. Low concentrations of SDS (0.01 to 0.1%) facilitate the transfer of larger polypeptides, but simultaneously increase the current generated during electrophoretic transfer, necessitating the use of vigorous cooling to prevent damage to the transfer apparatus.
4. Alternative staining procedures (reviewed in ***refs. 1-3***) utilize Coomassie blue, Ponceau S, Amido black, India drawing ink, colloidal gold, or silver. A highly sensitive technique utilizing eosin Y has also been described ***(35).***
5. A washing step in acidified alcohol is probably essential to immobilize the polypeptides on the nitrocellulose ***(3, 31, 32)***. The fast green staining procedure satisfies this requirement. Polypeptides are observed to elute from nitrocellulose under mild conditions if a wash in acidified alcohol is omitted ***(32, 36)***.
6. Various protein solutions have been utilized to block unoccupied binding sites on nitrocellulose (reviewed in ***refs. 2, 3***). These include 5–10% (w/v) powdered dry milk, 3% (w/v) bovine serum albumin, 1% (w/v) hemoglobin,

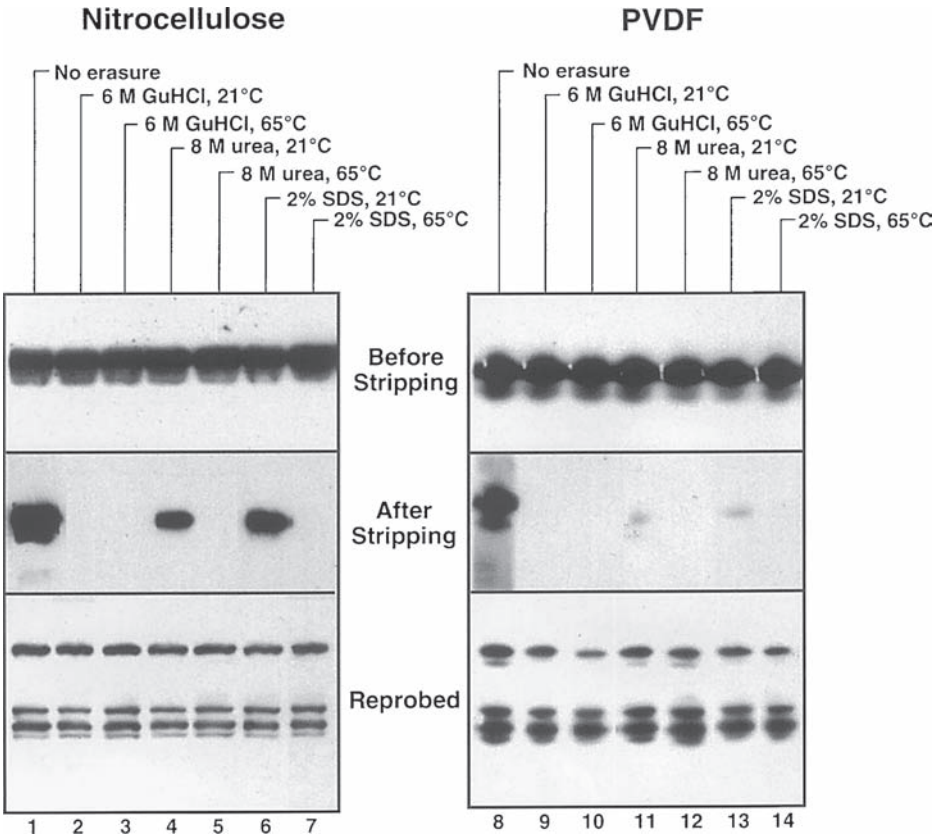

Fig. 2. Conditions for dissociating antibodies from nitrocellulose or PVDF after immunoblotting with enhanced chemiluminescence detection. Replicate samples containing whole cell lysates prepared from 3×10^5 K562 human leukemia cells were subjected to SDS-polyacrylamide gel electrophoresis followed by transfer to nitrocellulose (lanes 1–7) or PVDF (lanes 8–14). After unoccupied binding sites were blocked by incubation with TSM buffer, blots were incubated with a chicken polyclonal antiserum that reacts with the nucleolar protein B23 followed by peroxidase-labeled goat anti-chicken IgG. After detection with enhanced chemiluminescence reagents (upper panels), the blots were dried. The indicated strips were then incubated for 30 min at 21°C or 65°C with 62.5 mM Tris-HCl (pH 6.8 at 21°C) containing 100 mM 2-mercaptoethanol and 6 M guanidine hydrochloride (GuHCl), 8 M urea, or 2% (w/v) SDS as indicated. At the completion of the incubation, the strips were washed four times with PBS, recoated for 6 h in TSM buffer, and dried overnight. The strips were then reprobed with peroxidase-coupled goat anti-chicken IgG (**Subheading 3.2, steps 6–9**) to detect primary antibodies that were still bound (middle panels). After being dried again, strips were probed with rabbit anti-protein kinase Cδ followed by peroxidase-coupled goat anti-rabbit IgG to confirm that the cellular polypeptides remained bound to the strips (lower panels). Note that the efficacy of various treatments at removing antibodies varied depending upon the solid support, the buffer utilized for stripping, and the

and 0.1% (w/v) gelatin. Although the choice of protein can affect antibody binding (e.g., **Fig. 4C**), antibodies have been successfully stripped from blots of coated with any of these solutions ***(30)***.

4.2. Formation of Antigen-Antibody Complexes

7. No guidelines can be provided regarding the appropriate dilution of antibody to use. Some antisera are useful for blotting at a dilution of >1:20,000. Other antisera yield detectable signals only when used at a dilution of 1:5 or 1:10. When attempting to blot with an antiserum for the first time, it is reasonable to try one or more arbitrary concentrations in the range of 1:10 to 1:500. If a strong signal is obtained at 1:500, further dilutions can be performed in subsequent experiments.
8. Different investigators incubate blots with primary antibodies for different lengths of time and at different temperatures. Preliminary studies with some of our antibodies have indicated that the signal intensity is greater when blots are incubated with antibody overnight compared to 1–2 h at room temperature. Incubation at 4°C is specifically recommended for many currently available anti-phosphoepitope antisera, presumably because of instability of the affinity purified antibodies; and the 4°C incubation also yields good results with other antisera.
9. Most diluted antibody solutions can be reused multiple times. They should be stored at 4°C after additional aliquots of penicillin/streptomycin and sodium azide have been added. Some workers believe that the amount of nonspecific (background) staining on Western blots diminishes as antibody solutions are reutilized. Antibody solutions are discarded or supplemented with additional antibody when the intensity of the specific signal begins to diminish.
10. Choice of wash buffer after incubation with primary antibody: 2 M urea is included in the suggested wash buffer to diminish nonspecific binding. Alternatively, some investigators include a mixture of SDS and nonionic detergent (e.g., 0.1% (w/v) SDS and 1% (w/v) Triton X-100) in the wash buffers. For antibodies with low avidity (especially monoclonal antibod-

Fig. 2 (continued): temperature applied. After enhanced chemiluminescence detection, all of these denaturing buffers removed the anti-B23 antibodies at 65°C. At 21°C, urea and SDS left substantial amounts of antibody bound to nitrocellulose (middle panel, lanes 4 and 6) and small but detectable amounts of antibody bound to PVDF (middle panel, lanes 11 and 13). In each case, the stripping procedure had little or no effect on subsequent blotting with another antiserum (bottom panels).

ies and anti-peptide antibodies), the inclusion of 2 M urea or SDS might diminish the signal intensity. These agents are, therefore, optional depending upon the properties of the primary antibody used for blotting.

11. It is important to avoid sodium azide when using horseradish peroxidase-coupled antibodies, as the azide inhibits peroxidase ***(23, 24)***. For this reason, adding milk to PBS immediately before use of each aliquot of this buffer is advisable.
12. The concentration secondary antibody is determined empirically. Most suppliers recommend a dilution for their reagents, typically to the 0.1–0.5 µg/ml range.
13. The same enhanced chemiluminescence reagent can be transferred from one blot to another to develop several blots simultaneously.
14. The length of exposure required to give a good signal varies depending on the abundance of the antigen, the quality of the primary and secondary antibodies, and the nature of the solid support utilized. One convenient way to proceed is to expose each blot for an arbitrary time (e.g., 2 min) and then increase or decrease the exposure time based on the results of the trial exposure.
15. The signal obtained with some chemiluminescence reagents decays with a half-time of 30–60 min. With these reagents, it is important to expose film promptly after treating blots. Other chemiluminescence reagents continue to generate a strong signal for many hours.

4.3. Dissociation of Antibodies after Chemiluminescent Detection

16. Choice of erasure buffer: Experiments showing the effect of various erasure buffers on removal of primary antibodies are illustrated in **Fig. 2**. After detection by enhanced chemiluminescence, bound antibodies can be solubilized using 6 M guanidine hydrochloride, 8 M urea, or 2% SDS. None of these treatments elutes significant amounts of antigen from nitrocellulose (lower panel, **Fig. 2**). After enhanced chemiluminescent detection, antibodies appear to be more easily removed from PVDF than from nitrocellulose (cf. lanes 6 and 13 in **Fig. 2**).
17. a. Temperature of incubation: When blotting is performed after immobilization of polypeptides on nitrocellulose, complete removal of antibodies by either 8 M urea or 2% SDS requires heating to ≥ 50°C for 30 min ***(ref. 30***; see also **Fig. 2**, lanes 4–7).
    b. Length of incubation. When blotting is performed on nitrocellulose, complete dissociation of radiolabeled antibodies at 70°C requires a minimum of 20 min incubation with erasure buffer ***(30)***. Incubation times for removal of antibodies after chemiluminescent detection have not been systematically investigated.

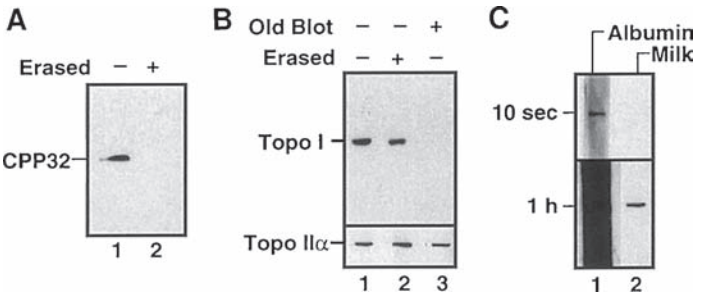

Fig. 3. Effect of various treatments on antigen recognition. (**A**) Replicate aliquots containing polypeptides from 2×10^5 K562 cells were separated by SDS-PAGE, transferred to nitrocellulose, and stained with fast green FCF (**Subheading 3.1, steps 1–11**). Strip 2 was then treated as described in Section 3.3 (steps 1–5) to simulate an erasure procedure. Strips were blocked with TSM buffer and blotted with a mouse monoclonal IgG recognizing CPP32/procaspase-3. The epitope recognized by this antibody was destroyed by erasure (lane 2). In contrast, many other epitopes are not (e.g., **Fig. 2,** lower panels). (**B**) Replicate gel lanes containing identical amounts of protein from a single batch of HL-60 leukemia cell lysate were transferred to nitrocellulose one week (strips 1 and 2) or three years (strip 3) prior to blotting. Strip 2 was treated as described in **Subheading 3.3, steps 1–5**, to simulate an erasure procedure. After unoccupied binding sites were reblocked by incubation with TSM buffer, the strips were incubated with the monoclonal antibodies C-21, which recognizes DNA topoisomerase I (upper panel), or Ki-S1, which recognizes DNA topoisomerase IIα (lower panel). After washing and incubation with peroxidase-coupled secondary antibodies, blots were subjected to chemiluminescent detection. The epitope recognized by antibody C-21 was damaged by prolonged storage (lane 3, upper panel) but not by the erasure procedure (lane 2, upper panel). In contrast, the epitope recognized by antibody Ki-S1 was unaffected by either manipulation. **C.** Effect of blocking solution on reactivity. Replicate gel lanes containing protein from 3×10^5 HL-60 cells were blocked with TS buffer containing 3% albumin (strip 1) or 10% milk (strip 2), then reacted with antibody Ki-S1 diluted 1:1000 in the corresponding protein solution. After reaction with peroxidase-coupled anti-mouse IgG diluted in the corresponding protein solution, blots were treated with luminol and exposed to Kodak XAR-5 film for 20 seconds (upper panel) or 1 h (lower panel). The signal was more rapidly detected when albumin was used as the blocking protein, but the background was much cleaner using milk as a blocking reagent.

18. Although most epitopes are resistant to the erasure procedure ***(29, 30),*** epitopes recognized by an occasional monoclonal antibody are destroyed (**Fig. 3A**, lane 2). Observations from our laboratory also indicate that certain epitopes are lost upon prolonged storage of blots (**Fig. 3B**, lane 3). There does not appear to be any relationship between the loss of epitopes upon blot storage and the damage of epitopes during the erasure procedure.

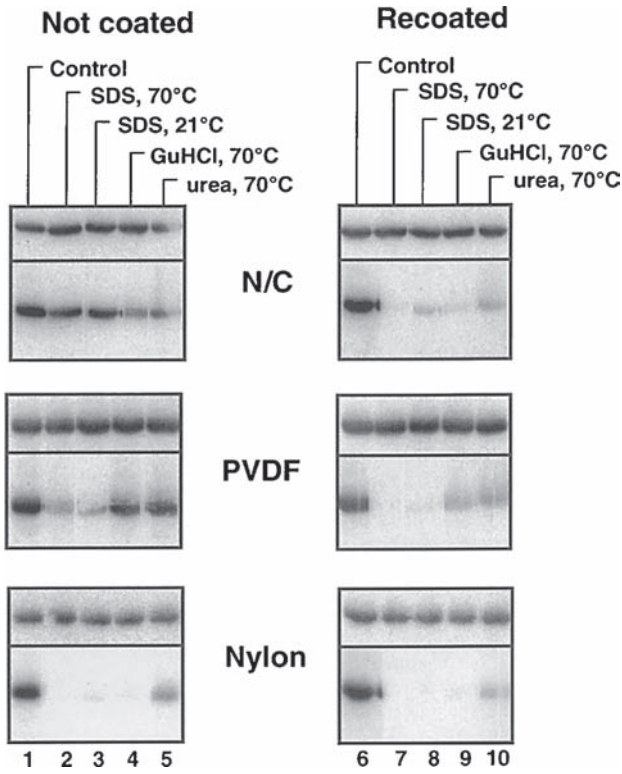

Fig. 4. Conditions for dissociating radiolabeled antibodies after immobilization of polypeptides on various solid supports. Replicate samples containing 2×10^6 rat liver nuclei were subjected to SDS-polyacrylamide gel electrophoresis followed by transfer to nitrocellulose, PVDF, or Nytran nylon sheets as indicated (*see* **Note 2**). After staining with fast green FCF and treatment with TSM buffer to coat unoccupied protein binding sites (**Subheading 3.1, steps 8–11**), blots were incubated with chicken polyclonal antiserum that reacts with the nuclear envelope polypeptide lamin B_1 (39) followed by (^{125}I)-labeled rabbit anti-chicken IgG (**Subheading 3.4, step 1**). Half of each blot (lanes 6–10) was recoated with milk-containing buffer for 5 min prior to drying (**Subheading 3.4, step 2**) and the other half (lanes 1–5) was dried without being recoated with protein. After autoradiography confirmed that the signals in all lanes of a given panel were comparable (upper panels), samples were incubated for 30 min at the indicated temperature with 50–62.5 mM Tris-HCl (pH 6.8) containing 100 mM 2-mercaptoethanol and one of the following denaturing agents: 2% (w/v) SDS, 6 M guanidine hydrochloride (GuHCl) or 8 M urea. Following this erasure procedure, strips were subjected to autoradiography again (bottom panels). In each case, untreated strips (lanes 1 and 6) served as controls. This analysis led to several conclusions. First, recoating with milk prior to drying (**Subheading 3.4, step 2**) did not affect the amount of radiolabeled antibody initially bound to the blots (cf. lanes 1 and 6). Second, the efficacy of various treatments at removing these antibodies varied depending upon the solid support. For nitrocellulose or PVDF, coating of the blots with protein prior to drying facilitated the subsequent dissociation

4.4. Removal of Antibodies After Autoradiographic Detection

19. The major modification suggested for removal of radiolabeled secondary antibodies is an incubation of blots with protein-containing buffer immediately prior to drying. For reasons that are unclear, this step appears to be essential for efficient dissociation of certain antibodies from nitrocellulose or PVDF paper after incubation with radiolabeled secondary antibodies **(Fig. 4)**, but not after incubation withperoxidase-coupled antibodies **(Fig. 2)**.
20. (^{125}I)-labeled protein A can be substituted for radiolabeled secondary antibody. Protein A, however, can bind to the immunoglobulins present in milk, causing a high background on the blot. Therefore, when (^{125}I)-labeled protein A is to be used, milk should not be utilized to block unoccupied binding sites (Section 3.1, step 11), nor as a diluent for antibodies (**Subheading 3.2.,** steps 2, 3 and 6). Instead, bovine serum albumin, hemoglobin, or gelatin should be considered (*see* **Note 6**).

4.5. General Notes

21. Some blotting procedures involve deposition of chromogenic reaction products directly on immunoblots by enzyme-coupled secondary antibodies ***(5, 37, 38)***. The technique described above is not useful for removing colored peroxidase reaction products (e.g., diaminobenzidine oxidation products) from blots.
22. A modification of the techniques described in **Subheading 3.2** allows the detection of glycoproteins by radiolabeled lectins. For this application, blots would be coated with albumin or gelatin, reacted with radiolabeled lectin (**Subheading 3.2.,** Steps 6–8), and recoated with albumin or gelatin (**Subheading 3.4.,** Steps 2 and 3) prior to drying. After autoradiography, the radiolabeled lectin would be solubilized in warm SDS under reducing conditions **(Subheading 3.3)**.

Fig. 4 (continued): of the anti-lamin B antibodies. In both cases, SDS-containing buffer (lanes 7,8) was more effective than guanidine hydrochloride (lane 9) or urea (lane 10). For nylon, SDS was again slightly more effective than urea at dissociating the antibodies (cf. lanes 2 vs. 5 and 7 vs. 10). Interestingly, when SDS-containing erasure buffer was used, it was not necessary to recoat nylon with protein prior to drying for autoradiography (cf. lanes 2 and 7). This was in contrast to nitrocellulose or PVDF, which were examined in the same experiment.

Acknowledgments

Technical assistance of Sharon J. McLaughlin, Phyllis A. Svingen, and Timothy J. Kottke in the preparation of **Figs. 1-4**, as well as secretarial assistance of Deb Strauss, are gratefully acknowledged. Studies in my laboratory are supported by grants from the National Cancer Institute.

The Use of Quantum Dot Luminescent Probes for Western Blot Analysis

Savvas C. Makrides, Christina Gasbarro, and Job M. Bello

1. Introduction

Western blot analysis ***(1,2)*** is one of the most widely used methods for analyzing specific protein targets using colorimetric or chemiluminescent substrates ***(3)***. However, the reporting labels that are typically used for protein detection are unsuitable for simultaneous detection of multiple targets. In order to detect different proteins the blot is usually stripped and reprobed, an approach that is time- and labor-intensive, and often leads to loss of immobilized proteins from the blot. Detection of multiple antigens on a single protein blot without stripping off prior antibodies is possible, but requires sequential reactions ***(4)***. More recent approaches employ multiple fluorescent probes made from small organic dye molecules (***(5)*** and references therein), but such probes have several limitations, described below. The use of QD luminescent labels has the potential to eliminate most of these problems.

QDs are semiconductor nanoparticles (e.g. CdSe, InP, InAs) with diameters in the range of 2 to 10 nm whose fundamental physical properties are influenced by quantum confinement effects ***(6)***. QDs exhibit absorption and emission peaks that progressively shift to longer wavelengths with increasing particle size. For applications as fluorescent markers, the relevant quantum confinement effect is the tuning of the semiconductor band gap and hence the color of the QD emission achieved simply by changing the size of the particle. In this way, the luminescence wavelength of QDs can be tuned from the infrared to the ultraviolet ***(7)***. **Fig. 1** shows the photoluminescence of CdSe nanocrystals spanning the visible spectrum with particles ranging in diameter from 2 to 6 nm.

QDs have significant advantages compared to standard fluorescent organic dyes. For example, dyes have narrow absorption bands, hence it is difficult

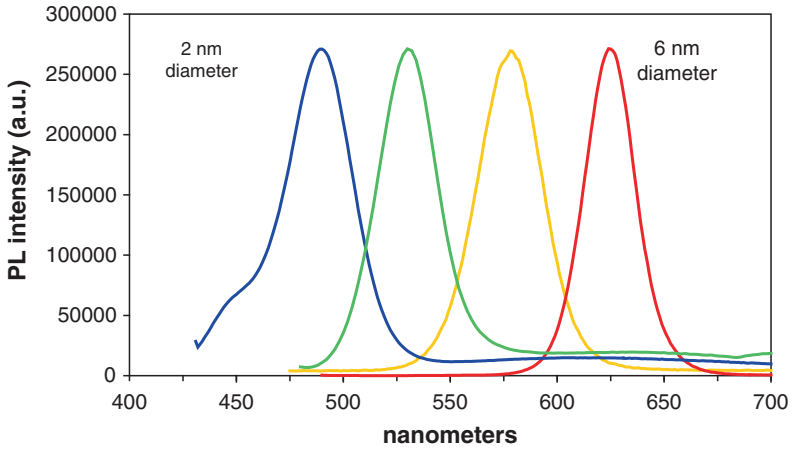

Fig. 1. Photoluminescence of CdSe nanocrystals with diameters ranging from 2 to 6 nm.

to excite several colors with a single excitation source. Moreover, the broad spectral overlap between the emissions of dyes requires complex mathematical analysis of the data. In contrast, QDs have a narrow, tunable, symmetric emission spectrum, permitting a larger number of probes within a detectable spectral region. Different-size populations of QDs can be excited with a single light source, making possible the development of simpler and more cost-effective instrumentation for multiplex detection of biomolecules. QDs are considerably more stable against photobleaching than organic dyes ***(8, 9)***. This is an important property, particularly for imaging applications, where the high photostability of QDs allows real-time monitoring of intracellular processes over longer periods of time ***(10, 11)***. QDs exhibit large Stokes shifts (the difference between the maximum absorbance and emission wavelengths). This property allows the target signals to be separated clearly from autofluorescence, and enables the entire emission spectra to be collected, in contrast to the use of fluorescent proteins, e.g., green fluorescent protein. The biological applications of QDs have been reviewed recently ***(12, 13)***.

In this chapter we describe a bioconjugation method that permits the facile generation of QD-based probes for multiplex detection of proteins in Western blots ***(14)***. The strategy for immobilization of antibodies to QDs utilizes the IgG-binding "Z" domain, which is based on the "B" domain of *Staphylococcus aureus* protein A ***(15, 16)***. The Z affinity tag (6.5 kDa) is highly specific for its ligand, IgG Fc, and can easily be purified by affinity chromatography using IgG-Sepharose. It has been shown ***(17)*** that the divalent ZZ domain exhibits ten times higher affinity (K_{aff} ~3×10^8 M^{-1}) for its IgG ligand, than the monovalent Z domain (K_{aff} ~2×10^7 M^{-1}). We engineered a ZZ protein fused to a peptide that

is biotinylated *in vivo* ***(18)***, followed by a hexahistidine tag. The biotinylated ZZ tag was produced in bacteria, purified on a monomeric avidin or Ni^{++}-NTA matrix, and coupled to streptavidin-coated QDs, thus enabling biospecific conjugation of any antibody to the functionalized QDs (**Fig. 2**).

Fusion proteins containing a specific biotinylation motif are biotinylated *in vivo* by biotin protein ligase, the product of the *birA* gene, which recognizes a 75-amino acid residue sequence as its biotinylation substrate ***(19)***. Such proteins can be affinity-purified using immobilized monomeric avidin and mild elution conditions that do not damage the biotinylated protein. This approach is advantageous over *in vitro* biotinylation, an indiscriminate process that may adversely affect the structure and/or function of the modified protein through the modification of critical lysine residues. Schatz ***(18)*** identified a consensus 13-residue peptide that is biotinylated *in vivo* at an invariant lysine residue. This sequence can replace the larger biotinylation signal, and has been used successfully for the purification of fusion proteins (e.g., ***(20)***). A potential disadvantage of the affinity chromatographic purification of *in vivo* biotinylated proteins is the need to remove free biotin from the cell lysate in order to avoid interference with the purification of the target protein. In addition, biotinylated host proteins may possibly be copurified with the target protein. These potential complications are easily avoided by including an additional affinity tag that facilitates protein purification by an alternative method prior to the use of avidin-chromatographic

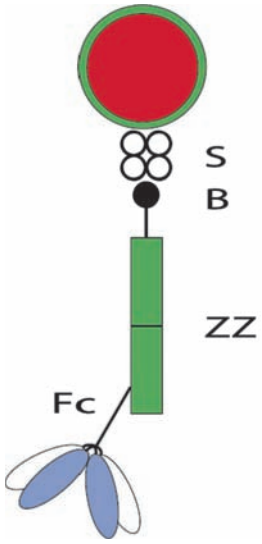

Fig. 2. Schematic representation of the QD-based probe. There are approximately 5–10 streptavidin molecules on the QD surface. S, streptavidin; B, biotin; ZZ, head-to-tail dimerized Z domain derived from protein A. The various probe components are not drawn to scale. Reprinted with permission from the publisher (14).

media ***(21)***. We included a $(His)_6$ tag located downstream of the biotinylation sequence to facilitate purification of the biotinylated ZZ using a Ni^{++}-NTA matrix. The ZZ tag was purified from *E. coli* using monomeric avidin as well as Ni^{++}-NTA, and analyzed by Western blot probed with an avidin-alkaline phosphatase conjugate. The results confirmed the presence of biotinylated ZZ protein, with no evidence of additional biotinylated bands, irrespective of the purification method ***(14)***.

The ZZ tag-derivatized surface of QDs enables facile conjugation to secondary (or primary) antibodies, eliminates the labor and expense of custom-labeling secondary antibodies with different enzymes, biotin, and other tags, and avoids the potential non-availability of secondary antibodies with the desired label. The only requirement for specificity of protein detection in our system is the matching of primary and secondary antibodies. This too can be avoided by directly conjugating primary antibodies to ZZ-functionalized QDs, although, in this case, the sensitivity of detection may be attenuated. The efficiency of ZZ biotinylation may also be enhanced by using a more efficient recognition sequence for *in vivo* biotinylation ***(22)***. An alternative approach for labelling QDs employs the full-length protein A. The advantage of our method is that the ZZ peptide does not bind the Fab region of Ig molecules, in contrast to all individual domains of protein A ***(23,24)***. This offers the advantage of a more uniform binding to antibodies (via the Fc region), leaving the Fab domain free to bind its target, unlike direct QD-antibody binding, which sterically blocks many of the antibody active sites. Thus, our QD bioconjugation strategy could be useful for quantitative assays.

2. Materials

2.1. Construction of pEZZ-B6H

1. Phagemid pEZZ18 (Amersham Biosciences, Piscataway, NJ).
2. TAE buffer: 40 m*M* Tris, 5 mM sodium acetate, 1 m*M* EDTA, pH 7.8.
3. GeneClean II Kit (Q-Biogene, Carlsbad, CA).
4. Synthetic oligonucleotides (Qiagen, Valencia, CA).
5. Rapid DNA Ligation Kit (Roche, Indianapolis, IN).
6. HiSpeed Plasmid Maxi Kit (Qiagen).
7. *E. coli* BL21 competent cells (Novagen, Madison, WI).
8. *E. coli* AVB101 competent cells (Avidity, Denver, CO).

2.2. Expression

1. LB medium: 2.5 g Bacto-Tryptone, 1.25 g Bacto-Yeast Extract, 2.5 g NaCl, pH 7.2–7.4, per liter H_2O.
2. Ampicillin (Sigma Chemical Company, St. Louis, MO).
3. Chloramphenicol (Sigma).
4. Biotin (Pierce, Rockford, IL).

5. Isopropyl β-D-thiogalactopyranoside (IPTG) (Sigma).

2.3. Purification of ZZ-B6H Protein

1. Phenylmethylsulfonyl fluoride (PMSF) (Roche).
2. Sucrose buffer: 0.5 *M* sucrose, 0.1 *M* Tris-HCl, pH 8.0, 1 m*M* EDTA.
3. 5 m*M* $MgSO_4$.
4. 0.45 μm nitrocellulose membrane filter (Nalgene, Rochester, NY).
5. Monomeric avidin column (Pierce).
6. Slide-a-Lyzer Cassettes (Pierce).
7. PBS: 0.01 *M* KH_2PO_4, 0.1 *M* Na_2HPO_4, 1.37 *M* NaCl, 0.027 *M* KCl.
8. Bovine serum albumin (Sigma).
9. BCA Protein Assay (Pierce).
10. Agarose-Ni^{++}-NTA chromatography column (Qiagen).
11. Wash buffer: 50 m*M* NaH_2PO_4, 300 m*M* NaCl, 20 m*M* imidazole, pH 8.0.
12. Elution buffer: 50 m*M* NaH_2PO_4, 300 m*M* NaCl, 250 m*M* imidazole, pH 8.0.
13. Amicon Ultra-15 centrifugal filters (5,000 nominal molecular weight limit, NMWL) (Millipore, Bedford, MA).

2.4. QD Probe Assembly

1. Streptavidin-functionalized CdSe/ZnS core/shell QDs of different size and emission wavelength (Invitrogen, Carlsbad, CA). QDs are provided in a solution which is 2 mM total Cd concentration. The CdSe core is encapsulated in a shell of ZnS and the polymer shell, which may prevent release of free Cd. However, QDs should be considered to be toxic and be disposed of accordingly (http://probes.invitrogen.com/products/qdot/faq.html).
2. YM-100 Microcon filters (100,000 NMWL) (Millipore).
3. Human apolipoprotein AI (EMD Biosciences, San Diego, CA).
4. Firefly luciferase (EMD Biosciences).
5. TBS-T buffer: 100 m*M* Tris-HCl pH 7.4, 150 m*M* NaCl, 0.1% (v/v) Tween-20.
6. Rabbit anti-apoAI (EMD Biosciences).
7. Goat anti-luciferase (Rockland Immunochemical, Gilbertsville, PA).

2.5. Western Blot

1. Electrophoresis apparatus (Invitrogen).
2. 1X LDS Sample Buffer (Invitrogen).
3. 4–12% NuPAGE Bis-Tris gels (Invitrogen).
4. 1X MES buffer (Invitrogen).
5. PVDF membranes (Immobilon-P) (Millipore).
6. Panther Semidry Electroblotter (model HEP-1) and buffer reagents (Owl Separation Systems, Portsmouth, NH).
7. SuperBlock blocking buffer (Pierce).
8. SeaBlock reagent (Pierce).
9. Simply Blue Safe Stain (Invitrogen).
10. Avidin-alkaline phosphatase (AP) conjugate (Pierce).

11. NBT/BCIP substrate (Pierce).
12. Biotinylated protein A (Pierce).

2.6. Image capture and analysis

1. UV light transilluminator (Fotodyne, Hartland, WI).
2. Minolta digital camera (model A1)
3. NIH Image J software (http://rsb.info.nih.gov/ij).

3. Methods

3.1. Construction of pEZZ-B6H

The phagemid pEZZ18 contains the protein A signal sequence (S), two Z domains, and a polylinker site located 3′ to the ZZ domain ***(16)***. Expression is controlled by the protein A constitutive promoter.

1. The polylinker of pEZZ18 is digested with *Eco*RI and *Pst*I, and the large vector fragment is purified from a 0.8% agarose gel in TAE buffer (40 m*M* Tris, 5 m*M* sodium acetate, 1 m*M* EDTA, pH 7.8) using the GeneClean II Kit.
2. Two synthetic complementary oligonucleotides, 115 and 107 bases long, respectively, are designed to encode the *in vivo* biotinylation signal sequence ***(18)*** and six histidine residues followed by two stop codons, including sequences to regenerate the *Eco*RI, *Bam*HI, and *Pst*I restriction sites (underlined): 5′ -AAT TCG GGC AGC GCG AGC AGC CTG CGC CAG ATT CTG GAT AGC CAG AAA ATT GAA TGG CGC AGC AAC GCG GGC GGC AGC GGC CAT CAT CAT CAT CAT CAT TAA TAA GGA TCC TGC A-3′ and 5′ -GGA TCC TTA TTA ATG ATG ATG ATG ATG ATG GCC GCT GCC GCC CGC GTT GCT GCG CCA TTC AAT TTT CTG GCT ATC CAG AAT CTG GCG CAG GCT GCT CGC GCT GCC CG-3′ . This DNA sequence is designed using the codon usage frequency for *E. coli* K12 (Codon Usage Database, http://www.kazusa.or.jp/codon).
3. The oligonucleotides are separately resuspended in 10 m*M* Tris-HCl, pH 8.0, 10 m*M* NaCl, and annealed by mixing equimolar amounts and heating to 100°C followed by slow cooling to 22°C.
4. The linearized vector is ligated to the double-stranded oligonucleotide using the Rapid DNA Ligation Kit. The resulting plasmid pEZZ-B6H (**Fig. 3**) is transformed into *E. coli* BL21 competent cells, and the plasmid is prepared using a HiSpeed Plasmid Maxi Kit. The plasmid is also transformed into AVB101 competent cells, which harbor a chloramphenicol-resistant plasmid pJS169 encoding the BirA biotin ligase gene.

3.2. Expression

1. *E. coli* AVB101 cells harboring plasmids pJS169 and pEZZ-B6H are grown in 250 ml LB medium containing 100 µg/ml ampicillin and 10 µg/ml chloramphenicol in baffled flasks at 37°C, 90 rpm, to an OD_{600nm} 0.5.

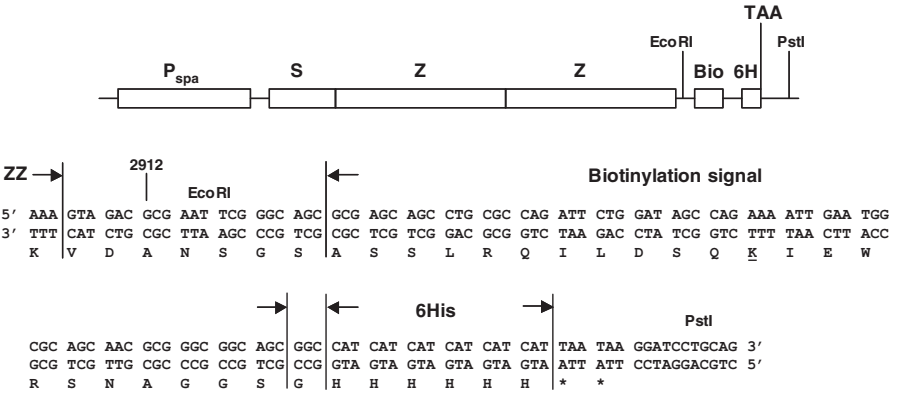

Fig. 3. Configuration and DNA sequence of selected genetic elements in vector pEZZ-B6H for production of the ZZ tag in *E. coli.* Pspa, promoter of the Staphylococcal protein A; S, signal peptide; ZZ, IgG-binding dimeric domain derived from protein A; Bio, in vivo biotinylation tag; 6H, hexahistidine tag; TAA (*), termination codon. The boundaries of the ZZ moiety, the biotinylation, and hexahistidine tags are shown, and the single lysine residue (K) that is biotinylated is underlined. The number 2912 refers to the nucleotide position in the parental plasmid pEZZ18 (GeneBank accession number M74186). Reprinted with permission from the publisher (14).

2. The medium is then supplemented with 50 µM biotin and 1 mM IPTG in order to induce the expression of the *birA* gene. The cells are further grown for 5 h.

3.3. Protein extraction and purification

1. The cells are harvested by centrifugation at 5,000g for 15 min at 4°C, and the ZZ tag (M.W. ~17,000) is extracted from the periplasm by the osmotic shock procedure ***(25)***, modified as follows:
2. The cell pellet is resuspended in 1/20 original culture volume of ice-cold sucrose buffer.
3. PMSF is added to 1 m*M* final concentration, and the suspension is stirred slowly at room temperature for 10 min.
4. The cells are collected by centrifugation at 15,000 g for 10 min at 4°C.
5. The cell pellet is resuspended in 12 ml ice-cold 5 m*M* $MgSO_4$, and stirred slowly for 10 min at 4°C.
6. The shocked cells are centrifuged at 15,000g for 10 min at 4°C, and the supernatant is filtered through a 0.45 µm nitrocellulose membrane filter.
7. The ZZ tag is purified on a monomeric avidin column using 2 m*M* biotin in PBS for elution.
8. Protein fractions identified by polyacrylamide gel electrophoresis (PAGE) and Western blotting are pooled and dialyzed at 4°C in Slide-a-Lyzer Cassettes (Pierce) against three changes of PBS.

9. The concentration of the ZZ peptide is determined using the BCA Protein Assay and bovine serum albumin as the standard.
10. Alternatively, ZZ is purified on an agarose-Ni^{++}-NTA chromatography column. The osmotic shock supernatant (12 ml) is loaded onto 4 ml Ni^{++}-NTA resin that is equilibrated with 40 ml wash buffer and ZZ is eluted using 20 ml elution buffer.
11. Fractions (1.5 ml) are analyzed by PAGE and Western blotting. Fractions of interest are pooled and concentrated in PBS via repeated centrifugation (5,000 g, 30 min in fixed angle rotor) using Amicon Ultra-15 centrifugal filter devices (5,000 NMWL).

3.4. Western Blotting of the Biotinylated ZZ Protein

1. ZZ samples (18 µl, ~2 µg) are prepared in 1X LDS Sample Buffer in a total volume of 25 µl, incubated at 70°C for 10 min, and loaded onto 4–12% NuPAGE Bis-Tris gels and electrophoresed at 200 V in 1X MES buffer under non-reducing conditions.
2. Gels are stained by immersing in Simply Blue Safe Stain (Invitrogen) for 60 min and destained in water.
3. The protein bands are electrotransferred to PVDF membranes (Immobilon-P) using the model HEP-1 Panther Semidry Electroblotter and buffer reagents according to the manufacturer's instructions (Owl). Transfer is carried out for 1 h at 1.6 mA/cm^2 (100 mA).
4. After sandwich disassembly the membrane is incubated in SuperBlock blocking buffer (Pierce) for 1 h at 22°C with gentle agitation, or stored in blocking buffer overnight at 4°C.
5. The gel is stained in order to confirm protein transfer.
6. The membrane is incubated for 2 h in blocking buffer containing a 1:1,000 dilution of avidin-alkaline phosphatase (AP) conjugate, and washed three times 10 min each with blocking buffer.
7. The membrane is incubated in NBT/BCIP substrate until bands indicating the presence of ZZ-bound avidin-AP are visible. The positive control lane contains 2 µg biotinylated protein A. The negative control lane contains 2 µg lysozyme.

3.5. QD Probe Assembly

1. Streptavidin-coated CdSe/ZnS core/shell QDs of different size and emission wavelength are coupled to primary antibodies via the ZZ tag, as follows:
2. QD aliquots (10–30 µl of 1 µM stock) are mixed with varying concentrations of dialyzed ZZ peptide in a final volume of 500 µl SeaBlock reagent, and rocked at room temperature for 60 min.
3. The mixture is then centrifuged at 14,000 g for 12 min in YM-100 Microcon filters (100,000 NMWL) in an Eppendorf microcentrifuge, and 450 µl SeaBlock reagent was added to the retentate, followed by centrifugation at 14,000 g for 12 min.
4. The filter device is inverted into a new tube and centrifuged at 1,000g for 3 min to recover the purified probe. Most of the QD probe is typically found in the retentate, with a very small amount of QDs present in the filtrate, as monitored with a hand-held long-wavelength UV lamp.

5. Each purified QD-ZZ conjugate (50 µl) is mixed with 10 µl primary or secondary antibody in a total volume of 500 µl Seablock and rocked at room temperature for 60 min.
6. The probe volume is adjusted to 10 ml (or 5 ml when using two probes together) using SeaBlock, followed by immunodetection.

3.6. Western blotting of test proteins

1. Proteins (human apolipoprotein AI and firefly luciferase) are electrophoresed and electrotransferred to PVDF membranes as described above.
2. The membranes are washed for 5 min in TBS-T and then blocked with SuperBlock or SeaBlock blocking buffer for 1 to 2 h with gentle agitation, or stored overnight at 4°C in blocking buffer.
3. The membranes are then incubated for 1 h with a 1,000-fold dilution of the primary antibodies in blocking buffer (rabbit anti-apoAI, Calbiochem; and goat anti-luciferase, Rockland Immunochemical).
4. The membranes are washed with TBS-T three times for 5 min each, and incubated for 1 to 2 h with QD_{565}-ZZ or QD_{655}-ZZ nanoparticles conjugated to secondary antibody and purified as described above.
5. The blots are then sequentially washed three times for 5 min each using TBS-T, and two times 3 min each using TBS.
6. The proteins are probed alone (**Fig. 4B** and **C**) and in combination (**Fig. 4D**), in order to confirm the specificity of each antibody. The negative-control Western blot is incubated in hybridization buffer without primary antibody. Protein bands are visualized under long-wavelength UV irradiation.
7. Images are captured using a model A1 Minolta digital camera and merged into false-color images using NIH Image J software (http://rsb.info.nih.gov/ij) which is in the public domain.

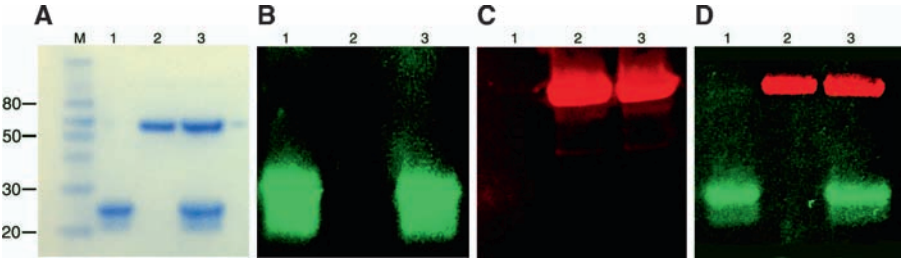

Fig. 4. Western blots of apolipoprotein AI and luciferase. (**A**) PAGE. (M) markers; (1) apoAI (28,330 M.W.); (2) luciferase (62,000 M.W.); (3) both proteins. (B-D): Western blots probed with anti-apoAI-QD565, green color (**B**); anti-luciferase-QD655, red color (**C**); anti-apoAI-QD565 plus anti-luciferase-QD655 (**D**). Control blots were probed with QD-ZZ probes minus primary antibody (not shown). The Western blots were photographed separately, hence band migration appears to be slightly different in different blots. Reprinted with permission from the publisher (**14**).

4. Notes

1. A list of frequently asked questions about QD technical background and troubleshooting tips may be found on the manufacturer's web site: http://probes.invitrogen.com/products/qdot/faq.html
2. QDs fluoresce brightly under a hand-held ultraviolet lamp (long wavelength). This provides a convenient method of monitoring the various experimental steps, e.g., filtration.
3. The detection of luminescent signals may be enhanced by using filters. A list of appropriate and optimal filters is available at: http://probes.invitrogen.com/products/qdot/filters.html
4. A high level of endogenous biotin in the sample may produce high nonspecific background. In this case, the sample may be blocked with BSA or animal serum which will decrease nonspecific binding of both antibodies and QD-streptavidin conjugates. Primary and secondary antibodies should preferably be diluted in the blocking buffer. Endogenous biotin in tissues may be blocked using an Avidin/Biotin blocking kit (Vector Laboratories, Burlingame, CA).

Acknowledgments

We are grateful to Per-Åke Nygren for advice on the ZZ protein. We thank Theresa Harper for technical advice on QDs, and Nancy Kawai for help with figure 4. Funding of this work by the DOE (DE-FG02-04ER83933) is gratefully acknowledged.

The Use of Infrared Fluorescent Dyes in Quantitative Immunoblotting

Ching-Hui Yang, Christopher Kasbek, and Harold A. Fisk

1. Introduction

Centrosomes are microtubule organizing centers that regulate assembly of the mitotic spindle apparatus ***(1)***. Because excess centrosomes generate aberrant mitotic spindles, the duplication of centrosomes must be tightly controlled ***(2)***. Centrosome duplication requires the activity of the Mps1 protein kinase ***(3)***, and Mps1 levels are regulated by proteasome-mediated degradation ***(4)***. Mps1 is a Cdk2 substrate, and phosphorylation of Mps1 by Cyclin-dependent kinase 2 (Cdk2) prevents the degradation of Mps1 as part of the mechanism restricting centrosome duplication within the cell cycle ***(4, 5)***. Accordingly, inhibition of Cdk2 activity with the small molecule roscovitine, or depletion of Cdk2 activity with cyclin A- or Cdk2-specific siRNAs, all lead to the loss of Mps1 from centrosomes and prevent centrosome duplication. However, these different means of inhibiting Cdk2 activity have different consequences for the whole-cell levels of Mps1; roscovitine can result in the near complete loss of Mps1 from the cell ***(4, 5)***, while Cdk2-specific siRNAs reduce whole-cell Mps1 levels only by roughly 25% and cyclin A-specific siRNAs have virtually no effect on whole-cell Mps1 levels ***(4)***. In addition, inhibition of the proteasome causes a 2.5-fold increase in centrosomal Mps1 levels, but causes only a modest increase in whole-cell Mps1 levels ***(4)***.

Due to unavoidable differences in sample loading such quantitative comparisons between samples require normalization to a loading control such as β-actin ***(6)***, αTubulin ***(3, 4, 7)***, or βTubulin ***(8)***. When comparing Mps1 between samples our choice has been αTubulin because its levels are not affected by Cdk2 or proteasome activity ***(3-5)***. However, Mps1 and αTubulin are present at dramatically

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

different levels and using enzymatic detection methods require dramatically different film exposures (seconds for αTubulin versus minutes for Mps1) that are incompatible with detection on the same blot. This requires that the two proteins be detected on separate blots, introducing an unavoidable source of error and limiting the utility of enzymatic detection methods. In contrast, proteins of vastly different abundance can be detected simultaneously in the same lane of an immunoblot when secondary antibodies conjugated to infrared dyes are used in conjunction with the Odyssey laser scanner (LI-COR, Lincoln, NE). Unlike film detection there is no signal spread in laser scanning detection, and blots can be scanned multiple times without any loss of signal. Therefore, antigens that differ in concentration by orders of magnitude can be simultaneously measured using the same secondary antibody. Furthermore, the Odyssey can detect two differently labeled secondary antibodies at the same time, allowing four or more antigens to be measured simultaneously in the same lane of an immunoblot, provided they are well separated by size and good quality primary antibodies are available. Accordingly, based on its sensitivity and accuracy over large concentration ranges, the LI-COR Odyssey is increasingly used for detection of low abundance proteins and quantitative immunoblotting ***(3, 4, 6–8)***.

2. Materials

2.1. Cell Culture, Tansfection, and Lysis

1. Standard growth medium is Dulbecco's Modified Eagle's Medium (DMEM) (Invitrogen, Carlsbad, CA) supplemented with Penicillin/Streptomycin (Invitrogen) and 10% (v/v) Fetal Bovine Serum (Hyclone, Ogden, UT).
2. Roscovitine and MG115 (EMD Biosciences/CalBiochem, San Diego, CA) are dissolved in culture grade dimethy sulfoxide (DMSO) at 50 m*M* and 10 m*M*, respectively (unless specifically noted, compounds are from Sigma, St. Louis, MO)
3. Hydroxyurea (HU) is dissolved at 1 *M* in water (*see* **Note 1**).
4. Cdk2 and Cyclin A Smart Pool siRNAs (Dharmacon, Lafayette, CO).
5. Six well tissue culture plates (Corning, Lowell, MA).
6. Oligofectamine reagent (Invitrogen) for siRNA transfection.
7. Lysis buffer: 50 m*M* Tris-HCl pH 8.0, 150 m*M* NaCl, 1% NP-40, 0.5% deoxycholic acid, 0.2% sodium dodecyl sulfate (SDS), 1X (v/v) mammalian protease inhibitor Cocktail (100X cocktail prepared in DMSO), and 2 m*M* 4-(2-aminoethyl) benzenesulfonyl fluoride hydrochloride (AEBSF, 1 M stock prepared in water).
8. Bradford assay reagent (BioRad, Hercules, CA).

2.2. SDS-PAGE

1. 5X SDS-PAGE Sample Buffer ***(4, 5)***: 250 m*M* Tris-HCl pH 6.8, 10% (w/v) SDS, 50% glycerol, 0.5 *M* dithiothreitol, 0.5% bromophenol blue.
2. EZ-RUN Pre-Stained Protein Ladder molecular weight standard (Fisher).

2.3. Two-Color Infrared Immunoblotting

1. Transfer buffer: 25 m*M* Tris, 192 m*M* glycine, 20% (v/v) methanol.
2. Hybond Nitrocellulose membrane (GE Health/Amersham, Swampscott, NJ) (*see* **Note 2**).
3. Ponceau S reversible protein stain, premixed solution.
4. Phosphate-buffered saline (PBS): 137 m*M* NaCl, 2.7 m*M* KCl, 10 m*M* Na_2HPO_4, and 2 m*M* KH_2PO_4, pH 7.0.
5. Blocking Buffer: 3% (w/v) nonfat dry milk in PBS. Blocking buffer does not contain Tween-20 or PBS (*see* **Note 2**).
6. PBS with 0.2% Tween-20 (PBS-T).
7. Primary antibodies diluted in PBS-T: DM1A mouse anti α-Tubulin (1:10,000) (Sigma); N1 mouse anti-Mps1 (1:1,000) ***(9)*** (Invitrogen); rabbit anti-Cdk2 (1:1,000) (Sigma).
8. Secondary antibodies diluted in PBS-T: Alexa680-conjugated donkey anti-rabbit IgG (1:10,000) (Invitrogen); IRDye800-conjugated donkey anti mouse IgG (1:10,000) (Rockland Immunochemicals, Gilbertsville, PA).

3. Methods

Because different methods of inhibiting Cdk2 activity differentially effect the cytoplasmic and centrosomal pools of Mps1 ***(4)***, it is necessary to examine Mps1 levels by both immunoblot and immunofluorescence. This chapter covers the use of the LI-COR Odyssey scanner and infrared fluorescence for comparing whole cell Mps1 levels between samples. In order to compare whole-cell Mps1 levels between samples, the Mps1 signal on immunoblots from each sample must first be normalized to that of αTubulin for the same sample. Using the Odyssey scanner we can simultaneously detect both proteins in the same lane of an immunoblot.

3.1. Preparation of Samples for Immunoblotting

1. Passage and process cells according to your specific needs. For analysis of Mps1 we typically seed HeLa cells at $0.5–1\times10^4$ cells per well of a 6 well dish. In the specific examples used here, cells are harvested after drug treatment or siRNA transfection. For drug treatment, cells are arrested in S-phase by incubation in medium containing 4 m*M* HU for 24 hr, and then treated with 180 μM roscovitine or 5 μM MG115 for 4–24 hours in the continued presence of HU. In case of siRNA transfection, cells are transfected for 24 h, then arrested in S-phase with a 24 h HU treatment.
2. Harvest the cells according to your specific needs. Mps1 is a low abundance protein, which requires us to generate high concentration cell lysates. Accordingly, we use standard cell passaging techniques to detach cells from culture dishes, collect them by centrifugation, wash to remove media and serum, and then lyse the resulting cell pellet in 25 μl of pre-chilled lysis buffer.

3. Protein determination (optional, *see* **Note 3**): For each sample to be assayed and a blank, add to a microcentrifuge tube in order 800 µl of water, 1 µl lysate (or lysis buffer for the blank), and 200 µl undiluted assay reagent. Cap tubes, mix by inversion, and measure absorbance at 595 nm. The background corrected absorbance is then compared to a standard curve to estimate the concentration of each lysate.
4. Combine between 10 and 40 µg of protein with 5 µl of 5X sample buffer and sufficient water to bring the final volume to 25 µl in a microcentrifuge tube. Samples are heated to 95 °C for 5 min, and centrifuged at full speed for 3 min. Do not return samples to ice, because SDS from the sample buffer may precipitate.

3.2. SDS-PAGE

1. Prepare SDS-PAGE gels according to your specific needs. These instructions are given for the Hoefer SE245 Dual Gel Caster and SE260 minivertical gel electrophoresis unit, using 10 cm gel plates, 0.75 mm spacers, and 10% Anderson's modified SDS-PAGE gels ***(10)***, but are by no means specific to this system.
2. Prepare samples (**Subheading 3.1.,** step 4) while the stacking gel is polymerizing.
3. Load 7 µl of prestained protein markers in the first well (prestained markers are not boiled). Load 20 µl of the samples prepared in **Subheading 3.1, step 4** to adjacent wells.
4. Perform electrophoresis according to the requirements of your experiment. We run minigels at 20 mA constant current at room temperature.

3.3. Two-Color Immunoblotting

1. This protocol assumes the use of the BioRad Mini Transblot, but should work well with any combination of gel and transfer apparatus.
2. Perform electrophoretic transfer according to the requirements of your protocol. We perform transfers with gentle stirring at 90V for 1 h at room temperature with a Bio-Ice cooling unit present in the buffer tank to absorb the heat generated during transfer, or at 30V overnight at 4°C.
3. After transfer, remove and disassemble the cassette and stain the membrane with Ponceau S solution for 5 min at room temperature (optional). Rinse the membrane several times with water to remove background staining and assess transfer. Ponceau S, which can be recycled and reused several times, is a reversible protein stain that will dissipate in subsequent steps and does not interfere with antibody binding.
4. Block the membrane in 100 ml blocking buffer for 1 h at room temperature with gentle rocking, or at 4°C overnight. Do not use Tween or BSA in the blocking step (*see* **Note 2**).
5. If primary antibody is to be recycled, rinse the membrane twice briefly with PBS-T to remove residual blocking agent. Incubate at room temperature for 1 h with gentle rocking in enough primary antibody solution to cover the membrane without drying.
6. Remove primary antibody and wash the membrane three times for 5 min with ~50 ml PBS-T on a rocking platform. Primary antibody can often be recycled with the addition of 1 mM sodium azide (from a 1 *M* stock solution) and storage at 4°C.

7. Incubate the membrane with secondary antibody mixture in the dark at room temperature for 1 h on a rocking platform. Because the secondary antibodies are conjugated to photo-labile fluorescent dyes it is essential that this and subsequent steps be performed in the dark (*see* **Note 4**).
8. Discard the secondary antibody solution and wash the membrane with PBS-T three times for 5 min on a rocking platform. Leave the last wash in the container.
9. Rinse the glass scanning bed of the Odyssey with water and wipe clean with Kimwipes. Note that paper towels should not be used to avoid scratching the scanning bed. It is not necessary for the scanning bed to be completely dried.
10. Place the membrane on the scanning bed, protein side facing down, with one corner of the blot at the origin (in the lower left corner). The scanning bed is designed to be wet, and the presence of a small amount of PBS-T facilitates the removal of bubbles.
11. Rinse the Teflon mat with water and place it on top of the membrane. Use the Teflon roller to remove any bubbles between the scanning bed, membrane, and mat.
12. Using the Odyssey software (current version 2.1), access the scanner, enter a name for the analysis, define the area to be scanned, and set the scanning parameters of resolution, intensity (each of two channels can be set independently over two orders of magnitude), and focus offset (formats such as microtiter plates and gels that require the lasers to be focused above the scanning bed can also be analyzed on the Odyssey). As defaults we scan at 169 μM resolution, an intensity setting of 5, and a focus offset of zero.
13. Start the scanner. Once the blot has been scanned (both lasers scan the membrane simultaneously), data can be viewed as individual gray scale images, individual pseudocolored images (red for Alexa680 and green for IRDye800), or as one merged pseudocolored image. While the detection range for the Odyssey spans multiple orders of magnitude, it is possible to saturate the detectors; this is indicated by a white signal in pseudocolored images and a cyan signal in gray scale images. If a signal is saturated (most common with high abundance proteins such as the αTubulin loading control) simply reduce the intensity in that channel and scan the membrane again.
14. The signals for the protein of interest and the loading control are determined using the Odyssey software to draw boxes around each band, and must be background corrected (*see* **Note 5**). **Fig. 1A** shows S-phase arrested cells treated with DMSO, Roscovitine, or MG115, and the blot was simultaneously stained with mouse anti-Mps1 and mouse anti-αTubulin. **Fig. 1B** shows S-phase arrested cells transfected with cyclin A- or Cdk2-specific siRNAs, and the blot was simultaneously stained with three antibodies; mouse anti-αTubulin, mouse anti-Mps1, and rabbit anti-Cdk2. Note that the prestained markers, or any blue dye (including Coomassie), can be detected in the 700 channel. **Fig. 1C** and **D** show the background corrected intensity for the relevant bands from **Fig. 1A** and **B**, respectively. From these values the ratio of target protein to loading control is determined and compared between samples. Note that despite overloading of the roscovitine treated sample (**Fig. 1A** and **C**, lane 2), the normalization procedure allows its comparison to other samples; roscovitine caused a 50% decrease in Mps1 while MG115 caused a

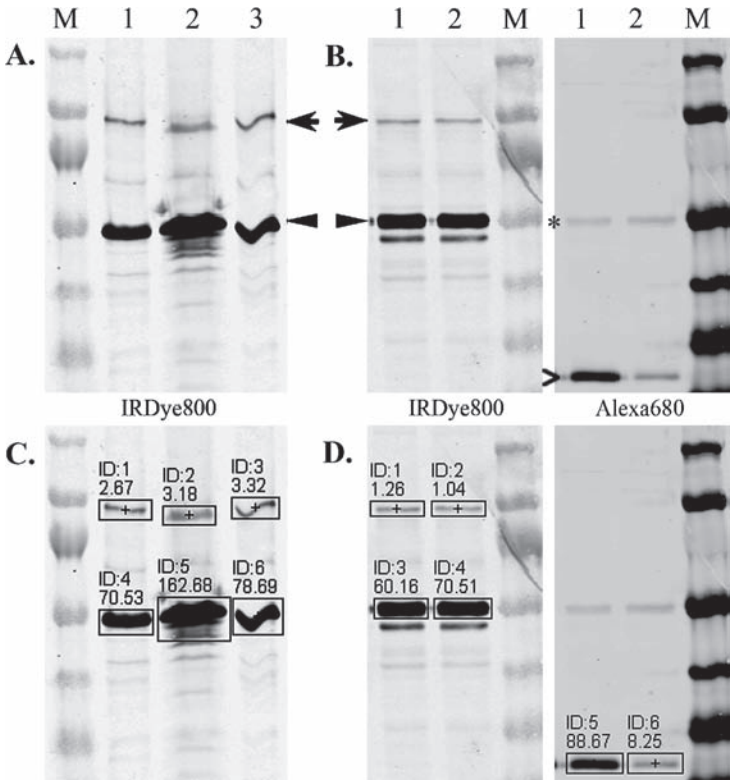

Fig. 1. Analysis of whole-cell Mps1 levels with two-color immunoblotting. **(A)** S-phase arrested HeLa cells treated with DMSO (lane 1), roscovitine (lane 2), or MG115 (lane 3) were processed for immunoblotting with mouse anti-αTubulin and mouse anti-Mps1; M, prestained molecular weight markers. **(B)** HeLa cells transfected with cyclin A-specific (lane 1) or Cdk2-specific (lane 2) siRNAs were arrested in S-phase and processed for immunoblotting with mouse anti-αTubulin, mouse anti-Mps1, and rabbit anti-Cdk2. **(C** and **D)** Background corrected signal intensities for bands in A and B. Images show Alexa680 anti-rabbit and IRDye800 anti-mouse signals in grayscale; arrowheads, αTubulin; arrows, Mps1; caret, Cdk2; asterisk indicates cross reactivity of Alexa680 anti-rabbit with the mouse anti-αTubulin primary antibody.

10% increase, as compared to DMSO (**Fig. 1A** and **C**), and Cdk2-specific siRNA reduced Cdk2 by 93% and Mps1 by 30% compared to cyclin A-siRNA, where neither is changed ***(4)*** (**Fig. 1B** and **D**).

4. Notes

1. A highly purified source of water, either double distilled or ultra filtered, should be used for preparation of all reagents (e.g. we use water purified with a Milli-Q Biocel unit, Millipore, Billercia, MA).

2. Several factors must be taken into consideration when preparing to detect infrared fluorescent dyes. First, special membranes have been specifically designed to reduce background when using fluorescent dyes; although their routine use is not required they may reduce background when working with difficult to detect proteins and may be helpful when trouble shooting. Second, the presence of Tween-20 and other detergents in the blocking step will cause high background when scanning. However, detergent can be added once the initial blocking is complete with no ill effect. Third, the use of BSA as a blocking agent can lead to high background when scanning. Serum or nonfat dry milk is therefore recommended.
3. Because the Mps1 signal is normalized to the αTubulin loading control for each individual sample and the ratio will be the same for each sample regardless of loading, it is not strictly necessary to load an equal amount of protein for each sample. Of course loading approximately equal amounts of protein in each sample generates more presentable immunoblots.
4. After adding secondary antibody it is necessary to perform all steps in the dark. This can be accomplished in a dark room, but the need to access waste disposal makes it more practical to cover the blots and perform subsequent incubations and washes in the standard laboratory setting. This can be accomplished several ways: Light tight plastic containers; a light tight box placed on top of a rocking platform; placing containers in light-tight x-ray cassette bags; construction of light-tight bags or containers from heavy duty black plastic; or wrapping containers in foil.
5. Values measured by the Odyssey software represent the signal intensity for the respective dye and are directly proportional to the amount of secondary antibody present. However, values must be corrected for background using one of two methods. First, the software can be set to "User-defined background" to define a specific box drawn at an appropriate place on the blot as background. The software uses the average pixel intensity in this box to estimate and subtract background from the value of other boxes. Second, the software can be set to "Automatic background correction." In this mode the software uses the pixels touching the edges of each box to estimate and subtract background from that box. This is preferable because it represents a local background correction method and background may differ across the blot. The values in **Fig. 1** were determined by the later method.

The Use of Infrared Fluorescent Dyes in Immunofluorescence Microscopy

Christopher Kasbek, Ching-Hui Yang, and Harold A. Fisk

1. Introduction

Centrosomes are microtubule organizing centers that regulate assembly of the mitotic spindle apparatus ***(1)***. Excess centrosomes such as those observed in a variety of human tumors generate aberrant mitotic spindles, and the duplication of centrosomes must be tightly controlled ***(2)***. The Mps1 protein kinase localizes to centrosomes and is required for centrosome duplication ***(3-5)***. However, Mps1 has many cellular localizations including kinetochores ***(3, 6-8)*** and nuclear pores ***(7)***, and has additional functions related to the mitotic spindle assembly checkpoint ***(9, 10)***. Recent evidence suggests that centrosome duplication specifically requires the centrosomal Mps1 pool, and that the accumulation of Mps1 at centrosomes is regulated by mutually exclusive Cdk2 phosphorylation and proteasome-mediated degradation ***(5)***. However, different means of inhibiting Cdk2 activity have different consequences for the centrosomal and whole-cell pools of Mps1 ***(5)***. Both inhibition of Cdk2 with the small molecule roscovitine and the depletion of Cdk2 activity with cyclin A-specific siRNAs leads to the loss of Mps1 from centrosomes. However, while Mps1 can be almost completely depleted from cells by roscovitine ***(3, 5)***, whole-cell Mps1 levels are virtually unchanged by cyclin A-specific siRNAs ***(5)***. In contrast, while overexpression of cyclin A only modestly increases in whole-cell Mps1 levels, it causes a 2.5-fold increase in centrosomal Mps1 levels that is sufficient to cause the over production of centrosomes during S-phase arrest ***(5)***.

2. Materials

2.1. Cell Culture, Transfection, and Lysis

1. Standard growth medium is Dulbecco's Modified Eagle's Medium (DMEM) (Invitrogen, Carlsbad, CA) supplemented with Penicillin/Streptomycin (Invitrogen) and 10% (v/v) Fetal Bovine Serum (Hyclone, Ogden, UT).
2. Hydroxyurea (HU) is dissolved at 1 *M* in water (*see* **Note 1**).
3. Six well tissue culture plates (Corning, Lowell, MA).
4. Effectene reagents for plasmid transfection (Qiagen, Valencia, CA).

2.2. Infrared Fluorescence Microscopy

1. Pre-cleaned frosted glass microscope slides and 12 mm round glass coverslips (Fisher Scientific, Pittsburgh, PA).
2. Poly-L-lysine, sterile 0.01% solution, cell culture tested.
3. Phosphate buffered saline containing $MgCl_2$ (PBS/Mg): 137 m*M* NaCl, 2.7 m*M* KCl, 10 m*M* Na_2HPO_4, 2 m*M* KH_2PO_4, 0.5 m*M* $MgCl_2$, pH 7.0 (*see* **Note 2**).
4. Fixative solution: 4% formaldehyde, 0.2% Triton X-100 in PBS/Mg; Prepared using 16% Electron microscopy grade formaldehyde (Ted Pella, Redding, CA), 20% Triton X-100 (Fisher), 1 *M* $MgCl_2$, and 20 X PBS.
5. Blocking buffer: 5% fetal bovine serum, 0.2% Triton X-100, 2 m*M* glycine in PBS/Mg.
6. Primary antibodies diluted in blocking buffer: Ag3 rabbit anti Mps1 (1:500) ***(4, 7)***; GTU-88 mouse anti γ-Tubulin (1:200) (Sigma).
7. Secondary antibodies diluted in blocking buffer: Alexa594-conjugated donkey anti rabbit (1:1,000) and Alexa750-conjugated donkey anti Mouse (1:200) (Invitrogen).
8. Nucleic acid stain: Hoehcst 33342, 1000 X stock solution at 1 mg/ml in water.
9. Humidified chamber. Place a wet paper towel in the bottom of an empty pipette tip box. For incubation in the dark, it is typically sufficient to place this humidified chamber in a drawer. Once the lid is closed the chamber will be sufficiently humidified to prevent the evaporation of small volumes of antibody.
10. SlowFade Mounting Medium (Invitrogen).
11. Clear nail polish

3. Methods

Because different methods of inhibiting Cdk2 activity differentially effect the cytoplasmic and centrosomal pools of Mps1 ***(5)***, it is necessary to examine Mps1 levels by both immunoblot and immunofluorescence. This chapter describes the use of infrared fluorescence microscopy for the analysis of the centrosomal Mps1 pool. Typically, we analyze whole cell and centrosomal Mps1 levels in identical populations by placing glass coverslips into the wells of a six well plate. After appropriate experimental manipulation, coverslips are harvested for Indirect Immunofluorescence (IIF), and the cells remaining on the surface of the dish are harvested for immunoblot analysis.

The comparison of centrosomal Mps1 levels requires that cells are processed and imaged under identical conditions. Practically, this limits such analysis to overexpression techniques where adjacent untransfected cells and transfected cells on the same coverslip can be imaged concurrently. The use of infrared fluorescent secondary antibodies and an efficient infrared light source and filter set allows centrosomes to be identified using infrared wavelengths, reserving the visible channels for imaging DNA, GFP, and Mps1.

3.1. Preparation of Samples for Infrared Fluorescence Microscopy

1. For microscopy cells are grown on acid washed and poly-L-lysine coated 12 mm round glass coverslips (*see* **Note 3**) added directly to 6-well plates. Coverslips are typically coated with poly-L-lysine (*see* **Note 4**) before plating cells.
2. Passage and process cells according to your specific needs. For analysis of Mps1 we typically seed HeLa cells at 1×10^4 cells per well of a 6 well dish. In the specific examples used here, coverslips are harvested after a 24 h plasmid transfection (in the example here cells are transfected with the pECE-GFP cyclin A ***(5)*** expression plasmid) followed by a 24 h treatment with 4 mM HU to achieve S-phase arrest.

3.2. Infrared Fluorescence Microscopy

1. Transfer individual coverslips from six-well plates into a 24-well plate, maintaining the same orientation as in the culture dish so that cells continue to face the ceiling.
2. Fix cells as required for the specific antigens and antibodies to be used, and rehydrate if necessary. We typically visualize centrosomes in cells that have been fixed for ten min at room temperature in 4% formaldehyde and 0.2 % triton X-100 in PBS/Mg, and remove excess fixative by washing four times with ~0.5 ml PBS containing 0.5 m*M* $MgCl_2$ (PBS/Mg) (*see* **Note 2**). Formaldehyde is volatile, toxic, and a potential carcinogen. Formaldehyde fixation should be performed in a fume hood, and both used fixative and the first wash should be disposed of as hazardous waste.
3. Incubate coverslips in blocking buffer for 1 h at room temperature, or overnight at 4°C, in a dark humidified chamber.
4. Incubate coverslips in primary antibody solution at room temperature for 1 h in a dark humidified chamber. Primary antibody incubations can be performed concurrently or consecutively according to the need to recycle antibodies.
5. Wash coverslips four times with ~0.5 ml PBS/Mg.
6. Incubate coverslips in secondary antibody solution at room temperature for 1 h in a dark humidified chamber, then wash coverslips four times with ~0.5 ml PBS/Mg. Do not remove the final wash. Secondary antibodies are typically not recycled and can be incubated concurrently with Hoechst.
7. Invert coverslips onto a small drop (~5 µl) of mounting medium. Taking care not to move coverslips, remove residual mounting medium and clean coverslips by gentle blotting with a damp paper towel. Once coverslips are dry seal around the edges with nail polish. By staggering, up to eight coverslips can fit on a single microscope slide.

8. Cells are then imaged under a 63x oil immersion objective using a Xenon lamp (*see* **Note 5**)**.** Hoechst is visualized through a standard DAPI filter set, GFP is visualized through a narrow band FITC filter set, Alexa 594 is visualized through a standard Texas Red filter set, and Alexa 750 is visualized through a Cy7 filter set.
9. Cells are identified using Hoechst, and transfected cells are distinguished by their GFP signal. The centrosomal protein γTubulin is visualized in the infrared channel (*see* **Note 5**) and is used to identify the centrosomal pool of Mps1. **Fig 1** shows typical results from the overexpression of GFP-cyclin A in HeLa cells. The Hoechst signal **(Fig. 1A)** reveals two cells in the field, the GFP signal **(Fig. 1B)** identifies a cell overexpressing GFP-cyclin A, the Alexa 594 signal reveals the Mps1 distribution **(Fig. 1C),** and the Alexa 750 signal identifies the location of centrosomes **(Fig. 1D).** The insets in **Fig. 1E** show 4-fold magnified images of the GFP, γTubulin, and Mps1 signals from the region surrounding a centrosome in the nontransfected cell, and that in **Fig. 1F** for the GFP-cyclin A-transfected cell. The increased Mps1 signal in the GFP-cyclin A expressing cell is evident, and was measured at 2.5-fold ***(5)*** using a local background correction method developed by Howell et al. ***(11)***.

4. Notes

1. A highly purified source of water, either double distilled or ultrafiltered, should be used for preparation of all reagents (e.g. we use water purified with a Milli-Q Biocel unit, Millipore, Billercia, MA).
2. Because divalent cations inhibit the action of trypsin-like enzymes and are required for the function of cell adhesion molecules, Calcium and Magnesium-free PBS is used when passaging cells. However, the inclusion of Magnesium and/or Calcium can prevent the loss of cells from coverslips during IIF (at 0.5 m*M* we have found no difference between $MgCl_2$ and $CalCl_2$).
3. To acid wash coverslips, gently place a box of 12 mm round glass coverslips (approximately a gross) into the bottom of a glass beaker, cover with 1 N HCl and incubate at 50–60 °C overnight. After extensively washing the coverslips with water, they are equilibrated to 70% ethanol with two brief 70% ethanol rinses and incubated in 70% ethanol for one h at room temperature. After this sterilization, coverslips are equilibrated to 95% ethanol with two brief 95% ethanol rinses, placed individually onto clean, sterile sheets of 3MM chromatography paper (approximately 100 coverslips per sheet is practical), then dried in a tissue culture hood under a UV lamp. Once dry, coverslips can be stored in bulk in a sterile 100 mm tissue culture dish.
4. For each coverslip to be coated with poly-L-lysine place a small drop (≤1 µl) of water or PBS on the surface of the dish and place a single coverslip directly on each drop. The surface tension created by the liquid will

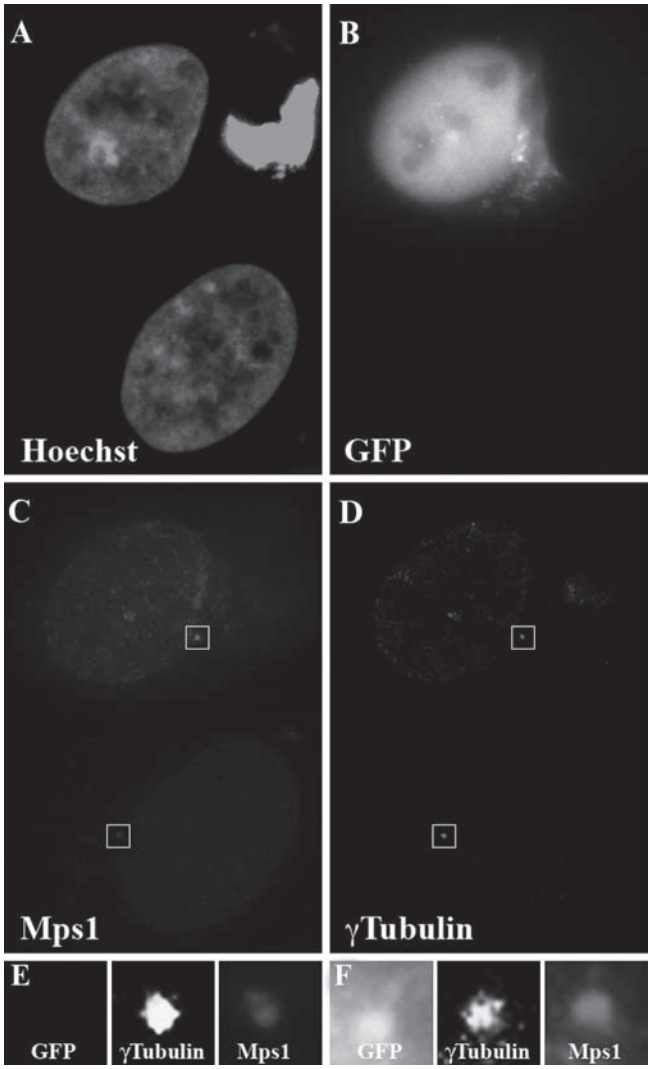

Fig 1. Identification of the centrosomal Mps1 pool using infrared fluorescence. **(A-F)** HeLa cells expressing GFP-cyclin A were arrested in S-phase and analyzed by IIF with antibodies against Mps1 and the centrosomal protein γTubulin. **(A)** Hoechst staining reveals two cells. **(B)** The GFP signal identifies the cell expressing GFP-cyclin A. **(C)** Alexa594 anti-rabbit reveals the Mps1 distribution. **(D)** Alexa750 anti-mouse identifies the position of centrosomes. Boxes in C and D indicate the region surrounding a centrosome in each cell. **(E and F)** Digitally magnified images showing the GFP, γTubulin, and Mps1 signals in the boxes surrounding the centrosomes in C and D as indicated. **(E)** A centrosome from the untransfected cell. **(F)** A centrosome from the GFP-Cyclin A expressing cell.

prevent the coverslips from moving during coating. Space the drops so that coverslips do not touch each other or the side of the dish. Pipette 50–100 µl of poly-L-lysine solution onto each coverslip. Discard coverslips that repel the poly lysine solution. Incubate for 1 h in a tissue culture hood. Remove liquid by placing an aspirator at the edge of the coverslip, and air-dry coverslips by drawing air across the surface. When coating multiple coverslips remove the majority of liquid from all coverslips, and then air-dry coverslips one by one. Wash coverslips four times with 5 ml of PBS per well for a 6-well plate, leaving the final wash until just before cells are plated. Coverslips can also be coated in bulk (e.g. in a 100 mm dish) and transferred to the experimental plate.

5. Visualization of Alexa750 and other infrared dyes requires the appropriate light source, filter set, and camera. We use a Xenon lamp, which illuminates more efficiently in the infrared wavelengths than Mercury lamps. Appropriate excitation and emission filter sets must also be used. We use the Olympus Cy7 filter set. Most digital microscope cameras can detect infrared fluorescence to some degree, although many cameras have infrared shields that must be removed. However, detection is optimal with cameras such as the QCAM Retiga Exi FAST 1394 with expanded sensitivity in the infrared wavelengths. IRDye800 can also be used in microscopy, but filter sets are not commercially available and must be special ordered (see the LI-COR website at http://www.licor.com/bio/IRDyes/IRReag.jsp for more information). Infrared fluorescence is not visible by eye, and the use of Alexa750 or IRDye800 for visualization requires a digital imaging software package capable of real time imaging (we use Slidebook 4.0 from Intelligent Imaging Innovations, Denver, CO)

Carboxymethylation of Cysteine Using Iodoacetamide/Iodoacetic Acid

Alastair Aitken and Michèle Learmonth

1. Introduction

If cysteine or cystine is identified in a protein it requires modification in order to be quantified. Thiol groups may be blocked by a variety of reagents including iodoacetic acid and iodoacetamide. Iodoacetate produces the *S*-carboxymethyl derivative of cysteine, effectively introducing new negative charges into the protein. Where such a charge difference is undesirable, iodoacetamide may be used to derivatize cysteine to *S*-carboxyamidomethylcysteine (on acid hydrolysis, as for amino acid analysis, this yields *S*-carboxymethylcysteine). The charge difference between these two derivatives has been utilized in a method to quantify the number of cysteine residues in a protein (***[1]***, *see* Chapter 115).

Carboxymethylation may be carried out without prior reduction to modify only those cysteine residues that are not involved in disulfide bridges.

If the protein is to be analyzed using gas-phase protein microsequencing, the derivatizing agent of choice is commonly vinylpyridine as this produces a well separated phenylthiohydantoin (PTH) derivative (PTH-*S*-pyridylethylcysteine), *see* Chapter 85.

2. Materials

1. Denaturing buffer: 6 *M* guanidinium hydrochloride (or 8 *M* deionized urea, *see* **Note 1**) in 0.6 *M* Tris-HCl, pH 8.6.
2. 4 m*M* Dithiothreitol (DTT), freshly prepared in distilled water.
3. β-Mercaptoethanol.
4. Sodium dodecyl sulfate (SDS).
5. Oxygen-free nitrogen source.
6. 500 m*M* Iodoacetic acid in distilled water, pH adjusted to 8.5 with NaOH. This is light sensitive and although the solution may be stored in the dark at −20°C, it is better to use it freshly prepared.
7. 500 m*M* Iodoacetamide freshly prepared in distilled water.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

8. 5 m*M* and 50 m*M* Ammonium bicarbonate in distilled water.
9. 0.1% (v/v) Trifluoracetic acid (TFA), high-performance liquid chromatography (HPLC) grade.
10. Acetonitrile, far UV HPLC grade (e.g. Romil, Cambridge, UK).
11. Microdialysis kit (such as that supplied by supplied by Pierce-Warriner).
12. HPLC apparatus.

3. Method

3.1. Large-scale Reaction

1. Dissolve protein (up to 30 mg) in 3 mL of 6 *M* guanidium hydrochoride (or 8 *M* deionized urea), 0.6 *M* Tris-HCl, pH 8.6.
2. Add 30 µL of β-mercaptoethanol (or 5 µL 4 *M* DTT) and incubate under N_2 for 3 h at room temperature. Some proteins require the presence of 1% SDS with an incubation time of up to 18 h at 30–40°C.
3. Add 0.3 mL of colorless iodoacetate (*see* **Note 2**) or iodoacetamide, with stirring, and incubate in the dark for 30 min at 37°C.

3.2 Small-scale Reaction

1. Dissolve the protein (1–10 µg) in 50 µL of denaturing buffer in an Eppendorf tube and flush with N_2.
2. Add an equal volume of 4 m*M* DTT solution to give a final concentration of 2 m*M*.
3. Wrap the tube in aluminium foil and then add 40 mL of iodoacetic acid (or iodoacetamide) dropwise with stirring. Keep under N_2, and incubate in the dark for 30 min at 37°C (*see* **Note 3**). Proceed to **Subheading 3.3.**

3.3. Purification

The removal of excess reagents may be carried out in a variety of ways.

1. Desalting on a 20 × 1 cm Sephadex G10 or Biogel P10 column, eluting with 5 m*M* ammonium bicarbonate, pH 7.8.
2. Dialysis or microdialysis using 50 m*M* ammonium bicarbonate, pH 7.8, as dialysis buffer.
3. By HPLC using a C_4 or C_8 matrix such as an Aquapore RP-300 column, equilibrated with 0.1% (v/v) TFA and eluting with an acetonitrile –0.1% TFA gradient (*see* **Note 4**).

4. Notes

1. Deionization of urea: Urea should be deionized immediately before use to remove cyanates, which react with amino and thiol groups. The method is to filter the urea solution through a mixed bed Dowex or Amberlite resin in a filter flask.
2. The iodoacetic acid used must be colorless. A yellow color indicates the presence of iodine, which will rapidly oxidize thiol groups, preventing

alkylation and may also modify tyrosine residues. It is possible to recrystallize from hexane.

3. Reductive alkylation may also be carried out using iodo–[^{14}C]acetic acid. The radiolabeled material should be diluted to the desired specific activity before use with carrier iodoacetic acid to ensure an excess over total thiol groups.
4. If the HPLC separation is combined with mass spectrometric characterization, this level of TFA (which is required to produce sharp peaks and good resolution of peptide) results in almost or complete suppression of signal. In this case it is recommended to use the new "low TFA," 218MS54, reverse-phase HPLC columns from Vydac (300 Å pore size). They are available in C_4 and two forms of C_{18} chemistries and in 1 mm diameter columns that can be used with as little as 0.005% TFA without major loss of resolution and minimal signal loss.

Performic Acid Oxidation

Alastair Aitken and Michèle Learmonth

1. Introduction

Where it is necessary to carry out quantitative amino acid analysis of cysteine or cystine residues, carboxymethylation (Chapter 82) or pyridethylation (Chapter 85) is not the method of choice as it may be difficult to assess the completeness of the reactions. It is often preferable to oxidize the thiol or disulfide groups with performic acid to give cysteic acid. This also has the effect of converting methionine residues to methionine sulfone. Tyrosine residues may be protected from reaction by the use of phenol in the reaction mixture.

Performic acid oxidation is also used in the determination of disulfide linkages by diagonal electrophoresis (*see* Chapter 113).

2. Materials

1. 30% (v/v) Hydrogen peroxide. **Note**: Strong oxidizing agent.
2. 88% (v/v) Formic acid.
3. Phenol (CARE). **Note:** Toxic and corrosive.
4. 1 m*M* Mercaptoethanol.

3. Method

1. Add 0.5 mL of 30% (v/v) H_2O_2 to 4.5 mL of 88% formic acid containing 25 mg of phenol.
2. After at least 30 min at room temperature, cool to 0°C.
3. Add this reagent (performic acid, HCOOOH) to the protein sample at 0°C to result in a final protein concentration of 1%.
4. After 16–18 h, dilute the solution with an equal volume of water and dialyze against two changes of 100 volumes of water at 4°C, and finally dialyze against 100 volumes of 1 m*M* mercaptoethanol at 4°C.

5. The derivatized protein can then be lyophilized or dried in a hydrolysis tube ready for acid cleavage and subsequent amino acid analysis.

Elution positions for separations of derivatized amino acids by ion-exchange chromatography are shown in **Table 1**.

Table 1
Elution Order of Amino Acids and Derivatives from Ion-Exchange Amino Acid Analyzers

1. O-Phosphoserine
2. O-Phosphothreonine
3. Cysteic acid
4. Urea
5. Glucosaminic acid
6. Methionine sulphoxides
7. Hydroxyproline
8. CM-Cysteine
9. Aspartic acid
10. Methionine sulphone
11. α-Methyl aspartic acid
12. Threonine
13. Serine
14. Asparagine
15. Glutamine
16. α-Methyl serine
17. Homoserine
18. Glutamic acid
19. α-Methyl glutamic acid
20. Proline
21. S-methylcysteine
22. Glycine
23. Alanine
24. S-Ethylcysteine
25. Glucosamine
26. Mannosamine
27. Galactosamine
28. Valine
29. Cysteine
30. Methionine
31. α-Methylmethionine
32. Isoleucine
33. Leucine
34. Norleucine

(continued)

Table 1
(Continued)

35. Tyrosine
36. Phenylalanine
37. Ammonia
38. Hydroxylysine
39. Lysine
40. 1-Methylhistidine
41. Histidine
42. 3-Methylhistidine
43. Tryptophan
44. Pyridylethyl-cysteine
45. Homocysteine thiolactone
46. Arginine

The precise elution order may vary depending on the exact instrument and the precise temperature, molarity, and pH of buffers.

Succinylation of Proteins

Alastair Aitken and Michèle Learmonth

1. Introduction

Modification of lysine with dicarboxylic anhydrides such as succinic anhydride prevents the subsequent cleavage of lysyl peptide bonds with trypsin. In addition, modified proteins act as better substrates for proteases. Succinic anhydride reacts with the ε-amino group of lysine and the amino-N-terminal α-amino group of proteins, in their non-protonated forms, converting them from basic to acidic groups ***(1)***. Thus one effect of succinylation is to alter the net charge of the protein by up to two charge units. This is an effect that has been exploited for the counting of integral numbers of lysine residues within a protein ***(2)***.

Succinic anhydride has been reported to react with sulfydryl groups. It is therefore advisable to modify any cysteines within the protein (*see* Chapters 82 and 85) prior to succinylation.

The reaction occurs between pH 7.0 and 9.0. The reaction is carried out using an approx 50-fold excess of the anhydride over native or carboxymethylated protein.

2. Materials

1. 8 *M* deionized urea (*see* **Note 1**).
2. Distilled water containing up to 0.1 *M* NaCl or 0.2 *M* sodium borate buffer, pH 8.5.
3. Succinic anhydride.

3. Method

1. The protein (5 mg) should be dissolved in 5 mL of buffer (*see* **Note 2**).
2. A pH electrode should be placed within the solution to allow monitoring of the pH. The solution should be continuously stirred.

3. The solid succinic anhydride should be added in 0.5 mg portions over a period of 15 min to 1 h to give a 50-fold excess. The pH should be adjusted back to 7 with sodium hydroxide after each addition.
4. The reaction should be allowed to proceed for at least 30 min after the last addition.
5. The modified protein may be separated from the side products of the reaction by dialysis against 50 m*M* ammonium carbonate buffer or by gel filtration (e.g., Sephadex G25) (*see* **Note 3**).

4. Notes

1. Deionization of urea: Urea should be deionized immediately before use to remove cyanates, which react with amino and thiol groups. The method is to filter the urea solution through a mixed-bed Dowex or Amberlite resin in a filter flask.
2. The choice of buffer is dependent on the solubility of the protein. Distilled water may be used or it may be necessary to use 0.1 *M* NaCl or 0.2 *M* sodium borate buffer in the presence of 8 *M* deionized urea.
3. Other dicarboxylic anhydrides may be used. Particularly common is citraconic anhydride ***(3)***. This reagent has the advantage of reversibility, being readily removed with acid. When used in conjunction with trypsin, the proteolytic reaction may be stopped by reducing the pH, which will also remove the lysine blocking groups.

Pyridylethylation of Cysteine Residues

Malcolm Ward

1. Introduction

To help maintain their three-dimensional structure, many proteins contain disulfide bridges between cysteine residues. Cysteine residues can cause problems during Edman sequence analysis, and quantification of cysteine and cystine by amino acid analysis is difficult since these residues are unstable during acid hydrolysis.
