Chemical modification of cysteine residues can enhance the solubility of the protein, enable more effective enzymatic digestion with proteases, such as trypsin, and facilitate quantification by amino acid analysis.

Oxidation with performic acid can be used to convert cysteine and cystine to cysteic acid ***(1)*** (and *see* Chapter 83). This, however, can lead to other nondesirable side reactions, such as oxidation of methionine residues and destruction of tryptophan residues. Alkylation with iodoacetic acid has been used extensively, since this enables the addition of negative charges to the protein. The use of iodoacetic acid containing ^{14}C provides a means of incorporating a radioactive label into the polypeptide chain (*see* Chapter 82) ***(2)***.

The method described in this chapter is an effective alternative, where reduction and alkylation can be achieved in one step. 4-Vinylpyridine is used to convert cysteine residues to *S*-pyridylethyl derivatives. The *S*-pyridylethyl group is a strong chromophore at 254 nm, which facilitates the detection of cysteine containing peptides as well as aiding the identification of cysteine residues during Edman sequencing (*see* **Note 1**).

2. Materials (*see* Note 2)

1. Denaturing buffer: 0.1 *M* Tris-HCl, pH 8.5, 6 *M* guanidine hydrochloride.
2. 4-Vinylpyridine: Store at −20°C.
3. 2-Mercaptoethanol.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Method

1. Dissolve 10–50 µg protein/peptide in the denaturing buffer (1 mL).
2. Add 2-mercaptoethanol (5 µL) and 4-vinyl-pyridine (2 µL) to the sample tube and shake. Since both reagents are extremely volatile and toxic, all experimental work should be carried out in a fumehood wearing appropriate safety clothing.
3. Blow nitrogen gas over the reaction mixture to expel any oxygen.
4. Seal the tubes with a screw cap.
5. Allow the reaction to proceed at 37°C for 30 min.
6. After this time, an aliquot of the reaction mixture may be taken and analyzed by mass spectrometry. Bovine insulin is shown as an example. This protein contains two interchain bridges and one intrachain bridge (**Fig. 1**). The matrix-assisted laser desorption ionization (MALDI) mass spectrum of reduced and alkylated insulin shows molecular ions at m/z 2763 and m/z 3612 corresponding to the two fully alkylated peptide chains (**Fig. 2**) (*see* **Note 3**). There are no other signals present, indicating that no side reactions have occurred.
7. The sample can now be loaded onto a hydrophobic column for either N-terminal sequence analysis, using the HPG1000A protein sequencer, or *in situ* enzymatic or chemical digestion.

4. Notes

1. The PTH-pyridylethylcysteine derivative can be readily assigned during Edman sequence analysis. The relative elution position on the HPLC system of the Applied Biosystems gas-phase sequencer is between PTH-valine and diphenylthiourea. On the Hewlett Packard G1000A system, PTH-pyridylethylcysteine elutes at 14.2 min just before PTH-methionine.
2. All reagents should be of the highest quality available.
3. The pyridylethylation reaction as described allows for fast, effective derivatization of cysteine residues. The reaction is efficient, giving a high yield of fully alkylated product with no side products.
4. The concept of monitoring chemical reactions by mass spectrometry is not new, yet the sensitivity and speed of MALDI provide a means of examining reaction products to enable the controlled use of reagents that have previously proven troublesome. A recent publication by Vestling et al. ***(3)*** describes the controlled use of BNPS Skatole, a reagent that to date has

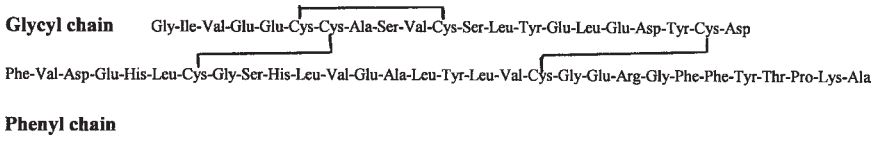

Fig. 1. Amino acid sequence of insulin showing position of disulfide bonds.

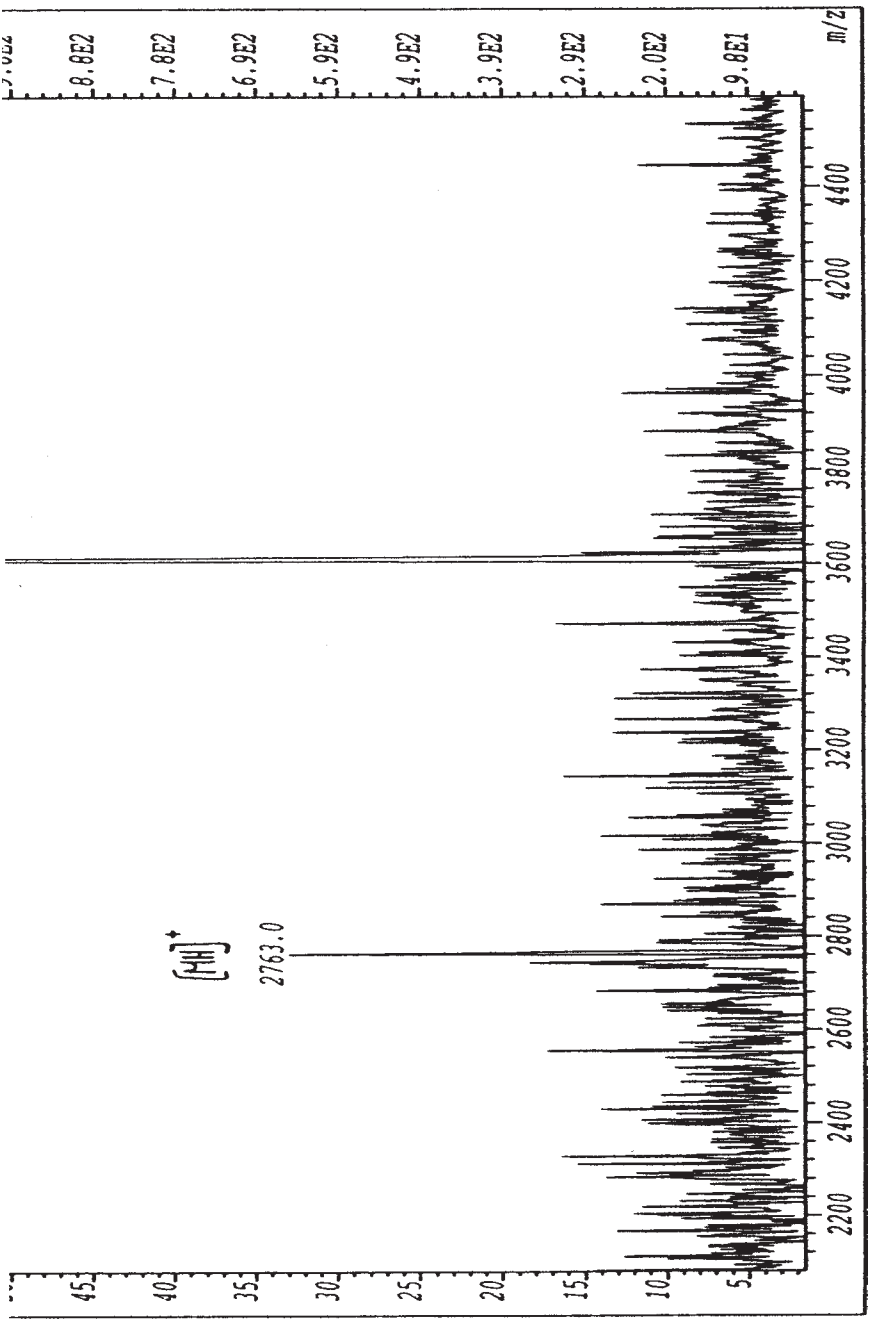

Fig. 2. The MALDI mass spectrum of reduced and alkylated insulin.

been seldom used owing to side reactions. The reactivity of such a reagent may be more widely used in the future now that the progress of the reaction can be easily monitored.

Side Chain Selective Chemical Modifications of Proteins

Dan S. Tawfik

1. Introduction

Chemical modifications of proteins may be performed simply and rapidly to provide preliminary data regarding the role of particular amino acids in a given protein. Many reviews and books cover these aspects of protein chemistry; only a few are cited here ***(1–4)***. In particular, the book by Means and Feeney ***(1)***, although about 30 yr old, is an excellent introduction and a practical guide to this field. Notably, even in the era of molecular biology, when site-directed mutagenesis has become widely accessible (including with nonnatural amino acids), selective chemical modifications are still applied regularly. In most cases, chemical modifications are used, often together with site-directed mutagenesis, to either identify or confirm the role of active site residues (for recent examples *see* **ref. *5–9***). But chemical modifications are also applied for the generation of improved and modified proteins for a variety of applications ***(10–12)***. More recent applications in the field of chemical biology include proteomics (e.g. protein arrays and mass spectroscopy analyses; **ref. 13**), and a broad range of side-chain modifications, including groups that mimic posttranslational modifications ***(14–16)***, and selective chemical modifications of proteins that make use of specific enzymes ***(17,18)***.

The modifications discussed in the following chapters are side chain selective, that is, *under appropriate conditions*, the reagents mentioned in this chapter (and additional reagents mentioned in **refs. *1–4***) react specifically with a single type of amino acid side chain. Hence, loss of activity (enzymatic, binding, or other biological activity) following treatment of the protein with such a

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

modifying reagent is considered to be an indication for the role of that side chain in the active site of the protein.

Data obtained by side chain modifications must be analyzed with caution (as is the case for data obtained by genetic site-directed mutagenesis). Loss of activity on treatment with a reagent might be the result of conformational changes or other changes that occur far from the active site. Some of the reagents, in particular when applied in large excess or under inappropriate conditions, may react with more than one type of side chain or may even disrupt the overall fold of the protein. In general, the type of modifications that alter the size of a particular residue, but not its charge, are preferred (*see* Chapters 90 and 91). In addition, the reactivity of a certain type of side chain in a protein varies by several orders of magnitude owing to interactions with neighboring groups that affect the accessibility and reactivity. For example, the pK_a of the carboxylate side chain of aspartic acid is generally approx 4.5; however, interactions with other side chains may increase the pK_a by more than three units. This change will have a major effect on the reactivity of such a carboxylate group toward the modifying reagent. Dramatic pK_a changes are often found in active sites; thus, certain residues might be particularly difficult to modify, thereby forcing conditions that result in a nonspecific loss of activity.

A number of quite simple experiments may strongly support the results obtained by chemical modifications:

1. A simple control that allows the modification to be ascribed to the active site of a protein is to demonstrate protection (i.e. lack of modification) in the presence of a specific ligand to that site, for example, a hapten for an antibody, a substrate or an inhibitor for an enzyme (for an example *see* Chapter 87).
2. The extent of modification is determined primarily by the molar excess of the modifying reagent, but also by other conditions such as pH, temperature, and reaction time. Reliable and reproducible results are generally obtained only after a wide range of reagent concentrations are applied under different reaction conditions. Following these modifications, one should determine not only the remaining biological activity but also, when possible, the number of modified side chains (details for each reaction are provided in the following chapters). These data may allow one to assess to what extent the modification is indeed site specific (e.g., loss of activity is the result of modification of one or two amino acids of the type modified) or whether loss of activity is due to a complete disruption of the protein due to, for example, the modification of a large number of amino acids.
3. Some of the modifications are reversible; for example, histidine side chains modified by diethyl pyrocarbonate can be recovered by a short treatment with hydroxylamine. Recovery of the activity of the modified protein following this treatment may demonstrate the specificity of the modification (*see* Chapter 88). Additional reversible modifications are described in Chapters 91 and 93.
4. Demonstrating pseudo-first-order kinetics for the inactivation of the protein may indicate that the modification proceeds like an ordinary bimolecular reaction and not via the formation of a binding complex as with affinity labelers or suicide inhibitors.

In the following chapters, I have provided basic protocols for the specific modifications of different side chains; these, or very similar, protocols can be applied with other reagents as well (*see* **refs. *1–4***). The first protocol for the nitration of tyrosine side chains with tetranitromethane (Chapter 87) is written for a specific protein (an antidinitrophenyl [DNP] antibody) and provides as many experimental details as possible. Hence it is recommended to read Chapter 87 (including the Notes) before applying any of the other modifications described in Chapters 88 to 93.

1.1. General Notes

1. To avoid misleading results it is important to be familiar with the *chemistry* of each of the reagents (*see* **refs. *1–4*** and references therein). A detailed mechanistic discussion is beyond the scope of this book, although examples for typical problems or side reactions are given in each chapter.
2. Many of the reagents and solvents described are harmful and should be used only in a well-ventilated hood and while applying other precautions such as wearing suitable gloves.
3. Examine the buffer you intend to use with your protein in light of the modification reaction. For example, while amidating carboxylate groups (*see* Chapter 90), the use of an acetate buffer, or of any other buffer that contains carboxylate groups or other nucleophiles (e.g., Tris buffer), should obviously be avoided. Likewise, the use of certain organic solvents should be avoided (e.g., acetone with 2-hydroxy-5-nitrobenzylbromide, *see* Chapter 92).
4. Most of the reagents described in the following chapters are reactive with water; however, in some cases, quenching the excess of unreacted reagent is required (for an example *see* Chapter 87).
5. Chemically modified proteins are often unstable. Likewise, some of the modifications are removed even under mild conditions. This must be taken into consideration while the protein is purified and its activity is being determined. Hence, when possible, it is best to determine the results of the modification reaction (i.e., the remaining biological activity and the number of modified residues) immediately after the reaction and minimize further manipulations of the protein (e.g., dialysis or gel filtration).

Nitration of Tyrosines

Dan S. Tawfik

1. Introduction

Tetranitromethane (TNM) reacts with the phenolic side chain of tyrosine under relatively mild conditions to give 3-nitrotyrosine ***(1)***. The protocol described in this chapter was developed for an anti-DNP antibody, but can be used with any other antibody or protein. The major side reaction is oxidation of thiols although under more extreme conditions tryptophans and methionines might be oxidized as well. As the reactive species is the phenolate ion, the main factor controlling the reactivity of protein tyrosyl side chains toward nitration by TNM is pH. Increasing the pH will usually enhance the rate of modification.

The number of nitrated tyrosines can be determined spectrophotometrically during the reaction. In addition, the stability of nitrotyrosine allows the specific site of modification to be determined by amino acid analysis of cleaved fragments of the protein. Finally, 3-nitrotyrosine has a much lower pK_a than tyrosine. Thus, examining the pH activity profile of the nitrated protein, for example, the binding of the protein to its ligand can be readily exploited not only to demonstrate the specificity of the modification but also to engineer the binding properties of the protein (*see* **Subheading 3.2.** and **refs. *2–5***).

2. Materials

1. Tris-buffered saline (TBS) 8.0: 0.05 *M* Tris-HCl, pH 8.0, 0.15 *M* NaCl.
2. 1–2 mg/mL monoclonal or polyclonal antibody preparation (purified by protein A affinity chromatography).
3. Acetonitrile.
4. TNM. Store in aliquots at −20°C.
   Note: TNM should be handled with care. Preparation of aliquots and of stock solutions should be done in a ventilated hood and with suitable gloves!

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

5. 2-Mercaptoethanol.
6. Phosphate buffered saline (PBS): 0.01 *M* phosphate buffer, pH 7.4, 0.15 *M* NaCl.
7. Dialysis tubes: 10,000 molecular weight cutoff.

3. Method

3.1. Nitration of Tyrosines with Tetranitromethane

1. Dialyze the antibody against TBS 8.0 (4 h at 4°C). Determine the protein concentration in the sample by measuring the absorbance at 280 nm (for IgG, $\varepsilon = 1.45\ cm^{-1}\ mg^{-1}\ mL$), and adjust it with TBS 8.0 to optical density (OD) 1.09 or 0.75 mg/mL (= 5 µ*M* antibody = 10 m*M* sites).
2. Prepare a set of TNM solutions in acetonitrile: 0, 2.1, 10.5, 42, 105, and 420 m*M* (corresponding to 21 times the final reagent concentration or to 0, 10, 50, 200, 500 and 2000 molar ratios of TNM per antibody sites) (*see* **Note 1**).
3. Add 5 µL of each of the TNM solutions to 100 µL aliquots of the cold antibody solution in Eppendorf tubes immersed in an ice bath. Incubate, with occasional stirring, for 1.5 h at 4°C and then for 30 min at room temperature.
4. Quench the reaction by adding 2 µL of 2-mercaptoethanol, to the samples containing 0–200 fold excess of TNM, and 10 µL to the samples containing 500–2000 fold excess of TNM. Incubate for 15 min at room temperature.
5. Dilute the samples with TBS to a total volume of 500 µL and dialyze them against TBS or PBS (at least twice; each round for 4 h at 4°C).
6. Determine the activity of the various antibody samples by enzyme-linked immunosorbent assay (ELISA) (or any other immunoassay) at increasing antibody dilutions (e.g., 1:50 up to 1:50,000 in PBS).
7. Determine the number of 3-nitrotyrosines per antibody molecule by measuring the optical density at 428 nm ($\varepsilon = 4100\ M^{-1}\ cm^{-1}$ at pH ≥ 8.5; *see* **Note 2**).
8. For modification in the presence of the hapten-dinitrophenol (DNPOH): Incubate the antibody with 1 m*M* DNPOH for 30–60 min at 4°C.
9. Proceed with the addition of teranitromethane, quenching and dialysis as described in the preceding (*see* **Note 3**).
10. Determine the number of 3-nitrotyrosines by measuring the optical density at 428 nm (and compare it to the number of tyrosines modified under the same conditions in the absence of the hapten) (*see* **Note 4**).

3.2. pH Dependency of Binding of Nitrated Antibodies

Nitration of the phenolic group of tyrosine induces a dramatic shift in the pK_a of this residue. The pK_a of tyrosine is normally around 10; thus the hydroxyl group is mostly protonated under pH ≤ 9.5. In contrast, the pK_a of 3-nitrotyrosine is around 7.0 ***(1)***; hence, loss of activity of the nitrated protein is often the result of deprotonation of the hydroxyl group at pH above 7.0. In such cases, activity could be recovered at pH < 6.0, at which the hydroxyl of the nitrated tyrosine regains its proton. This was originally demonstrated with several antibodies (including an anti-DNP antibody) in which a pH dependency

of binding was observed after site-specific modification of tyrosine with TNM ***(2)***. More recently, this approach was applied to other antibodies ***(3)***, and also with avidin, leading to pH-dependent, reversible biotin binding ***(4)***. Recovery and loss of binding of these antibodies to the corresponding haptens (at pH < 6.0 and at pH > 8.0, respectively) were ascribed to the protonation and deprotonation of the hydroxyl group of a 3-nitrotyrosine side chain at their binding sites.

This approach can be utilized to determine the role of the modified tyrosine residue at the binding site; it may also find use in a variety of applications in which controlled modulation of binding under mild conditions is required —for example, affinity chromatography ***(4)***, cell sorting or immunosensors.

1. Nitrate the antibody as described in **Subheading 3.1., steps 1–5**).
2. Perform a series of dilutions of the nitrated antibody (1:50–1:50,000; *see* **Note 5**) in 50 m*M* 2-morpholinoethane sulfonic acid (MES) saline buffer pH 5.8, and in TBS, pH 9.0.
3. Determine the binding activity of the diluted antibody at pH 5.8 and 9.0 by ELISA on microtiter plates coated with DNP-bovine serum albumin (BSA) (*see* **Note 6**).

4. Notes

1. In the first modification experiment of a protein a wide range of TNM concentrations of should be applied, for example, 0–10,000 molar excess. If loss of activity is not observed it is recommended to try again at higher pH (e.g., at pH 9.0) and with longer incubations at room temperature.
2. Although proteins hardly absorb at this 428 nm, a sample of the same concentration of the unmodified protein should be used as blank. Relatively high quantities of a protein are required for the determination of low modification ratios; for example, a single 3-nitrotyrosine per site (i.e., two per antibody molecule) would give an OD_{428nm} of approx 0.11 at antibody concentration of 2 mg/mL (13.3 m*M*).
3. Demonstrating specificity by modifying the protein in the presence of an active site specific ligand should be done under the mildest conditions that cause full loss of activity; these conditions (e.g., excess of TNM and pH) should be determined in a preliminary experiment. In some cases dialysis with 6 *M* urea (or a similar reagent) is required to release the ligand from the protein to allow the determination of its activity. In any case, control samples (without the addition of TNM) containing the protein alone and the protein incubated with the ligand should be included for comparison of the remaining activity after modification.
4. Nitrated proteins (and other chemically modified proteins as well) are often unstable. Therefore, measure the residual activity soon after modification and avoid freezing and defrosting of the samples. In those cases in which

the activity assay can be performed at low protein concentrations, for example, measuring the binding activity of an antibody by ELISA, dialysis that follows the quenching can be avoided. Protein stability can be improved by adding an equal volume of a 10 mg/mL BSA solution after the addition of the 2-mercaptoethanol.

5. To be able to observe pH-dependent binding the nitration should be performed under mild modification conditions (e.g., 200 molar excess of TNM at pH 8.3); under more extreme conditions, e.g., 1000 molar excess of TNM, the antibody is irreversibly inactivated, that is, hapten-binding is not recovered at pH 5.8 ***(2)***.
6. Conditions of the binding assay (e.g., ELISA) should be optimized to clearly identify the pH dependency of binding; in particular, the concentration of the immobilized ligand (DNP in this example) must be low enough so that the differences in binding affinities at pH 5.8 vs pH 9.0 may be observed. Thus, antigen carrying low ratios of DNP (3–10 DNPs per molecule of BSA) should be used and its concentration for the coating of the ELISA microtiter plates should be determined.

Ethoxyformylation of Histidine

Dan S. Tawfik

1. Introduction

Diethylpyrocarbonate (DEP) reacts with various nucleophiles (amines, alcohols, thiols, imidazoles, or guanido groups) to yield the respective ethoxyformyl derivatives. At low pH (generally < 6.0) the reaction is quite selective for histidine, as the main side reaction with the ε-amino group of lysine proceeds very slowly (*see* e.g., **ref.** ***1***). Still, side reactions even with hydroxyl groups (e.g., of serine or tyrosine) were observed ***(2)***. The fact that the ethoxyformyl group can be removed from the imidazole side chain by mild treatment with hydroxylamine can be exploited to ascribe the modification to a histidine residue. In addition, ethoxyformylation of histidines is characterized by an increase in absorbance at 242 nm, which is also used to determine the number of modified histidines ***(1–3)***.

2. Materials

1. (DEP) (*see* **Note 1**).
2. Acetonitrile.
3. Protein for modification (approx 5 μ*M*) diluted in 0.1 *M* sodium acetate buffer, pH 5.0.
4. 1 *M* Hydroxylamine, pH 7.0.

3. Method

1. Prepare a series of *fresh* DEP solutions in acetonitrile (1–30 m*M*) (*see* **Note 2**).
2. Add 5-μL aliquots of each of the DEP solutions to 95-μL aliquots of the protein solution (*see* **Note 3**).
3. Incubate for 15–60 min.
4. Determine the activity of the modified protein.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

5. To assay the recovery of the ethoxyformylated histidine residues (*see also* **Notes 4** and **5**):
   a. Add to a solution of the modified protein 1/10 of a volume of 1 *M* hydroxylamine, pH 7.0, and incubate for 10 min.
   b. Dilute with acetate buffer and dialyze extensively against a buffer suitable for the protein being studied.
   c. Determine the activity of the protein.

4. Notes

1. The concentration of commercial DEP is often lower than indicated owing to hydrolysis. The concentration of the sample after dilution with an organic solvent can be readily determined by adding an aliquot of an imidazole solution (1–10 m*M* in phosphate, pH 7.0) and measuring the increase in absorbance at 230 nm after 5 min ($\varepsilon = 3000\,M^{-1}\,cm^{-1}$).
2. The final acetonitrile concentration in the protein reaction mixture should be 5< %, *see* Chapter 87, **Subheading 3.1** for typical dilutions and reaction volumes.
3. A molar excess of 10–300 of DEP is usually sufficient; however, with some proteins higher concentrations of the reagent might be needed. Likewise, if no modification is observed at pH 5.0, the reaction can be performed at higher pH. In such cases it is recommended that one ensure that loss of activity is indeed due to the ethxyformylation of histidine (*see* **Note 4**).
4. Measuring the differential UV spectra during modification with DEP is useful not only to determine the number of modified histidines but also to eliminate the possibility that residues other than histidines were modified. The ethoxyformylation of histidine side chains by DEP should result in an increase in the absorbance of the protein at 242 nm ($\varepsilon = 3200\,M^{-1}\,cm^{-1}$). Likewise, restoration of the activity of the modified protein after treatment with hydroxylamine should be accompanied by a parallel decrease in the absorbance at 242 nm. Ethoxyformylation of the hydroxyl of tyrosine would increase the absorbance at approx 280 nm whereas similar modification of serine or threonine does not cause a significant changes of absorbance at this range.
5. The ethoxyformyl product is quite unstable. Because the reagent is rapidly hydrolyzed (to give ethanol and carbonate) there is hardly a need to purify the protein after modification. In any case, dialysis even in neutral buffers may result in a significant removal of the ethoxyformyl group. Hence, purification by exclusion chromatography (e.g., on Sephadex G-25) is preferred.

Modification of Arginine Side Chains with *p*-Hydroxyphenylglyoxal

Dan S. Tawfik

1. Introduction

A variety of dicarbonyl compounds including phenylglyoxal, 2, 3-butanendione, and 1, 2-cyclohexanedione selectively modify the guanidine group of arginine ***(1–3)***. The main advantage of *p*-hydroxyphenylglyoxal is in the ability to determine the number of modified arginines spectrophotometrically. This reagent is also reactive at mildly alkaline pH (usually 8.0–9.0) and yields a single product that is relatively stable ***(1)***.

2. Materials

1. *p*-Hydroxyphenylglyoxal.
2. 1 *M* NaOH.
3. Protein for modification (approx 10 µ*M*) diluted in 0.1 *M* sodium pyrophosphate buffer, pH 9.0.
4. Sephadex G-25 column.

3. Method

1. Prepare a 100 m*M* solution of *p*-hydroxyphenylglyoxal in water and adjust the pH of the solution with 1 *M* NaOH to 9.0.
2. Prepare a series of dilutions (5–50 m*M*; *see* **Note 2**) of the solution in **Step 1** in 0.1 *M* sodium pyrophosphate buffer, pH 9.0 (*see* **Note 1**).
3. Add 10-µL aliquots of the p-hydroxyphenylglyoxal solutions to 90-µL aliquots of the protein solution. Check the pH and if necessary adjust it back to pH 9.0.
4. Incubate for 60–180 min *in the dark*.
5. Pass the sample through a Sephadex G–25 column. Elute with deionized water or with an appropriate buffer (*see* **Note 4**).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

6. Determine the activity of the modified protein.
7. Determine the number of modified arginines by measuring the absorbance of the *purified* protein (*see* **Notes 3** and **4**) at 340 nm (at pH 9.0, $\varepsilon = 18{,}300 M^{-1}\ cm^{-1}$).

4. Notes

1. An optimal rate and selectivity of modification is generally obtained at pH 8.0–9.0; however, in some proteins a higher pH might be required to modify a particular arginine residue.
2. A molar excess of *p*-hydroxyphenylglyoxal in the range of 50–500 is usually sufficient for a first trial.
3. The absorbance of *p*-hydroxyphenylglyoxal modified arginines changes with the pH. Maximal absorbance is observed at 340 nm at pH ≥ 9.0 ($\varepsilon = 18{,}300 M^{-1}\ cm^{-1}$) ***(1)***.
4. Prolonged dialysis in neutral or mildly alkaline buffers may cause a significant release of the modifying group. Purification of the protein to determine the extent of modification should therefore be performed using exclusion chromatography ***(1)***.

Amidation of Carboxyl Groups

Dan S. Tawfik

1. Introduction

Several reactions have been described for the modification of the carboxylic side chains of aspartic and glutamic acids ***(1,2)***; of these, amidation, using an amine and a water-soluble coupling carbodiimide reagent, is most often applied to proteins. The advantages of this approach are the stability of the modification (an amide bond) and the ability to achieve some site specificity (namely, to selectively modify a particular carboxylic side chain) by using different carbodiimide reagents and by variations in the structure (e.g., size, charge, hydrophobicity) of the amine ***(3–4)***.

The methyl or ethyl esters of glycine are commonly used as the amine nucleophile. Hydrolysis of these groups by a short treatment with 0.1 *M* hydroxyl amine (pH 8.0, 5–30 min) or a base (0.1 *M* carbonate pH 10.8, 2–6 h) affords a free carboxyl group (e.g., protein—COOH is converted into protein—CO-NHCH$_2$COOH). Hence, a mild modification that affects only the size but not the charge of the aspartyl or glutaryl side chains of the protein is achieved. Determination of the number of modified carboxylate group can be performed only by labeling the amine group, for example, by using a radiolabeled glycine ethyl ester (which is commercially available). In principle, different amines can be used to achieve selectivity or to assist the identification of the modified residues. It is important, however, to ensure that the reaction with these amines is rapid enough and yields a single product ***(3)***.

Several side reactions (e.g., with tyrosines and cysteines) may occur mainly at neutral or mildly basic pH; most of these can be ruled out by demonstrating that the activity of the modified protein is not regained after treatment with hydroxylamine.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2. Materials

1. 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) (*see* **Note 1**).
2. Glycine ethyl ester.
3. Protein for modification (approx 5 µg/mL) diluted in 0.1 *M* 2-morpholinoethanesulfonic acid (MES) buffer, pH 5.5.
4. 0.1 *M* Acetate buffer, pH 5.0.

3. Method

1. Add the glycine ethyl ester to the protein solution to give a final concentration of up to 50 m*M* (*see* **Note 2**); check the pH and if necessary adjust it back to pH 5.5 (*see* **Note 3**).
2. Add EDC to a final concentration of 0.5–10 m*M* and incubate for 1–6 h (*see* **Note 4**).
3. Add one volume of acetate buffer to quench the reaction.
4. Dialyze against an appropriate buffer or pass the sample through a Sephadex G-25 column.
5. Determine the activity of the modified protein.

4. Notes

1. 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) is most commonly used. Several other water-soluble carbodiimide reagents are available (e.g., 1-cyclohexyl-3-[2-morpholinoethyl]carbodiimide) and can be used for this reaction; these reagents, however, are usually derived from more bulky side chains than EDC and may therefore have more limited accessibility to certain carboxylic residues of the protein.
2. Crosslinking of the protein in the presence of the coupling reagent is avoided by using relatively dilute protein solutions (≤ 0.5 mg/mL) and a large excess of the amine nucleophile (e.g., glycine ethyl ester).
3. The reaction is usually performed at acidic pH (4.5–5.5) to minimize side reactions. However, the modification of particular carboxylate side chains may require higher pH (*see* Chapter 86).
4. The reaction is usually run at ambient temperature; nevertheless, lowering the temperature to 4°C may eliminate the appearance of certain side products.

91

Amidination of Lysine Side Chains

Dan S. Tawfik

1. Introduction

Perhaps the largest variety of modifications available is that for ε-amino group of lysine ***(1–4)***. The amino side chain can be acylated (using e.g., acetic anhydride) or alkylated by trinitrobenzenesulfonic acid (TNBS); these reactions alter both the size and the charge of the amino group. Other modifications, using anhydrides of dicarboxylic acids (e.g., succinic anhydride), replace the positively charged amino group with a negatively charged carboxyl group. Amidinations ***(5, 6)*** and reductive alkylations (*see* **ref. *7, 8***) offer an opportunity to modify the structure of the ε-amino group of lysines, while maintaining the positive charge. Modifications that usually do not disrupt the overall structure of the protein are preferred, particularly in those cases when one wishes to identify the specific role of lysine in the active site of the protein being studied.

Amidination is performed by reacting the protein with imidoesters such as methyl or ethyl acetimidate at basic pH. The reaction proceeds solely with amino groups to give mainly the positively charged acetimidine derivative, which is stable under acidic and mildly basic pH. Side products can be avoided by maintaining the pH above 9.5 throughout the reaction (*see* **Note 1** and **2**, **ref. *6***). The modification can be removed at a higher pH (≥ 11.0) and in the presence of amine nucleophiles (e.g., ammonia) (***5, 6***, and *see* **Note 2**).

A major drawback of this modification is that the number of amidinated lysines cannot be readily determined. However, it is possible to take advantage of the fact that the amidine group is not reactive with amine modifying reagents such as TNBS and thereby to indirectly determine the number of the remaining unmodified lysine residues after the reaction ***(9)***.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2. Materials

1. Methyl acetimidate hydrochloride.
2. 0.1 *M* and 1 *M* NaOH.
3. Protein for modification.
4. 0.1 *M* borate buffer, pH 9.5.

3. Method

1. Dissolve the protein (1–2 mg/mL) in 0.1 *M* borate buffer pH 9.5; check the pH and if necessary adjust it back to 9.5 using 0.1 *M* NaOH.
2. Dissolve 110 mg of methyl acetimidate hydrochloride in approx 1.1 mL of 1 *M* NaOH (approximately 0.9 *M*); check the pH and if necessary adjust it to approx 10 with 1 *M* NaOH (*see* **Note 1**).
2. Add an aliquot of the methyl acetimidate solution to the protein solution and check the pH again (*see* **Note 1**).
3. Incubate for 40 min.
4. Dialyze the sample against an appropriate buffer (pH < 8.5) or filter on a Sephadex G-25 column.
5. Determine the activity of the protein.

4. Notes

1. The amidination reaction proceeds with almost no side products only at pH > 9.5; at lower pH, the side reactions proceed very rapidly. Hence it is important to add the methyl acetimidine solution to the buffered protein solution without causing a change of pH ***(6)***. The methyl acetimidine is purchased as the hydrochloride salt, which is neutralized by dissolving it in 1 *M* NaOH (*see* **Subheading 3.,** step 2). The pH of the resulting solution should be approx 10; if necessary the pH may be adjusted before the addition to the protein solution with 1 *M* NaOH or 1 *M* HCl. As acetimidates are rapidly hydrolyzed at basic pH, the entire process should be performed very rapidly. It is therefore recommended, in a preliminary experiment, to dissolve the methyl acetimidine hydrochloride and determine the exact amount of 1 *M* NaOH that yields a solution of pH 10. The same process is then repeated with a freshly prepared methyl acetimidine solution which is rapidly added to the protein.
2. The acetimidyl group may be removed by treatment of the modified protein with an ammonium acetate buffer prepared by adding concentrated ammonium hydroxide solution to acetic acid to a pH of 11.3 **(Caution! Preparation of this buffer must be done carefully and in a well-ventilated chemical hood)**.
3. Amidination is obviously unsuitable for the modification of proteins that are sensitive to basic pH. Reductive alkylation, using formaldehyde and sodium cyanoborohydride (*see* **ref. *7***), can be performed at neutral pH and is recommended for the modification of such proteins.

Modification of Tryptophan with 2-Hydroxy-5-Nitrobenzylbromide

Dan S. Tawfik

1. Introduction

2-Hydroxy-5-nitrobenzylbromide, Koshland's reagent ***(1)***, reacts rapidly and under mild conditions with tryptophan residues. At low pH (< 7.5) this reagent exhibits a marked selectivity for tryptophan; under more basic pH or at higher reagent concentrations, cysteine, tyrosine, and even lysine residues can be modified as well (*see* **Note 1**). The reaction is extremely rapid either with the protein or with water. The reagent is relatively insoluble in water; it is therefore necessary to first dissolve it in an organic solvent (e.g., dioxane) and then to add it to the protein solution in buffer. Unlike that of most other modifying reagents, the final organic solvent concentration in the reaction mixture is relatively high (5–15%). Determination of the number of modified tryptophans is done spectrophotometrically.

2. Materials

1. 2-Hydroxy-5-nitrobenzylbromide.
2. Dioxane (water free) (*see* **Note 2**).
3. Protein for modification: 1 mg/mL in 0.1 *M* phosphate buffer, pH 7.0.
4. 1 *M* NaOH.
5. A Sephadex G-25 column.

3. Method

1. Prepare a *fresh* solution of 200 m*M* 2-hydroxy-5-nitrobenzylbromide in dioxane (keep the solution *in the dark*).
2. Dilute this solution in dioxane to 10× the final reagent concentration (*see* **Note 3**).
3. Add 10 µL of the 2-hydroxy-5-nitrobenzylbromide solution to a 90-µL aliquot of the protein solution and shake for 2 min (e.g., on a Vortex).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

4. Centrifuge (for few minutes at 10,000 rpm) if a precipitate forms (*see* **Note 4**).
5. Filter on a Sephadex G-25 and then dialyze against an appropriate buffer (*see* **Note 4**).
6. Determine the number of modified tryptophans by measuring the absorbance of the purified protein at 410 nm at pH ≥ 10 ($\varepsilon = 18{,}450\,M^{-1}\,cm^{-1}$).
7. Determine the activity of the protein.

4. Notes

1. At neutral and slightly acidic pH the reaction is generally selective. At higher pH, the major side reaction is the benzylation of sulfhydryl groups; to prevent the modification of free cysteine residues the protein can be carboxymethylated prior to the modification with 2-hydroxy-5-nitrobenzylbromide.
2. Avoid the use of acetone, methanol, or ethanol as organic co-solvents for this reagent. Water-free dioxane is commercially available or can be prepared by drying dioxane over sodium hydroxide pellets.
3. At high reagent concentrations a precipitate of 2-hydroxy-5-nitrobenzyl alcohol is sometimes observed and can be removed by centrifugation. Purification of the modified protein from *all* the remaining alcohol product is sometimes difficult and may require extensive dialysis in addition to gel filtration.
4. The reaction of hydroxy-5-nitrobenzylbromide is accompanied by the release of hydrobromic acid. The pH of the reaction should be maintained if necessary by the subsequent addition of small aliquots of 1 *M* NaOH solution.

93

Modification of Sulfhydryl Groups with DTNB

Dan S. Tawfik

1. Introduction

5-5 -Dithio-*bis* (2-nitrobenzoic acid) (DTNB or Ellman's reagent; **ref. *1***) reacts with the free sulfhydryl side chain of cysteine to form an S–S bond between the protein and a thionitrobenzoic acid (TNB) residue. The modification is generally rapid and selective. The main advantage of DTNB over alternative reagents (e.g., *N*-ethylmaleimide or iodoacetamide) is in the selectivity of this reagent and in the ability to follow the course of the reaction spectrophotometrically. The reaction is usually performed at pH 7.0–8.0 and the modification is stable under oxidative conditions. The TNB group can be released from modified protein by treatment with reagents that are routinely used to reduce S–S bonds, for example, mercaptoethanol, or by potassium cyanide ***(2)*** (*see* **Note 1**). In addition, the often highly pronounced differences in reactivity of different cysteine side chains in the same protein or even active site, and the availability of a variety of thiol-modifying reagents can be exploited to selectively modify cysteine side chains in proteins in the presence of other, more reactive cysteine residues ***(3)***.

2. Materials

1. DTNB.
2. 0.1 *M* Tris-HCl, pH 8.0.
3. Protein for modification: approx 5 µ*M* in 0.1 *M* Tris-HCl, pH 8.0.

3. Method

1. Prepare fresh solutions of DTNB (0.5–5 mM; see Note 2) in 0.1 M Tris-HCl, pH 8.0.
2. Add 20-µL aliquots of the DTNB solution to 180 µL of the protein solution and incubate for 30 min.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Determine the number of modified cysteines by measuring the absorbance of the released TNB anion at 412 nm (= 14,150 M−1 cm−1) (*see* **Note 3**).
4. Dialyze against an appropriate buffer (*see* **Note 4**).
5. Determine the activity of the protein.

4. Notes

1. Release of the TNB modification can be achieved by treatment of the modified protein (preferably after dialysis) with thiols (e.g., mercaptoethanol) or by potassium cyanide (20 m*M* final concentration; 10–60 min). The release of the TNB anion can be followed spectrophotometrically at 412 nm ***(2)***.
2. A molar excess of 10–100 of DTNB and an incubation time of 30 min is usually sufficient with most proteins. The modification of a particular cysteine residue may require a higher DTNB concentration, a longer reaction time, or a higher pH.
3. The extent of modification is determined by measuring the absorbance of the *released* TNB anion and hence can be followed during the reaction and in the presence of an excess of unreacted DTNB.
4. Dialysis of the reaction mixture is not always necessary; in many cases the activity of the protein (enzymatic or binding) can be determined directly after the reaction (for an example *see* **ref. *2***).

94

Chemical Cleavage of Proteins at Methionyl-X Peptide Bonds

Bryan John Smith

1. Introduction

One of the most commonly used methods for proteolysis uses cyanogen bromide to cleave the bond to the carboxy-(C)-terminal side of methionyl residues. The reaction is highly specific, with few side reactions and a typical yield of 90–100%. It is also relatively simple and adaptable to large or small scale. Because methionine is one of the least abundant amino acids, cleavage at that residue tends to generate a relatively small number of peptides of large size—up to 10,000–20,000 Da. For this reason the technique is usually less useful than some other methods (such as cleavage by trypsin) for identification of proteins by mass mapping, which is better done with a larger number of peptides. Cleavage at Met-X can be useful for other purposes, however:

1. Generation of internal sequence data, from the large peptides produced ***(1)***.
2. Peptide mapping.
3. Mapping of the binding sites of antibodies ***(2)*** or ligands ***(3)***.
4. Generation of large, functionally distinct domains (e.g., from hirudin, by Wallace et al. ***[4]***) or proteins of interest from fusion proteins ***(5)***.
5. Confirmation of estimates of methionine content by amino acid analysis, which has a tendency to be somewhat inaccurate for this residue ***(6)***. This is by determination of the number of peptides produced by cleavage at an assumed 100% efficiency.

2. Materials

1. Ammonium bicarbonate (0.4 *M*) solution in distilled water (high-performance liquid chromatography [HPLC] grade). Stable for weeks in refrigerated stoppered bottle.
2. 2-Mercaptoethanol. Stable for months in dark, stoppered, refrigerated bottle.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Trifluoroacetic acid (TFA), Aristar grade. Make to 70% v/v by addition of distilled water (HPLC grade), and use fresh (*see* **Notes 1** and **2**).
4. CNBr. Stable for months in dry, dark, refrigerated storage. Warm to room temperature before opening. Use only white crystals, not yellow ones. **Beware of the toxic nature of this reagent: hydrogen cyanide is a breakdown product. Use in a fume cupboard** (*see* **Note 3**).
5. Sodium hypochlorite solution (domestic bleach).
6. Equipment includes a nitrogen supply, fume hood, and suitably sized and capped tubes (e.g., Eppendorf microcentrifuge tubes).

3. Methods

3.1. Reduction

1. Dissolve the polypeptide in water to between 1 and 5 mg/mL, in a suitable tube. Add one volume of ammonium bicarbonate solution, and add 2-mercaptoethanol to between 1% and 5% (v/v).
2. Blow nitrogen over the solution to displace oxygen, seal the tube, and incubate at room temperature for approx 18 h.

3.2. Cleavage

1. Dry down the sample under vacuum, warming if necessary to help drive off all of the bicarbonate. Any remaining ammonium bicarbonate will form a nonvolatile salt on subsequent reaction with the TFA that follows. If a white salty deposit remains, redissolve in water and dry down again.
2. Redissolve the dried sample in 70% v/v TFA, to a concentration of 1–5 mg/mL.
3. Add excess white crystalline CNBr to the sample solution, to 10-fold or more molar excess over methionyl residues. Practically, this amounts to approx equal weights of protein and CNBr. To very small amounts of protein, add one small crystal of reagent. Carry out this stage in the fume hood (*see* **Notes 3** and **4**).
4. Seal the tube and incubate at room temperature for 24 h.
5. Terminate the reaction by drying down under vacuum. Store samples at −10°C or use immediately (*see* **Note 5**).
6. Immediately after use decontaminate equipment that has contacted CNBr by immersion in hypochlorite solution (bleach) until effervescence stops (a few minutes). Wash decontaminated equipment thoroughly.

4. Notes

1. The mechanism of the action of cyanogen on methionine-containing peptides is shown in **Fig. 1**. For further details, see the review by Fontana and Gross *(7)*. The methioninyl residue is converted to homoseryl or homoseryl lactone. The relative amounts of these two depend on the acid used, but when 70% TFA is the solvent, homoserine lactone is the major derivative. Peptides generated are suitable for peptide sequencing by Edman

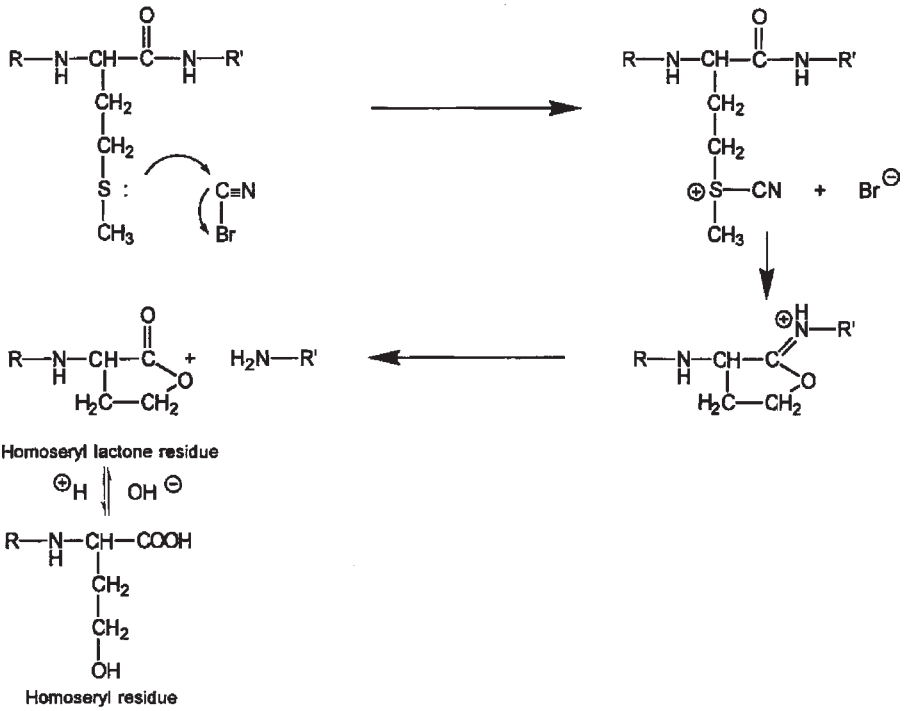

Fig. 1. Mechanism of cleavage of Met-X bonds by CNBr.

chemistry. Methionine sulfoxide does not take part in this reaction and the first step in the method is intended to convert any methionyl sulfoxide to methionyl residues, and so maximize cleavage efficiency. If the reduction is not carried out, the efficiency of cleavage may not be greatly diminished. If virtually complete cleavage is not necessary, partial cleavage products are desired (*see* **Note 6**), the sample is small and difficult to handle without loss, or speed is critical, the reduction step may be omitted. An acid environment is required to protonate basic groups and so prevent reaction there and maintain a high degree of specificity. Met-Ser and Met-Thr bonds may give significantly less than 100% yields of cleavage and simultaneous conversion to methionyl to homoseryl residues within the uncleaved polypeptide. This is because of the involvement of the β-hydroxyl groups of seryl and threonyl residues in alternative reactions, which do not result in cleavage ***(7)***. Morrison et al. ***(8)*** however, have found that use of 70% v/v TFA gives a better yield of cleavage of a Met-Ser bond in apolipoprotein A1 than does use of 70% formic acid (*see* **Note 2**). Using model peptides, Kaiser and Metzka ***(9)*** analyzed the cleavage reaction at Met-Ser and Met-

Thr and concluded that cleavage that efficiency is improved by increasing the amount of water present, and for practical purposes 0.1 *M* HCl is a good acid to use, giving about 50% cleavage of these difficult bonds. Remaining uncleaved molecules contained either homoserine or methionyl sulfoxide instead of the original methionyl. Cleavage efficiency improved with increasing strength of acid, but there was an accompanying risk of degradation in the stronger acids. Utilization of C-terminal homoseryl lactone for linkage to solid phase is discussed in **Note 7**.

2. Acid conditions are required for the reaction to occur. In the past, 70% v/v formic acid (pH 1) was commonly used because it is a good protein solvent and denaturant, and also volatile. However, it may damage tryptophan and tyrosine residues ***(8)*** and also cause formation of seryl and threonyl side chains (showing up during analysis by mass spectroscopy as an increase of 28 amu per modification ***[9,10]***). Use of other acids avoids this problem. TFA (also volatile) may be used in concentrations in the range 50%–100% (v/v). The pH of such solutions is approx pH 0.5 or less. The rate of cleavage in 50% TFA may be somewhat slower than in 70% formic acid, but similar reaction times of hours, up to 24 h will provide satisfactory results. Caprioli et al. ***(11)*** and Andrews et al. ***(12)*** have illustrated the use of 60% and 70% TFA (respectively) for cyanogen bromide cleavage of proteins. Acetic acid (50%–100% v/v) may be used as an alternative but reaction is somewhat slower than in TFA. Alternatively, 0.1 *M* HCl has been used ***(9,10)***. To increase solubilization of proteins, urea or guanidine·HCl may be added to the solution. Thus, in 0.1 *M* HCl, 7 *M* urea, for 12 h at ambient temperature, a Met-Ala bond was cleaved with 83% efficiency, and the more problematical Met-Ser and Met-Thr bonds with 56% and 38% efficiency, respectively ***(9)***.
3. Although the specificity of this reaction is excellent, some side reactions may occur. This is particularly so if colored (yellow or orange) CNBr crystals are used, when there may be destruction of tyrosyl and tryptophanyl residues and bromination may also be detected by mass spectroscopy. Treatment of samples in other formats is discussed in **Notes 8** and **10**.
4. The above protocol describes addition of solid CNBr to the acidic protein solution, to give a molar excess of CNBr over methionyl residues. This has the advantage that pure white crystals may be selected in favor of pale yellow ones showing signs of degradation (*see* **Note 3**). It does not allow accurate estimation of the quantity of reagent used, however. The work of Kaiser and Metzka ***(9)*** suggests that more than a 10-fold molar excess of CNBr over methionyl residues does not increase the extent of cleavage. If in doubt as to the concentration of methionyl residues, however, err on the side of higher cyanogen concentration. If accurate quantification of CNBr is required, solid cyanogen bromide may be weighed out and dissolved to a given concentration by addition of the appropriate volume of 70% v/v

TFA, and the appropriate volume of that solution added to the sample. The CNBr will start to degrade once in aqueous acid, so use when fresh. An alternative is to dissolve the CNBr in acetonitrile, in which it is more stable. CNBr in acetonitrile solution is available commercially, for instance, at a concentration of 5 *M* (Aldrich). While such a solution may be seen to be degrading by its darkening color, this is not so obvious as it is with CNBr in solid form. For use, sufficient acetonitrile solution is added to the acidic protein solution to give the desired excess of cyanogen bromide over protein (e.g., 1/20 dilution of a 5 *M* CNBr solution to give a final 250 m*M* solution). The data of Kaiser and Metzka ***(9)*** indicate that high concentrations (70–100%) of acetonitrile can interfere with the cleavage reaction by decreasing the amount of water present, but below a concentration of 30% (in 0.1 *M* HCl) the effect is noticeable in causing a small decrease of Met-Ser and Met-Thr bond cleavage, but negligible for the Met-Ala bond.

5. The reagents used are removed by lyophilization, unless salt has formed following failure to remove all the ammonium bicarbonate. The products of cleavage may be fractionated by the various forms of electrophoresis and chromatography currently available. If analyzed by reverse phase HPLC, the reaction mixture may be applied to the column directly without lyophilization. Since methionyl residues are among the less common residues, peptides resulting from cleavage at Met-X may be large and therefore in HPLC, use of wide-pore column materials may be advisable (e.g., 30 µm pore size reverse-phase column, using gradients of acetonitrile in 0.1% v/v TFA in water). Beware that some large peptides that are generated by this technique may prove to be insoluble (fore instance, if the solution is neutralized after the cleavage reaction) and therefore form aggregates and precipitates.
6. Incomplete cleavage, generating combinations of (otherwise) potentially cleaved peptides, may be advantageous, for ordering peptides within a protein sequence. Mass spectrometric methods are suitable for this type of analysis ***(10)***. Such partial cleavage may be achieved by reducing the duration of reaction, even to less than 1 h ***(10)***. The acid conditions employed for the reaction may lead to small degrees of deamidation of glutamine and asparagine side chains (which occurs below pH 3) and cleavage of acid-labile bonds, for example, Asp-Pro. A small amount of oxidation of cysteine to cysteic acid may occur, if these residues have not previously been reduced and carboxymethylated. Occasional cleavage of Trp-X bonds may be seen, but this does not occur with good efficiency, as it does when the reduction step of this technique is replaced by an oxidation step (for a description of this approach to cleavage of Trp-X bonds). Rosa et al. ***(13)*** cleaved both Met-X and Trp-X bonds simultaneously by treatment of protein with 12 m*M* CNBr in 70% TFA solution, plus 240 µM potassium bromide.

7. As described in **Note 1**, the peptide to the N-terminal side of the point of cleavage, has at its C-terminus a homoserine or homoserine lactone residue. The lactone derivative of methionine can be coupled selectively and in good yield ***(17)*** to solid supports of the amino type, for example, 3-amino propyl glass. This is a useful technique for sequencing peptides on solid supports. The peptide from the C-terminus of the cleaved protein will, of course, not end in homoserine lactone (unless the C-terminal residue was methionine!) and so cannot be so readily coupled. Similarly, the C-terminal peptide carboxyl can react (if not amidated) with acidic methanol, to become a methyl ester (with a corresponding mass increment of 14 amu). Homoserine lactone, present as the C-terminal residue on other peptides in a CNBr digest, will react with acidic methanol and show a mass increase of 32 amu. With account made for side chain carboxyl residues, this is a means to identify C-terminal peptides by mass spectroscopy ***(18)***.
8. Frequently, the protein of interest is impure, in a preparation containing other proteins. Polyacrylamide gel electrophoresis (PAGE) is a popular means by which to resolve such mixtures. Proteins in gel slices may be subjected to treatment with CNBr ***(14)***, as follows: The piece of gel containing the band of interest is cut out, lyophilized, and then exposed to vapor from a solution of CNBr in TFA for 24 h, at room temperature in the dark. The vapor is generated from a solution of 20 mg CNBr in 1 mL of 50% v/v TFA by causing it to boil by placing it under reduced pressure, in a sealed container together with the sample. The gel piece is then lyophilized again, and the peptides in it analyzed by PAGE.
9. Proteins that have been transferred from polyacrylamide gel to polyvinylidene difluoride (PVDF) membrane may be cleaved *in situ*, as described by Stone et al. ***(15)***. The protein band (of a few micrograms) is first cut from the membrane on the minimum size of PVDF (as excess membrane reduces final yield). The dried membrane is then wetted with about 50 µL of CNBr solution in acid solution—Stone et al. ***(15)*** report the use of CNBr applied in the ratio of about 70 µg per 1 g of protein. Note that although PVDF does not wet directly in water, it *does* do so in 70% formic acid, or in the alternative of 50% or 70% v/v TFA. Cleavage is achieved by incubation at room temperature, in the dark for 24 h. Oxidation of methionine during electrophoresis and blotting was not found to be a significant problem in causing reduction in cleavage yield, being about 100% in the case of myoglobin ***(15)***. The peptides generated by cleavage may be extracted for further analysis, first in the solution of CNBr in the acid solution, second in 100 µL of acetonitrile (40% v/v, 37°C, 3 h), and thirdly in 100 µL of TFA (0.05% v/v in 40% acetonitrile, 50°C. All extracts are pooled and dried under vacuum before any subsequent analysis.

10. Analysis of protein samples in automated peptide sequencing may sometimes yield no result. The alternative causes (lack of sample or amino-(N)-terminal blockage) may be tested by cleavage at methionyl residues by CNBr. Generation of new sequence(s) indicates blockage of the original N-terminus. The method is similar if the sample has been applied to a glass fiber disk, or to a piece of PVDF membrane in the sequencing cartridge. The cartridge containing the filter and/or membrane is removed from the sequencer, and the filter and/or membrane saturated with a fresh solution of CNBr in acid solution. The cartridge is wrapped in sealing film to prevent drying out, and then incubated in the dark at room temperature for 24 h. The sample is then dried under vacuum, replaced in the sequencer and sequence started again. Yields tend to be poorer than in the standard method described in the preceding. If the sample contains more than one methionine, more than one new N-terminus is generated, leading to a complex of sequences. This may be simplified by subsequent reaction with orthophthaladehyde which blocks all N-termini except those bearing a prolyl residue ***(16)***. For success with this approach, prior knowledge of the location of proline in the sequence is required, the reaction with orthophthaladehyde being conducted at the appropriate cycle of sequencing.
11. The reagents used are removed by lyophilization, unless salt has formed following failure to remove all of the ammonium bicarbonate. The products of cleavage may be fractionated by the various forms of electrophoresis and chromatography currently available. If analyzed by reverse-phase HPLC, the reaction mixture may be applied to the column directly without lyophilization. As methionyl residues are among the less common residues, peptides resulting from cleavage at Met-X may be large, and so in HPLC use of wide-pore column materials may be advisable (e.g., 30-μm pore size reverse-phase columns, using gradients of acetonitrile in 0.1% v/v TFA in water). Beware that some large peptides that are generated by this technique may prove to be insoluble (e.g., if the solution is neutralized after the cleavage reaction) and so form aggregates and precipitates.

Chemical Cleavage of Proteins at Tryptophanyl-X Peptide Bonds

Bryan John Smith

1. Introduction

Tryptophan is represented in the genetic code by a single codon and has proven useful in cloning exercises in providing an unambiguous oligonucleotide sequence as part of a probe or primer. It is also one of the less abundant amino acids found in polypeptides, and cleavage of bonds involving tryptophan generates large peptides. This may be convenient for generation of internal sequence information (the usual purpose to which this technique is put), but is less useful for identification of proteins by mass mapping, where a larger number of smaller peptides makes for more successful database searching. Development of mass spectrometric approaches (determination of short sequences from short peptides) in recent years has meant that methods of cleavage at Tryptophanyl residues have become used more rarely.

While there is no protease that shows specificity for tryptophanyl residues, various chemical methods have been devised for cleavage of the bond to the carboxy-(C)-terminal side of tryptophan. These are summarized in **Table 1**. Some show relatively poor yields of cleavage, and/or result in modification of other residues (such as irreversible oxidation of methionine to its sulfone), or cleavage of other bonds (such as those to the C-terminal side of tyrosine or histidine). The method described in this chapter is one of the better ones, involving the use of cyanogen bromide (CNBr). Cleavage of bonds to the C-terminal side of methionyl residues (*see* Chapter 94) is prevented by prior reversible oxidation to methionine sulphoxide. Cleavage by use of *N*-bromosuccinimide or *N*-chlorosuccinimide remains a popular method, however, despite some chance of alternative reactions (*see* **Table 1**).

Table 1
Summary of Methods for Cleavage of Trp-X Bonds in Polypeptides

Brief method details[a]	Comments	Example ref.
1. Incubation in molar excess of cyanogen bromide: a. Incubation in glacial acetic acid: 9 *M* HCl (2/1 [v/v] with DMSO, room temperature, 30 min. b. Neutralization c. Incubation with CNBr in acid (e.g., 60% formic acid) 4°C, 30 h in the dark.	*See text* for further details. Yields and specificity excellent; Met oxidized to sulfoxide by step a.	*4*
2. Incubation in very large (up to 10,000-fold) molar excess of CNBr over Met, in heptafluorobutyric acid–88%–HCOOH (1/1 [v/v]), room temperature, 24 h in the dark.	To inhibit Met-X cleavage, Met is photooxidized irreversibly to Met sulfone; yield poor.	*8*
3. a. Incubate protein for 30 min, room temperature, in: 21.6 mg/mL of phenol in glacial acetic acid 12 *M* HCl–DMSO:24:12:1, b. Add 0.1 vol of 48% HBr, 0.03 by volume of DMSO, and incubate for 30 min, room temperature.	Cys and Met oxidized; some deamidation and cleavage around Asp may occur; fresh, colorless HBr required. Trp converted to dioxindolylalanyl lactone. Protein containing dioxindolylalanine derivatives(s) but remaining uncleaved may be cleaved to improve yield to approx 80% as follows: *Incubate in* 10% acetic acid, 60°C 10–15 h.	*9*
4. Incubate in BNPS-skatole[b] 100-fold molar excess over Trp) in 50% acetic acid (v/v) room temperature, 48 h, in the dark.	Reagent is unstable—fresh reagent required to minimize side reactions; some reactions with Tyr may occur, but addition of free Tyr to reaction mixture minimizes this; Met and Xys may be oxidized, yields up to 60%.	*10*

	Alternative conditions for rapid reaction: neat acetic acid 47°C 15–60 min; adaptable for cleavage of proteins bound to glass fiber or PVDF[c].	*11*
5. Incubation in *N*-bromosuccinimide (NBS, 3-fold molar excess over His, Trp, and Tyr), pH 3.0–4.0 (e.g., pyridine–acetic acid pH 3.3) 1 h, 100°C.	Also less rapid cleavage at His-X and Tyr; yields moderate to poor; Trp converted to lactone derivative.	*12*
6. Incubation in *N*-chlorosuccinimide (NCS,10-fold molar excess) 13 over (protein) in 27.5% acetic acid, 4.68 *M* urea; room temperature, 30 min; stopped by addition of *N*-acetyl-L-methionine.	Yield approx 50%; oxidation of methionine (to sulfone) and (to cysteic acid), especially in higher concentrations; *N*-chloro–succinate; Tyr and His not modified or cleaved (cf. *N*-bromo–succinimide; method 5); adaptable for cleavage of proteins in gels.	*13* *14*
7. Incubate in 80% acetic acid containing 4 *M* guanidine; HCI, 13 mg/mL iodosobenzoic acid; 20 mL *p*-cresol, for 20 h, room temperature, in the dark.	Specificity and yields good; the *p*-cresol is used to prevent cleavage at Tyr; Trp converted to lactone derivative.	*15*

[a]All methods cleave bond to the C-terminal side of residue.
[b]BNPS-skatole = 3-bromo-3-methyl-2-(2'-nitrophenylsulfenyl) indolenine.
[c]PVDF = polyvinylidene difluoride.

Apart from its use in peptide mapping and generation of peptides for peptide sequencing, cleavage at tryptophan residues has also been used to generate peptides used to map the binding site of an antibody ***(1)***, or the sites of phosphorylation ***(2)***. Another application has been generation of a recombinant protein from a fusion protein ***(3)***: tryptophan was engineered at the end of a β-galactosidase leader peptide, adjacent to the N-terminus of phospholipase A_2. Reaction with *N*-chlorosuccinimide allowed subsequent purification of the enzyme without leader peptide.

2. Materials

1. Oxidizing solution: Mix together 30 vol of glacial acetic acid, 15 vol of 9 *M* HCl, and 4 vol of dimethyl sulfoxide (DMSO). Use best grade reagents. Although each of the constituents is stable separately, mix and use the oxidizing solution when fresh.
2. Ammonium hydroxide (15 *M*) (*see* **Note 4**).
3. CNBr solution in formic acid (60% v/v): Bring 6 mL of formic acid (minimum assay 98%, Aristar grade) to 10 mL with distilled water. Add white crystalline cyanogen bromide to a concentration of 0.3 g/mL. Use when fresh (*see* **Note 5**.) Store CNBr refrigerated in the dry and dark, where it is stable for months. Use only white crystals. **Beware of the toxic nature of this reagent. Use in a fume hood**.
4. Sodium hypocholorite solution (domestic bleach).
5. Equipment includes a fume hood and suitably sized capped tubes (e.g., Eppendorf microcentrifuge tubes).

3. Methods

1. Oxidation: Dissolve the sample to approx 0.5 nmol/µL in oxidizing solution (e.g., 2–3 nmol in 4.9 µL of oxidizing solution). Incubate at 4 °C for 2 h (*see* **Notes 6** and **7**).
2. Partial neutralization: To the cold sample, add 0.9 volume of ice-cold NH_4OH (e.g., 4.4 µL of NH_4OH to 4.9 µL of oxidized sample solution). Make this addition carefully so as to maintain a low temperature (*see* **Note 7**.)
3. Cleavage: Add 8 vol of CNBr solution. Incubate at 4 °C for 30 h in the dark. Carry out this step in a fume hood.
4. To terminate the reaction, lyophilize the sample (all reagents are volatile). (*See* **Note 8**).
5. Decontaminate equipment such as spatulas that have contacted CNBr, by immersion in bleach until the effervescence stops (a few minutes) and thorough washing.

4. Notes

1. The method described is that of Huang et al. ***(4)***. Although full details of the mechanism of this reaction are not clear, it is apparent that tryptophanyl residues are converted to oxindolylalanyl residues in the oxidation step, and the bond to the C-terminal side at each of these is readily

cleaved in excellent yield (approaching 100% in **ref. *4***) by the subsequent CNBr treatment. The result is seemingly unaffected by the nature of the residues surrounding the cleavage site. During the oxidation step, methionyl residues become protected by conversion to sulfoxides, bonds at these residues not being cleaved by the cyanogen bromide treatment. Cysteinyl residues will also suffer oxidation if they have not been reduced and alkylated beforehand. Rosa et al. ***(5)*** cleaved both Trp-X and Met-X bonds simultaneously by omission of the oxidation step and inclusion of 240 µ*M* potassium iodide in the reaction of protein with 12 m*M* CNBr in 70% TFA solution. The peptide to the C-terminal side of the cleavage point has a free amino-(N)-terminus and so is suitable for amino acid sequencing by Edman chemistry.

2. Methionyl sulfoxide residues in the peptides produced may be converted back to the methionyl residues by incubation in aqueous solution with thiols (e.g., dithiothreitol, as described in **ref. *3***, or see use of 2-mercaptoethanol above).
3. The acid conditions used for oxidation and cleavage reactions seem to cause little deamidation ***(4)***, but one side reaction that can occur is hydrolysis of acid-labile bonds. The use of low temperature minimizes this problem. If a greater degree of such acid hydrolysis is not unacceptable, speedier and warmer alternatives to the reaction conditions described above can be used as follows:

   a. Oxidation at room temperature for 30 min, but cool to 4 °C before neutralization.
   b. Cleavage at room temperature for 12–15 h.

4. As alternatives to the volatile base NH_4OH, other bases may be used (e.g., the nonvolatile potassium hydroxide or Tris base).
5. Formic acid is a good protein denaturant and solvent, and is volatile and so relatively easy to remove. However, it has been noted that use of formic acid can cause formulation of seryl and threonyl residues ***(6)*** in the polypeptide (seen as an 28 amu increase in molecular mass) and damage to tryptophan and tyrosine (evidenced by spectral changes ***[7]***). As an alternative to formic acid, 5 *M* acetic acid may be used, or as in the use of CNBr in cleaving methionyl-X bonds, 70% (v/v) trifluoroacetic acid may prove an acceptable alternative ***(5)***.
6. Samples eluted from sodium dodecylsulfate (SDS) gels may be treated as described, but for good yields of cleavage, Huang et al. (4) recommend that the sample solutions are acidified to pH 1.5 before lyophilization in preparation for dissolution in the oxidizing solution. Any SDS present may help to solubilize the substrate and, in small amounts at least, does not interfere

with the reaction. However, nonionic detergents that are phenolic or contain unsaturated hydrocarbon chains (e.g., Triton, Nonidet P-40) and reducing agents are to be avoided.

7. The method is suitable for large-scale protein cleavage, requiring simple scaling up. Huang et al. ***(4)*** made two points, however:
   a. The neutralization reaction generates heat. As this might lead to protein or peptide aggregation, cooling is important at this stage. Ensure that the reagents are cold and are mixed together slowly and with cooling. A transient precipitate is seen at this stage. If the precipitate is insoluble, addition of SDS may solubilize it (but will not interfere with the subsequenttre atment).
   b. The neutralization reaction generates gases. Allow for this when choosing a reaction vessel.
8. At the end of the reaction, all reagents may be removed by lyophilization and the peptide mixture analyzed, for example, by polyacrylamide gel electrophoresis or by reverse-phase high-performance liquid chromatography (HPLC). Peptides generated may tend to be large, ranging up to a size of the order of 10,000 Da or more. Some of these large peptides may not be soluble, for example, if the solution is neutralized following the cleavage reaction, and consequently they aggregate and precipitate.
9. Note that all reactions are performed in one reaction vial, eliminating transfer of sample between vessels, and so minimizing peptide losses that can occur in such exercises.
10. Alternative methods for cleavage of tryptophanyl-X bonds are outlined in **Table 1**. The method (vi) that employs *N*-chlorosuccinimide is the most specific but shows only about 50% yield. BNPS-skatole is a popular Trp-X-cleaving reagent whose reaction and products have been studied in some detail (e.g., *see* **refs. *16*** and ***17***)
11. Both BNPS-skatole and N-chlorosuccinimide methods (**Table 1**, iv and vi, respectively) have been adapted to cleave small amounts (micrograms or less) of proteins on solid supports or in gels. Thus, proteins bound to glass fiber (as used in automated peptide sequences) may be cleaved by wetting the glass fiber with 1 µg/mL BNPS-skatole in 70%, (v/v) acetic acid, followed by incubation in the dark for 1 h at 47 °C. After drying, sequencing may proceed as normal. Alternatively protein blotted to polyvinylidene difluoride membrane may be similarly treated and resulting peptides eluted for further analysis ***(11)***. Alternatively, protein in slices of polyacrylamide gel (following polyacrylamide gel electrophoresis [SDS–PAGE]) may be cleaved by soaking for 30 min 0.015 *M* in N-chlorosuccinimide, in 0.5 g/mL of urea in 50%, (v/v) acetic acid. Following washing, peptides may be electrophoresed to generate peptide maps ***(14)***.

Chemical Cleavage of Proteins at Aspartyl-X Peptide Bonds

Bryan John Smith

1. Introduction

Some methods for chemically cleaving proteins, such as those described in Chapters 94 and 95, are fairly specific for a particular residue, show good yields, and generate usefully large peptides (as reaction occurs at relatively rare amino acid residues). There may be cases, however, when such peptides (or indeed, proteins) lacking these rarer residues need to be further fragmented, and in such instances cleavage at the more common aspartyl residue may prove useful. The method described in this chapter (and in **ref. *1***) for cleavage to the carboxy-(C)-terminal side of aspartyl residues is best limited to smaller polypeptides rather than larger proteins because yields are <100% and somewhat variable according to sequence. Partial cleavage of Asp-X bonds in a larger protein leads to a very complex set of peptides that may be difficult to analyze. Partial hydrolysis of smaller peptides yields correspondingly simpler mixtures. This may even be preferable to complete fragmentation for some purposes, such as peptide sequencing or mass spectrometry whereby the series of overlapping peptides may be used to order the peptides in the protein sequence (as in **ref. *2*** in which partial cleavage at methionyl-X bonds by CNBr was used).

2. Materials

1. Dilute HCl (approx 0.013 *M*) pH 2 ± 0.04: Dilute 220 µL of constant boiling (6 *M*) HCl to 100 mL with distilled water.
2. Pyrex glass hydrolysis tubes.
3. Equipment includes a blowtorch suitable for sealing the hydrolysis tubes, a vacuum line, and an oven for incubation of samples at 108˚C.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Method

1. Dissolve the protein or peptide in the dilute acid to a concentration of 1–2 mg/mL in a hydrolysis tube.
2. Seal the hydrolysis tube under vacuum; that is, with the hydrolysis (sample) tube connected to a vacuum line, using a suitably hot flame, draw out and finally seal the neck of the tube.
3. Incubate at 108°C for 2 h *(see* **Note 5**).
4. To terminate the reaction, cool and open the hydrolysis tube, dilute the sample with water, and lyophilize.

4. Notes

1. The bond most readily cleaved in dilute acid is the Asp-X bond, by the mechanism outlined in **Fig. 1(A)**. The bond X-Asp may also be cleaved, in lesser yields (*see* **Fig. 1[B]**). Thus, either of the peptides resulting from any one cleavage may keep the aspartyl residue at the point of cleavage, or neither might, if free aspartic acid is generated by a double cleavage event. Any of these peptides is suitable for sequencing.
2. The amino acid sequence of the protein can affect the lability of the affected bond. Thus, the aspartyl-prolyl bond is particularly labile in acid conditions

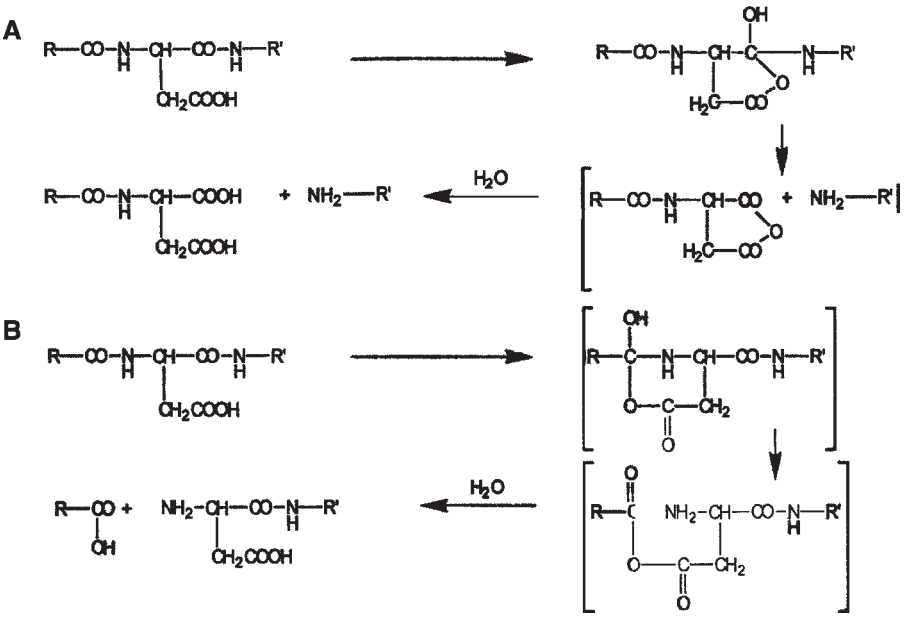

Fig. 1 Mechanisms of the cleavage of bonds to the COOH site (scheme A) and to the NH2 site (scheme)

(*see* **Note 3**). Ionic interaction between the aspartic acid side chains and basic residue side chains elsewhere in the molecule can adversely affect the rate of cleavage at the labile bond. Such problems as these make prediction of cleavage points somewhat difficult, particularly if the protein is folded up (e.g., a native protein). The method may well prove suitable for use in cleaving small proteins or peptides, in which such intramolecular interactions are less likely. Nevertheless, yields are <100%—up to about 70% have been reported ***(1)***.

3. As noted in the preceding the aspartyl-prolyl bond is particularly acid labile and the following conditions have been proposed to promote cleavage of this particular bond ***(3)***: dissolution of the sample in guanidine·HCl (7 *M*) in dilute acid (e.g., acetic acid, 10% v/v, adjusted to pH 2.5 with pyridine); incubation at moderate temperature (e.g., 37°C) for prolonged periods (e.g., 24 h); terminate by lyophilization. Inclusion of guanidine. HCl, intended to denature the protein, may still fail to render all aspartyl-prolyl bonds sensitive to cleavage.
4. The conditions of low pH can be expected to cause a number of side reactions: cleavage at glutamyl residues; deamidation of (and possibly some subsequent cleavage at) glutaminyl and asparaginyl residues; partial destruction of tryptophan; cyclization of amino-(N)-terminal glutaminyl residues to residues of pyrrolidone carboxylic acid; α-β shift at aspartyl residues. The last two changes create a blockage to Edman degradation. The short reaction time of 2 h is intended to minimize these side reactions. A small degree of loss of formyl or acetyl groups from N-termini ***(1)*** is another possible side reaction but is not recognized as a significant problem, generally.
5. A polypeptide substrate that is insoluble in cold dilute HCl may dissolve during the incubation at 108°C. Formic acid is a good protein denaturant and solvent and may be used instead of HCl as follows: dissolve the sample in formic acid (minimum assay 98%, Aristar grade), then dilute 50–fold to pH 2; proceed as in method for HCl. Note, however, that incubation of protein in formic acid may result in formylation (increased molecular mass ***[2]***) and damage to tryptophan and tyrosine residues (altered spectral properties ***[4]***).
6. The comments concerning the effect of the amino acid sequence and of the environment around potentially labile bonds, and the various side reactions that can occur, indicate that the consequences of incubation of a protein in dilute acid are difficult to predict—they are best investigated empirically by monitoring production of peptides by electrophoresis or high-performance liquid chromatography (HPLC).
7. The method described has the benefit of simplicity. It is carried out in a single reaction vessel, with reagents being removed by lyophilization at the

end of reaction. Thus, sample handling and losses incurred during this are minimized. This makes it suitable for subnanomolar quantities of protein, although the method may be scaled up for larger amounts also.

8. Note that bonds involving aspartyl residues may also be cleaved by commercially available enzymes. Endoproteinase Asp-N hydrolyzes the bond to the N-terminal side of an aspartyl residue, but also of a cysteinyl residue. Glu-C cleaves the bond to the C-terminal side of glutamyl and aspartyl residues.
9. The literature has various examples of unwanted cleavage of Asp-X bonds as the result of incubation of protein in acid conditions. The conditions encountered during N-terminal sequencing by Edman chemistry cause cleavage at Asp-X, generally somewhat inefficiently but sufficient to cause gradually increasing background. Cleavage may occur during protein isolation, for instance, of guanylin by 1 *M* acetic acid, which causes artificial cleavage from its corresponding prohormone ***(5)***. Cleavage of labile bonds may also occur during heating of samples in sodium dodecyl sulfate (SDS) solution in preparation for SDS-polyacrylamide gel elctrophoresis (SDS-PAGE) ***(6)***. Cleavage of Asp-X bonds has also been noted to occur in the process of matrix-assisted mass spectrometry ***(7)***.

Chemical Cleavage of Proteins at Cysteinyl-X Peptide Bonds

Bryan John Smith

1. Introduction

Cysteine is a significant amino acid residue in that it can form a disulfide bridge with another cysteine (to form cystine). Such disulfide bridges are important determinants of protein structure. No known endoproteinase shows specificity solely for cysteinyl, or cystinyl, residues, although endoproteinase Asp-N is able to hydrolyze bonds to the amino-(N)-terminal side of aspartyl or cysteinyl residues. Modification of aspartyl residues ***(1)*** can generate specificity for cysteinyl residues. Again, as discussed by Aitken ***(2)***, modification of cysteinyl to 2-aminoethylcysteinyl residues makes the bond to the carboxy-(C)-terminal side susceptible to cleavage by trypsin, or the bond to the N-terminal side sensitive to Lys-N. However, specific cleavage of bonds to the N-terminal side of cysteinyl residues may be achieved in good yield by chemical means [***(3)***; *see* **Note 1**]. The cleavage generates a peptide blocked at its N-terminus as the cysteinyl residue is converted to an iminothiazolidinyl residue, but peptide sequencing can be carried out after conversion of this residue to an alanyl residue ***(4)***.

Cysteine is one of the less frequent amino acids in proteins, and cleavage at cysteinyl residues tends to generate relatively large peptides. Thus, the method described in this chapter has been used to generate separate domains of troponin C for the purpose of studying Ca and peptide binding ***(5)***, and peptides from vinculin to study talin- and anti-vinculin antibody binding ***(6)***. It has also been adapted for the purposes of "footprinting": Cys residues that remain protected in a native protein remain noncyanylated on reaction with 2-nitro-5-thiocyanobenzoate, and remain uncleaved upon alteration of the pH to 9.0. Thus the protected Cys residues can be mapped within the proteins sequence ***(7)***.

2. Materials

1. Modification buffer: 0.2 *M* Tris-acetate, pH 8.0, 6 *M* guanidine.HCl, 10 m*M* dithiothreitol. Use Analar grade reagents and high-performance liquid chromatography (HPLC)-grade water. (*See* **Note 4.**)
2. 2-Nitro-5-thiocyanobenzoate (NTCB): Commercially available (Sigma) as a yellowish powder. Contact with skin, eyes, etc. may cause short-term irritation. Long-term effects are unknown, so handle with care (wear protective clothing). Sweep up spillages. Store at 0–5 °C.
3. NaOH solution, sufficiently concentrated to allow convenient alteration of reaction pH. For example: 2 *M* in HPLC-grade water.
4. Deblocking buffer: 50 m*M* Tris-HCl, pH 7.0.
5. Raney nickel activated catalyst: Commercially available (e.g., from Sigma as 50% slurry in water, pH >9). Wash in deblocking buffer prior to use. A supply of N_2 gas is also required for use with the Raney nickel. (*See* **Note 7**.)

3. Methods (*see* Note 3)

1. Dissolve the polypeptide to a suitable concentration (say, 2 mg/mL) in the modification buffer (pH 8.0). To reduce disulfides in the dithiothreitol, incubate at 37 °C for 1–2 h. (*See* **Note 4**.)
2. Add NTCB to 10-fold excess over sulfhydryl groups in polypeptide and buffer. Incubate at 37 °C for 20 min.
3. To cleave the modified polypeptide, adjust to pH 9 by addition of NaOH solution. Incubate at 37 °C for 16 h or longer (*see* **Note 2**).
4. Dialyze against water. Alternatively, submit to gel filtration or reverse-phase HPLC to separate salts and peptides. Lyophilize peptides.
5. If it is necessary to convert the newly formed iminothiazolidinyl N-terminal residue to an alanyl group, proceed as follows: Dissolve the sample to, say, 0.5 mg/mL in deblocking buffer, (pH 7); add to Raney nickel (10-fold excess, [w/w] over polypeptide); and incubate at 50 °C for 7 h under an atmosphere of nitrogen. Cool and centrifuge briefly to pellet the Raney nickel. Store supernatant at −20 °C, or further analyze as required (s*ee* **Notes 5–8**).

4. Notes

1. The reactions described in **Subheading 3** are illustrated in **Fig. 1**. The method described is basically that used by Swenson and Fredrickson *(5)*, an adaptation of that of Jacobson et al. (***8***; *also see* **ref. *3***). The principal difference is that the earlier method ***(3,8)*** describes desalting (by gel filtration or dialysis) at the end of the modification step (*see* **Subheading 3**), followed by lyophilization and redissolution in a pH 9 buffer to achieve cleavage. Simple adjustment of pH as described in **Subheading 3.,** step 3 has the advantages of speed and avoiding the danger of sample loss upon desalting.

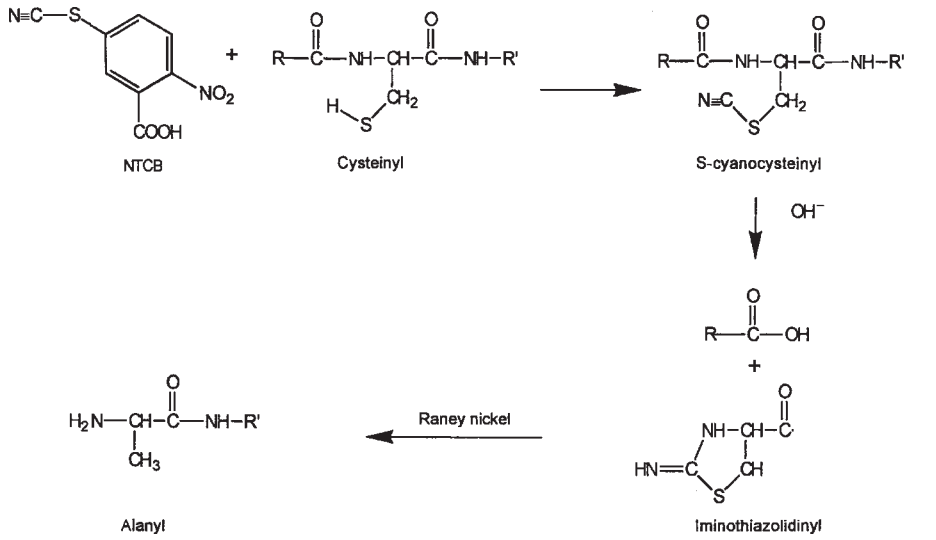

Fig. 1. Reactions in modification of, and cleavage at, cysteinyl residues by NTCB, and subsequent generation of alanyl N-terminal residue.

2. Swenson and Fredrickson ***(5)*** describe cleavage (**Subheading 3.,** step 3) at 37 °C for 6 h, but report yields of 60–80%. Other references recommend longer incubations of 12 h or 16 h at 37 °C to obtain better yields ***(3,8,9)***.
3. A slightly modified procedure is described in ***(9)***:
   a. 1 mg/mL sample in 20 m*M* borate buffer, pH 8.0, 6 *M* urea, mixed with NTCB, added as a 0.1 *M* solution in 33% (v/v) dimethylformamide, at the rate of 40 µL/mL sample solution. Incubation was at 25 °C for 1 h.
   b. Cleavage was by adjusting to pH 9.0 with NaOH and incubation at 55 °C for 3 h.
   c. Reaction was quenched by addition of 2-mercaptoethanol to an 80-fold excess over NCTB.
4. If the sample contains no intramolecular or intermolecular disulfide bonds, the DDT content of the modification buffer may be made less, at 1 m*M*. Note that nominally nonbonded cysteinyl residues may be involved in mixed disulfides with such molecules as glutathione or free cysteine.
5. If blockage of the N-terminal residue of the newly generated peptide(s) to the C-terminal side of the cleavage point(s) is not a problem (i.e., if sequencing is not required, e.g., **ref. *5***), step 5 in **Subheading 3** may be omitted.

6. Reaction with Raney nickel (**Subheading 3.**, step 5) converts methionyl residues to (β-aminobutyryl residues.
7. Although Raney nickel is available commercially, Otieno ***(4)*** has reported that a more efficient catalyst may be obtained by the method he described, starting from Raney nickel– aluminum alloy. This is reacted with NaOH, washed, deionized, and washed again (under H_2 gas).
8. Treatment of protein with Raney nickel *without* prior treatment with NTCB causes desulfurization of methioninyl residues (to give (β-aminobutyryl residues) and of cysteinyl and cystinyl residues (to alanyl residues). Otieno ***(4)*** has suggested that this modification might be used to study dependence of protein function on Met and Cys content.

Chemical Cleavage of Proteins at Asparaginyl-Glycyl Peptide Bonds

Bryan John Smith

1. Introduction

Reaction with hydroxylamine has been used to cleave DNA and to deacylate proteins (at neutral pH; *see* **Note 6**). At alkaline pH, however, hydroxylamine may be used to cleave the asparaginyl-glycyl bond (*see* **Note 1**). This cleavage tends to generate large peptides, as this pairing of relatively common residues is relatively uncommon, representing about 0.25% of amino acid pairs, according to Bornstein and Balian ***(1)***. It is therefore generally not useful for identification of proteins by mass mapping, which is better served by larger numbers of peptides. It may be a useful method for further cleavage of large peptides.

Cleavage at Asn-Gly bonds has been used for:

1. Generation of peptides for sequencing purposes (e.g., **ref. *2***).
2. Generation of peptides for use in mapping ligand binding sites (e.g. **ref. *3***) and phosphorylation sites (e.g. **ref. *4***).
3. Identification of sites of succinimide (cyclic amide) sites in proteins ***(5)***.
4. Cleavage of a fusion protein at the point of fusion of the constituent polypeptides (although it was noted that formation of hydroxamates may occur ***[6]***, as may minor cleavage reactions ***[3]***).

2. Materials

1. Cleavage buffer: 2 *M* hydroxylamine.HCl, 2 *M* guanidine.HCl, 0.2 *M* KCO_3, pH 9.0.

Use Analar grade reagents and HPLC grade water (*see* **Note 2**). **Beware the mutagenic, toxic and irritant properties of hydroxylamine**. Wear protective clothing. Clear wet spillages with absorbent material or clear dry spillages with a shovel, and store material in containers prior to disposal.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

1. Stopping solution: Trifluoroacetic acid, 2% (v/v) in water (high-performance liquid chromatography [HPLC] grade).

3. Method

1. Dissolve the protein sample directly in the cleavage buffer, to give a concentration in the range 0.1–5 mg/mL. Alternatively, if the protein is in aqueous solution already, add 10 vol of the cleavage buffer (i.e., sufficient buffer to maintain pH 9.0 and high concentration of guanidine·HCl and hydroxylamine). Use a stoppered container (Eppendorf tube or similar) with small headspace, so that the sample does not dry out during the following incubation (*see* **Notes 3** and **4**).
2. Incubate the sample (in stoppered vial) at 45°C for 4 h.
3. To stop reaction, cool and acidify by addition of three volumes of stopping solution. Store frozen (−20°C) or analyze immediately (*see* **Note 5**).

4. Notes

1. The reaction involved in this cleavage is illustrated in **Fig. 1** and is described in more detail in **ref. *1***, with the proposed role of the succinimide being confirmed by Blodgett et al. ***(7)***. Note that the reaction of hydroxylamine is actually with the cyclic imide that derives from the Asn-Gly pair. The Asn-Gly bond itself is resistant to cleavage by hydroxylamine. Kwong and Harris ***(5)*** have reported cleavage at a presumed succinimide at an Asp-Gly bond. The succinimide occurs as an intermediate in the isomerization of aspartyl to *iso*-aspartyl, a reaction that involves the Gly residue. This can occur at sites that are in regions flexible enough to accommodate the three structures, so it is influenced by the neighboring sequence. This therefore affects cleavage efficiency. Bornstein and Balian ***(1)*** have reported an Asn-Gly cleavage yield of about 80% but lower efficiency may be experienced (as reported in **ref. *5***, for various conditions). Cleavage is to the carboxy-(C)-terminal side of the succinimide. The peptide generated to the C-terminal side is available for amino-(N)-terminal sequence analysis, for generation of internal sequence or to identify the site of the succinimide. The succinimide is stable enough to be found in proteins ***(5,8)***. Isomerization of the Asp to iso-Asp can affect immunogenicity and function (for instance, *see* ***[8]***). The *iso*-Asp may be detected by other assays (see ***[9]*** and references therein), or by termination of N-terminal sequencing, for both it and the succinimidyl residue are refractory to Edman sequencing chemistry. The succinimidyl version of a polypeptide is slightly more basic (by one net negative charge) than the aspartate version that forms after incubation in neutral pH ***(5)***. In addition to cleavage at Asn-Gly, treatment with hydroxylamine may generate other, lower yielding, cleavages. Thus, Bornstein and Balian ***(1)*** mention cleavage of Asn-Leu, Asn-Met, and Asn-Ala, while Hiller et al ***(3)*** report cleavage of Asn-Gln, Asp-Lys,

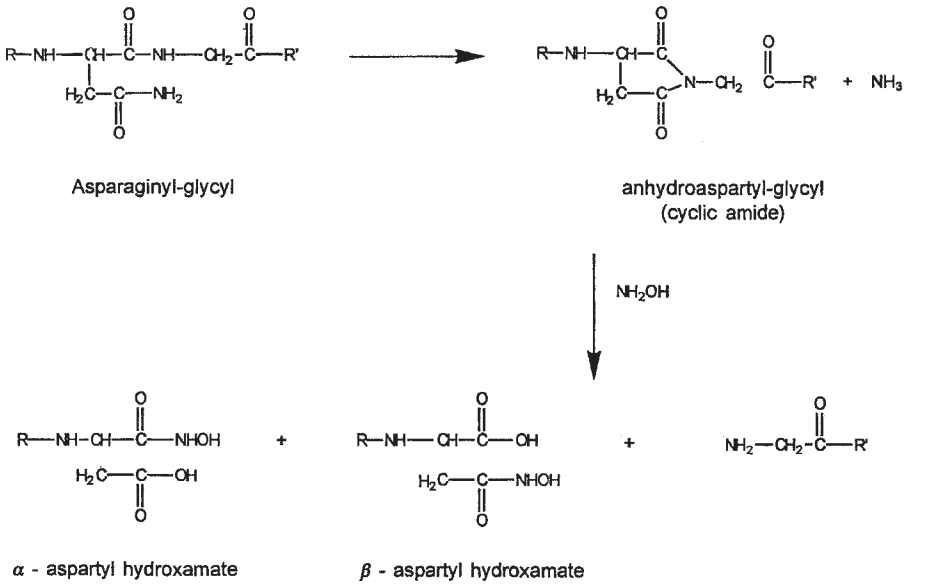

Fig. 1. Illustration of reactions leading to cleavage of Asn-Gly bonds by hydroxylamine.

Gln-Pro, and Asn-Asp. Prolonged reaction times tend to generate more of such cleavages. Treatment of protein with hydroxylamine may generate hydroxamates of asparagine and glutamine, these modifications producing more acidic variants of the protein ***(6)***.

2. Inclusion of guanidine.HCl as a denaturant seems to be a factor in improving yields. Kwong and Harris ***(5)*** reported that omission of guanidine. HCl eliminated cleavage at an Asn-Gly site while allowing cleavage at an Asp-Gly site. The literature has other examples of the use of buffers lacking guanidineá·HCl, for instance, **refs. *3*** and ***5***. Both of these examples report use of a Tris-HCl buffer of approx pH 9.0, with **ref. *5*** including 1 m*M* EDTA and ethanol (10% v/v). Yet other examples ***(1,2,10)*** describe the use of more concentrated guanidine·HCl, at 6*M*, the cleavage buffer being prepared by titrating a solution of guanidine·HCl (6*M*, final) and hydroxylamine·HCl (2*M*, final) to pH 9.0 by addition of a solution of lithium hydroxide (4.5*M*). Note that preparation of this lithium hydroxide solution may generate insoluble carbonates that can be removed by filtration. Other reaction conditions were as described in **Subheading 3.**
3. As when making peptides by other cleavage methods, it may be advisable, prior to the above operations, to reduce disulfide bonds and alkylate cysteinyl residues (*see* Chapter 82). This denatures the substrate and prevents formation of interpeptide disulfide bonds. Niles and Christen ***(10)*** describe

alkylation and subsequent cleavage by hydroxylamine on scale of a few microliters.

4. The hydroxylamine cleavage method has been adapted to cleave proteins in polyacrylamide gel pieces ***(11)***. The cleavage buffer was 2 *M* hydroxylamine.HCl, 6 *M* guanidine.HCl, in 15 m*M* Tris titrated to pH 9.3 by addition of 4.5 *M* lithium hydroxide solution. Pieces of gel that had been washed in 5% methanol to remove sodium dodecyl sulfate (SDS), and then dried *in vacuo* were submerged in the cleavage solution (50–200 µL per 3 µL of gel) and incubated at 45°C for 3 h. Analysis by electrophoresis on a second SDS gel then followed. Peptides of about 10,000 Da or less tended to be lost during washing steps, and about 10% of sample remained bound to the treated gel piece. Recoveries in the second (analytical) SDS gel were reported to be approx 60% and cleavage yield was about 25%.
5. After the cleavage reaction has been stopped by acidification, the sample may be loaded directly onto reverse-phase HPLC or gel filtration for analysis/peptide preparation. Alternatives are dialysis and polyacrylamide gel electrophoresis (PAGE). The reaction itself may be stopped not by acidification, but by mixing with SDS-PAGE sample solvent and immediate electrophoresis ***(3)***.
6. In approximately neutral pH conditions, reaction of protein with hydroxylamine may cause esterolysis, and so may be a useful method in studying posttranslational modification of proteins. Thus, incubation in 1 *M* hydroxylamine, pH 7.0, 37°C for up to 4 h cleaved carboxylate ester-type ADP–ribose–protein bonds (on histones H2A and H2B) and arginine–ADP–ribose bonds (in histones H3 and H4) ***(12)***. Again, Weimbs and Stoffel ***(13)*** identified sites of fatty acid-acylated cysteine residues by reaction with 0.4 *M* hydroxylamine at pH 7.4, such that the fatty acids were released as hydroxamates. Omary and Trowbridge ***(14)*** adapted the method to release [^{3}H] palmitate from transferrin receptor in polyacrylamide gel pieces, soaking these for 2 h in 1 *M* hydroxylamine·HCl titrated to pH 6.6 by addition of sodium hydroxide.

Enzymatic Digestion of Proteins in Solution and in SDS Polyacrylamide Gels

Kathryn L. Stone, Erol E. Gulcicek, and Kenneth R. Williams

1. Introduction

The completion of numerous genomes and the advancement of mass spectrometric analysis have enabled proteins of interest from complex biological mixtures to be identified at lower levels and considerably faster than using classical edman chemical sequencing. The approach is to enzymatically or chemically cleave the protein into smaller peptide fragments and analyze the digest / cleavage products using either high mass accuracy matrix assisted laser desorption ionization mass spectrometry (MALDI-MS) ***(1)*** or tandem mass spectrometry (MS/MS) utilizing either MALDI or Electrospray ionization (ESI) sources ***(2)***. Following the mass spectral acquisition, proteins of interest are identified *in-silico* by matching the corresponding accurate peptide mass data (peptide mass fingerprinting) and the peptide fragment data (ion matching) to the theoretically digested and fragmented peptides in protein databases ***(3)***. For both of these types of mass spectrometric analyses, as well as for digests destined for edman chemical sequencing, it is important to obtain a high efficiency of digestion, with peptides in the 8 to 30 residue lengths preferable. Although several different approaches may be taken to cleave proteins, one of the most common is to digest the protein enzymatically with a relatively specific protease such as trypsin or lysyl endopeptidase. Since final purification is often dependent on SDS-PAGE, cleavage procedures that can either be carried out in the polyacrylamide gel matrix ***(4, 5)*** or that may be used on samples that have been blotted from SDS polyacrylamide gels onto PVDF ***(6)*** or nitrocellulose ***(6,7)*** membranes are extremely useful. The proteins are usually stained with Coomassie blue, or digestion compatible silver stains (used with polyacrylamide gels) prior to excision and proteolytic digestion. The resulting peptides are separated

by reverse-phase HPLC or UPLC (ultra high pressure or ultra performance liquid chromatography), and in most instances, the LC system is directly attached to a mass spectrometer for real time protein identification analysis. Relatively straightforward solution and in-gel digestion procedures, including robotic digestion, that have been used extensively in the W. M. Keck Foundation Biotechnology Resource Laboratory at Yale University will be described in this chapter, whereas a procedure suitable for in situ digestion of SDS-PAGE blotted proteins is described in Chapter 101.

2. Materials

2.1. Enzymatic Digestion of Proteins

1. Enzymatic digestion of proteins is usually accomplished using either sequencing grade, modified trypsin (from Promega, [Madison, WI] or Boehringer Mannheim, [Indianapolis, IN]) or lysyl endopeptidase (Achromobacter Protease I from Achromobacter lyticus) from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Occasionally, chymotrypsin or endoproteinase Glu-C from (Boehringer Mannheim) may also be used. All enzyme stocks are divided into 100 µL aliquots and stored at −20 °C.
2. Sequencing-grade chymotrypsin and modified trypsin (Boehringer Mannheim): prepare by dissolving the dried manufacturer supplied 100-µg aliquots in 1 mL 1 m*M* HCl to make a 0.1 mg/mL stock solution that appears to be stable for at least 6 months at −20 °C.
3. Sequencing grade, modified trypsin (Promega): dissolve the manufacturer supplied 20-µg aliquot in 200 µL 1 m*M* HCl to make a 0.1 mg/mL stock solution that appears to be stable for at least 6 months at −20 °C.
4. Endoproteinase Glu-C: dissolve the 50-µg aliquot from the manufacturer in 500 µL 50 m*M* NH_4HCO_3. According to the manufacturer, the dissolved enzyme is stable for 1 month at −20 °C.
5. Lysyl endopeptidase: dissolve 2.2 mg as purchased in 2.2 mL of 2 m*M* Tris-HCl, pH 8.0, to make a 1 mg/mL stock, which according to the manufacturer is stable for at least 2 years when stored at −20 °C. More dilute solutions are made by adding 10 µL of this 1 mg/mL stock solution to 90 µL 10mM NH_4HCO_3, pH 8.0, for a 0.1 mg/mL stock.
6. Pepsin (Sigma Chemical Co., St. Louis, MO): dissolve in 5% formic acid (Mallinckrodt-Baker, Phillipsburg, NJ) at a concentration of 0.1 mg/mL.
7. Digestion buffer for in-solution digestion: 8 *M* urea, 0.4 *M* NH_4HCO_3. Prepare by dissolving 4.8 g Pierce Sequanal-Grade urea and 0.316 g Mallinckrodt-Baker ammonium bicarbonate in H_2O to make a final volume of 10 mL.
8. 50% CH_3CN/water: : add 5mL 100% CH_3CN to 5 mL H_2O.
9. 50% CH_3CN/50mM NH_4HCO_3: dissolve 0.0395 g in 5 mL H_2O plus 5mL 100% CH_3CN
10. 50% CH_3CN/10mM NH_4HCO_3: dissolve 0.0079 g in 5 mL H_2O plus 5mL 100% CH_3CN

11. In gel digestion buffer 10mM NH_4HCO_3 (manual digestion): dissolve 0.0079 g in 10 mL H_2O
12. 5mM NH_4HCO_3 (robotic digestion): dissolve 0.0079 g in 20 mL H_2O.
13. 45 m*M* DTT, Pierce Chemical Co. (Rockford, IL) solution for protein reduction: dissolve 69 mg DTT in 10 mL H_2O.
14. 100 m*M* iodoacetic acid (IAA), Pierce Chemical Co. (Rockford, IL) solution for alkylation: dissolve 185.9 mg IAA in 10 mL H_2O.
15. 200 m*M* methyl 4-nitrobenzene sulfonate, Aldrich Chemical Co. (St. Louis, MO) solution for cysteine modification: is made by dissolving 0.0434 g methyl 4-nitrobenzene sulfonate in 100% CH_3CN. This solution is made immediately before use and is not stored.
16. 0.1% TFA/60% CH_3CN solution for peptide extraction from the gel slices: add 50 µL 100% trifluoracetic acid (TFA) to 20 mL H_2O and 30 mL 100% CH_3CN.
17. For dissolving dried digest: 70% formic acid: prepare from Pierce 99+% formic acid by mixing 70 µL 99% formic acid with 30 µL H_2O.
18. 0.1% TFA for sample dilution prior to HPLC or MS analysis: add 50 µL 100% trifluoracetic acid (TFA) to 50 mL H_2O.

3. Methods

3.1. Digestion of Proteins in Solution

3.1.1. Sample Preparation for in Solution Digestion

Proper sample preparation for proteins is critical both in avoiding sample loss and in ensuring successful digestion (*see* **Note 1**). If the sample contains a sufficiently low level of salt and glycerol (such that the concentration of salt and glycerol in the final digest will be less than the equivalent of 1 *M* NaCl and 15% glycerol, respectively), it may simply be reduced to dryness in a SpeedVac prior to carrying out the digest in the tube in which it was dried. Samples containing higher levels of salts, glycerol, and/or detergents, such as SDS, may be precipitated using either trichloroacetic acid (TCA) or acetone in order to remove the salts, glycerol, and detergents. To TCA-precipitate the protein, 1/9th volume of 100% TCA is added to the sample prior to incubating on ice for 30 min. The sample is then centrifuged (10,000g/15 min) and the supernatant is removed. Residual TCA is then removed by suspending the pellet in 50 µL cold acetone. After vortexing and centrifuging, the supernatant is removed with a pipet. The air-dried pellet is then digested as described below. To acetone precipitate the protein, it is often necessary first to reduce the salt concentration by dialysis vs 0.05% SDS, 5 m*M* NH_4HCO_3. At this point, the volume is reduced to <50 µL in a SpeedVac, and 9 volumes of cold acetone are added followed by a 1 h incubation at −20 °C. The sample is then centrifuged and the pellet washed (as described in **Subheading 3.1**) with 50 µL cold acetone. When large amounts of SDS are present, the acetone wash should be repeated once or twice to remove

excess detergent. The recommended minimum protein concentration during either precipitation is 100 µg/mL, and for TCA precipitation, the glycerol concentration should be below 15%.

Newer digestion additives such as RapiGest™ (Waters Corp., Milford, MA) and PPS Silent™ (Protein Discovery, Inc., Knoxville, TN) surfactants aid in denaturing and solubilizing proteins. For either denaturant, a volume equal to the protein solution volume is added for a 1:1 ratio.

3.1.2. Digestion of Proteins in Solution with Trypsin, Lysyl Endopeptidase, Chymotrypsin, and Endoproteinase GLUC

After the salts and detergents have been removed/minimized, the sample is ready for digestion. Typically, trypsin is the enzyme of choice because of its relatively high cleavage specificity (the COOH-terminal side of lysine and arginine) and its ability to digest insoluble substrates. That is, proteins that are only partially soluble in the digest buffer will often cleave with trypsin as evidenced by rapid clearing of the solution. Cleavage occurs more slowly when there is an acidic residue following the lysine or arginine and not at all when a lysine-proline or arginine-proline linkage is present. Lysyl endopeptidase only cleaves on the COOH-terminal side of lysine. As a result, it provides longer peptides than trypsin. Based on the average occurrence of lysine (5.7%) and arginine (5.4%) in proteins in the Protein Identification Resource Database (as of 2001), the average length of a tryptic and lysyl endopeptidase peptide is about 9 and 18 residues, respectively. However, since lysyl endopeptidase does not generally cleave insoluble substrates and since we have occasionally encountered proteins that will digest with trypsin, but not with lysyl endopeptidase, we generally use trypsin. Occasionally, if there is sufficient protein to carry out two separate digests (if needed to increase protein coverage), we would initially use lysyl endopeptidase, and then do a second digest using trypsin.

Chymotrypsin is occasionally used to redigest larger peptides or proteins that fail to digest with trypsin. It readily cleaves on the COOH-terminal side of tryptophan, tyrosine, and phenylalanine, and generally gives partial cleavage after leucine, methionine, and several other amino acids. However, its specificity is too broad to be of general use. Endoproteinase Glu-C is relatively specific in that it cleaves after glutamic acid in either ammonium bicarbonate (pH 8.0) or ammonium acetate (pH 4.0) buffers and after both aspartic acid and glutamic acid in phosphate buffers (pH 7.8). It also does not generally cleave insoluble substrates, and the HPLC profiles we have obtained with this enzyme usually suggest relatively incomplete cleavage with the resulting generation of overlapping peptides in lower yield than might often be obtained with trypsin.

Although this brief survey of proteolytic enzymes is far from complete, it does cover most of the enzymes that are frequently used. The enzymatic digestion protocol outlined below may be used with any of these four enzymes, providing the appropriate buffer changes are made in the case of Glu-C.

1. Dissolve the dried or precipitated protein in 20 µL 8 *M* urea, 0.4 *M* NH_4HCO_3. At this point, an aliquot can be removed for acid hydrolysis/ion-exchange amino acid analysis if > 1µg of sample is expected (*see* **Note 2**). If using the RapiGest or PPS Silent Surfactant, dissolve the dried pellet in 20 µl of 0.2%. Add an equal volume of water for a final concentration of 0.1% denaturant.
2. Check the pH of the sample by spotting 1–2 µL on pH paper. If necessary, adjust the pH to between 7.5 and 8.5.
3. Add 5 µL 45 m*M* DTT and incubate at 50 °C for 15 min to reduce the protein (*See* **Note 3**).
4. After cooling to room temperature, alkylate the protein by adding 5 µL 100 m*M* IAA and incubating at room temperature for 15 min (*see* **Note 3**).
5. For samples in urea, dilute the digestion buffer with H_2O so the final digestion will be carried out in 2 *M* urea, 0.1 *M* NH_4HCO_3.
6. Add the enzyme in a 1/25, enzyme/protein (wt/wt) ratio (*see* **Note 4**).
7. Incubate at 37 °C for 16–24 h.
8. Stop the digest by acidifying the sample with TFA for injection onto a reverse-phase HPLC system or by freezing it.

3.1.3. Digestion of Proteins in Solution with Pepsin

Although the very broad specificity of pepsin hinders its routine use for comparative peptide mapping, its low optimum pH performance enables it to cleave proteins that might otherwise be intransigent. It is also applicable for digesting relatively small peptides and, particularly, for studies directed at identifying disulfide bonds (*see* **Note 5**). Although pepsin cleaves preferentially between adjacent aromatic or leucine residues, it has been shown to cleave at either the NH_2- or COOH- terminal side of any amino acid, except proline. A typical digestion procedure is as follows:

1. Dissolve the dried protein in 100 µL 5% formic acid.
2. Add pepsin at a 1:50, enzyme:protein ratio(wt:wt).
3. Incubate the sample at room temperature for 1–24 h. with the time of incubation being dependent on the desired extent of digestion.
4. Dry the digest in a SpeedVac prior to dissolving in 0.05% TFA and immediately inject onto a reverse-phase HPLC system.

3.2. Digestion of Proteins in SDS Polyacrylamide Gels

3.2.1. Sample Preparation for in Gel Digestion

As in the case of samples destined for in-solution digests, care must also be exercised in preparing samples for SDS-PAGE so that sample losses are minimized

(*see* **Note 6**) and so that the final ratio of protein/gel matrix is as high as possible (*see* **Note 7**). Although prior carboxymethylation does not appear to be essential with in-gel digests, the presence of greater than 10–20% carbohydrate (by weight) often appears to hinder cleavage significantly (*see* **Note 3**). Samples that have been purified by SDS-PAGE can be digested directly in the gel matrix, thereby eliminating the need for electroelution or electroblotting of the intact proteins from the gel.

SDS PAGE-separated proteins destined for in-gel digestion can be stained in a variety of ways, including using commercially available staining kits. The sensitivity of the stains vary with the Coomassie blue R250 being the least sensitive. Several of the more common stains are 1) classical Coomassie blue R250 staining using 0.1% Coomassie blue in 50% methanol, 10% acetic acid for 1 h. prior to destaining with 50% methanol, 10% acetic acid for a minimum of 2 h. (*see* **Note 8**). 2) Colloidal Blue staining such as with the GelCode® Blue Stain Reagent from Pierce 3) digestion compatible silver staining which can be done using Invitrogen's SilverQuest™ kit and 4) UV-based SYPRO® Ruby Protein Gel Stain (Molecular Probes™). Alternatively, staining the proteins of interest can be avoided when sufficient sample is available (*see* **Note 9**) and the band of interest is well separated. This can be done with stained Molecular Weight markers in an additional guide lane, or running the sample of interest in 2 lanes and staining the 1 lane. The protein of interest can then be excised from the gel using this guide. However, in this instance, the gel still must be exposed to 50% methanol, 10% acetic acid for 3 h. to ensure adequate removal of SDS prior to excising the protein band of interest.

The % polyacrylamide gel that is used is determined by the size of the protein. Proteins >100 kDa are typically electrophoresed in 7–10% polyacrylamide gels, whereas smaller proteins are electrophoresed in 10–17.5% polyacrylamide. The in gel digestion procedure is suitable for both 1 and 2 dimensional gels with the latter digests often performed on a digester robot. The protein of interest is excised using a razor blade and tweezers, and the gel spots are then placed in an eppendrof tube that has been pre-washed with 0.1% TFA/ 60% CH_3CN (to minimize contaminants). Alternatively, a robotic gel picker such as the GE Healthcare Ettan Spot Picker can be used to excise the proteins of interest. This spot picker cuts out a 2mm disc and deposits the gel piece in a 96 well plate. Care must always be taken to avoid keratin contamination which can confound any protein identification analysis. **Figure 1** contains a typical MALDI-Tof/Tof spectra of an in gel tryptic digest.

3.2.2. In-Gel Digestion of Proteins with Trypsin and Lysyl Endopeptidase

1. Determine the approximate volume of gel to be digested (length × width × thickness).
2. Cut the gel band(s) containing the protein of interest into approx 1 × 2 mm pieces, and place them in an Eppendorf tube or a 96 well plate for robotic digestion. Repeat for the "blank" section of gel.

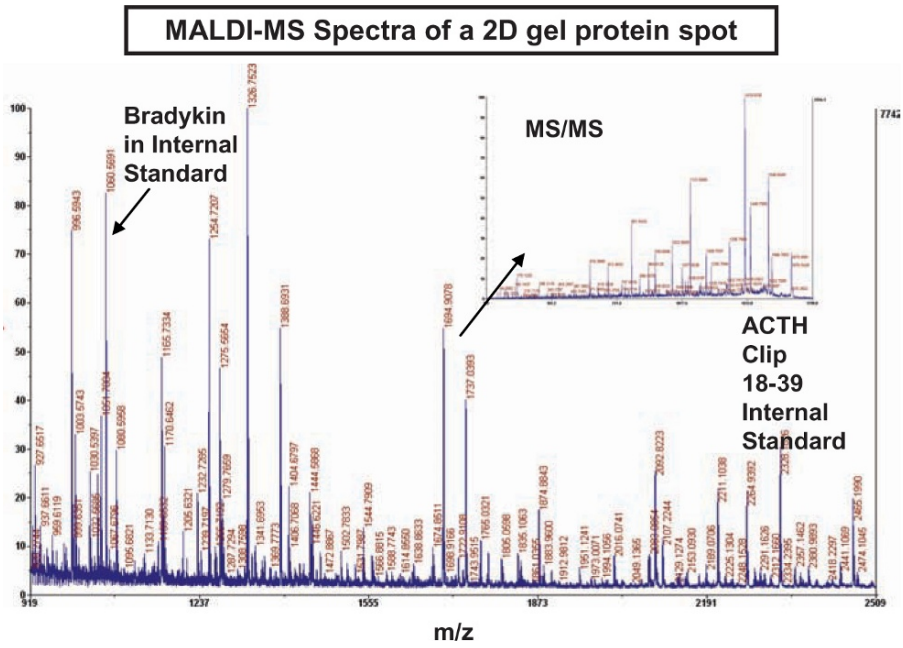

Fig. 1. In-gel trypsin digestion of an unknown protein spot from a 2D gel. Human plasma was analyzed by 2D gel electrophoresis following IgY12 depletion (Beckman-Coulter) and Cy dye labeling as per the GE Healthcare Differential (fluorescence) gel electrophoresis protocol. Protein spots of interest were determined using GE Healthcare DeCyder software of the fluorescent gel image, and excised robotically (GE Healthcare Ettan Spot Picker) as described in **Subheading 3.** 100% of the digest was loaded onto an AB 4800 MALDI-Tof/Tof plate after dissolving in 0.6nl of the alpha-cyano-4-hydroxy cinnamic acid matrix containing 1 fmol of bradykinin and 2 fmols of ACTH clip as internal standards. The sample was analyzed using both peptide mass fingerprint and MS/MS of 10 peptides. The inset panel shows the MS/MS spectra obtained from the mass at 1694.9. A Mascot (Matrix Science) database search identified this sample as Vitamin D-binding protein precursor. The estimated amount of sample analyzed is 0.5 to 1 fmol based on the bradykinin internal standard.

3. Add 250 µL (or more, if necessary to cover the gel pieces) 50% CH_3CN/50% water to the gel pieces.
4. Wash for 5 min at room temperature on a rocker table.
5. Remove wash.
6. Repeat steps 3–5 using 250 µl 50% CH_3CN/50mM NH_4HCO_3
7. Repeat steps 3–5 using 250 µl 50% CH_3CN/10mM NH_4HCO_3
8. Dry the washed gel pieces in a SpeedVac
9. Make up the enzyme solution by diluting 5 µL 0.1 mg/mL enzyme stock solution with 10 µL 10mM NH_4HCO_3 for every 15 mm^3 gel that is to be digested.

10. Rehydrate gel pieces with the enzyme solution from **step 9**, which should be equal in volume to that of the gel pieces and should provide a final enzyme ratio of about 0.5 µg/15-mm^3 gel volume.
11. If the gel pieces are not totally immersed in the enzyme solution, add an additional volume of 10mM NH_4HCO_3 to submerge the gel pieces totally.
12. Incubate at 37 °C for 5 to 16 h.
13. After incubation, the supernatant can be removed and injected on to a HPLC column or LC-MS/MS system. Gels pieces can also be further extracted as in steps 19–20 and Cysteine modification, if desired, can be performed as follows in steps 14 – 18
14. Estimate the total volume of the sample plus gel.
15. Calculate the volume of 45 m*M* DTT needed to give a final (DTT) of about 1 m*M* in the sample.
16. Add the above volume of 45 m*M* DTT and then incubate at 50 °C for 20 min.
17. Remove samples from the incubator; cool to room temperature and add an equal volume of 100 m*M* IAA or 200 m*M* methyl 4-nitrobenzene sulfonate (MNS) (*see* **Note 10**) as the volume of DTT added in step 16.
18. For IAA alkylation, incubate at room temperature in the dark for 20 min; for MNS treatment, incubate at 37 °C for 40 min.
19. Extract peptides by adding at least 100 µL 0.1% TFA, 60% CH_3CN (or, if it is greater, a volume equal to the gel volume estimated in step 2), and shake on a rocker table at room temperature for at least 40 min.
20. Sonicate for 5 min in a water bath sonicator.
21. Remove and save the supernatant, which contains the released peptides, and repeat steps 19 and 20.
22. SpeedVac dry the combined washes from step 21.
23. Redissolve the dried samples in 3 to 5 µL 70% formic acid (to dissolve the peptides) and bring to proper injection volume using 0.1% TFA.
24. The sample is now ready for reverse-phase HPLC peptide separation as described in Chapter 102 or mass spectrometric analysis.

3.2.3. In-Gel Robotic Digestion of Proteins with Trypsin

A digester robot such as the GE Healthcare Ettan Ta digester is required for robotic digestion.

1. Excise the protein of interest by hand or using a gel picker (e.g. Ettan spot picker) and place in an 96 well plate (*see* **Note 11**).
3. Add 50 µL 50% CH_3CN/50% water to the gel pieces.
4. Wash for 3 min at room temperature.
5. Remove wash.
6. Repeat steps 3–5.
7. Repeat steps 3–5 using 50 µl 5mM NH_4HCO_3.
8. Air dry gel pieces for 5 min.
9. Make up the enzyme solution by diluting 100 µL 0.1 mg/mL enzyme stock solution with 2.9 mL 5mM NH_4HCO_3.
10. Rehydrate gel pieces with 15 µl of the enzyme solution from step 9.

11. Incubate at 37 °C for 5 to 16 h.
12. After incubation, the supernatant can be removed and injected on to a HPLC column or LC-MS/MS system. For MALDI-MS analysis, speedvac the digest to dryness and re-dry two times from 20 µl water. The sample is now ready to be dissolved in matrix and analyzed.

4. Notes

1. In many instances, large losses occur during the final purification steps when the protein concentrations are invariably lower. Hence, although ultrafiltration or dialysis of a 5 mg/mL crude solution of a partially purified enzyme may lead to nearly 100% recovery of activity, similar treatment of a 25 µg/mL solution of the purified protein might well lead to significant, if not total loss of activity owing to nonspecific adsorption. Similarly, the effectiveness of organic and acid-precipitation procedures often decreases substantially as the final protein concentration is decreased below about 100 µg/mL. Whenever possible, therefore, the final purification step should be arranged such that the resulting protein solution is as concentrated as possible and, ideally, can simply be dried in a SpeedVac prior to enzymatic digestion. In this regard, it should be noted that a final NaCl concentration of 1 *M* does not significantly affect the extent of trypsin digestion ***(8)***. When it is necessary to carry out an organic or acid precipitation to remove salts or detergents, the protein should first be dried in a SpeedVac (in the 1.5-mL tube in which it will ultimately be digested) prior to redissolving or suspending in a minimum volume of water and then adding the acetone or TCA. In this way, the protein concentration will be as high as possible during the precipitation and losses will be minimized. Two common contaminants that are extremely deleterious to enzymatic cleavage are detergents (as little as 0.005% SDS will noticeably decrease the rate of tryptic digests carried out in the presence of 2 *M* urea ***[8]***) and ampholines. Since detergent removal is often associated with protein precipitation, and since many detergents (such as SDS) form large micelles, which cannot be effectively dialyzed, it is usually preferable to extract the detergent from the protein (that has been dried in the tube in which it will be digested) rather than to dialyze it away from the protein. In the case of ampholines, our experience is that even prolonged dialysis extending over several days with a 15,000-Dalton cutoff membrane is not sufficient to decrease the ampholine concentration to a level that permits efficient trypsin digestion. Rather, the only effective methods we have found for complete removal of ampholines are TCA precipitation, hydrophobic or reverse-phase chromatography, or SDS-PAGE followed by staining and destaining.

2. It is particularly important to quantify samples using amino acid analysis if protein profiling (i.e. comparative analysis) is to be done. For samples in solution, the aliquot for amino acid analysis should be taken either immediately prior to drying the sample in the tube in which it will be digested or after redissolving the sample in 8 *M* urea, 0.4 *M* NH_4HCO_3. Although up to 10 µL of 8 *M* urea is compatible with acid hydrolysis/ion-exchange amino acid analysis, this amount of urea may not be well tolerated by PTC amino acid analysis. Hence, in the latter case, the amino acid analysis could be carried out prior to drying and redissolving the sample in urea. Samples destined for comparative 2D gel analysis such as DIGE should also be quantified using amino acid analysis prior to running the 2D gel. The aliquot for analysis can be taken after the samples have been dissolved in the gel loading buffer. By having an accurate protein concentration, comparative protein profiling experiments are themselves more accurate.
3. Since many native proteins are resistant to enzymatic cleavage, it is usually best to denature the protein prior to digestion. Although some proteins may be irreversibly denatured by heating in 8 *M* urea, this treatment is not sufficient to denature transferrin. In this instance, prior carboxymethylation, which irreversibly modifies cysteine residues, brings about a marked improvement in the resulting tryptic peptide map ***(8)***. Another advantage of carboxymethylating the protein is that this procedure enables cysteine residues to be identified during edman amino acid sequencing. Cysteine residues have to be modified in some manner prior to edman sequencing to enable their unambiguous identification. Under the conditions that are described in **Subheading 3.**, the excess dithiothreitol and iodoacetic acid do not interfere with subsequent digestion. Although carboxymethylated proteins are usually relatively insoluble, the 2 *M* urea that is present throughout the digestion is frequently sufficient to maintain their solubility. However, even in those instances where the carboxymethylated protein precipitates following dilution of the 8 *M* urea to 2 *M*, trypsin and chymotrypsin will usually still provide complete digestion. Often, the latter is evidenced by clearing of the solution within a few minutes of adding the enzyme. Alternatively, the newer denaturants RapiGest™ and PPS Silent™ Surfactant can be used to try to better solubilize the proteins of interest. If carboxymethylation is insufficient to bring about complete denaturation of the substrate, an alternative approach is to cleave the substrate with cyanogen bromide (1000-fold molar excess over methionine, 24 h at room temperature in 70% formic acid). The resulting peptides can then either be separated by SDS-PAGE (since they usually do not separate well by reverse-phase HPLC) or, preferably, they can be enzymatically digested with trypsin or lysyl endopeptidase and then separated by reverse phase HPLC or LC-MS/MS.

If this approach fails, the protein may be digested with pepsin, which, as described above, is carried out under very acidic conditions or can be subjected to partial acid cleavage ***(9)***. However, the disadvantage of these latter two approaches is that they produce an extremely complex mixture of overlapping peptides. Finally, extensive glycosylation (i.e., typically >10–20% by weight) can also hinder enzymatic cleavage. In these instances, it is usually best to remove the carbohydrate prior to beginning the digest. In the case of in gel digests, this may often be best carried out immediately prior to SDS-PAGE, which thus prevents loss (owing to insolubility) of the deglycosylated protein and effectively removes the added glycosidases.

4. Every effort should be made to be used as a high substrate and enzyme concentration as possible to maximize the extent of cleavage. Although the traditional 1:25, weight:weight ratio of enzyme to substrate provides excellent results with milligram amounts of protein, it will often fail to provide complete digestion with low nanogram amounts of protein. For instance, using the procedures outlined above, this weight:weight ratio is insufficient to provide complete digestion when the substrate concentration falls below about 20 µg/mL ***(8)***. The only reasonable alternative to purifying additional protein is either to decrease the final digestion volume or to compensate for the low substrate concentration by increasing the enzyme concentration. The only danger in doing this, of course, is the increasing risk that some peptides may be isolated that are autolysis products of the enzyme. Assuming that only enzymes, such as trypsin, chymotrypsin, lysyl endopeptidase, and Protease V8 are used, whose sequences are known, it is usually better to risk sequencing a peptide obtained from the enzyme (which can be quickly identified via a data base search) than it is to risk incomplete digestion of the substrate. Often, protease autolysis products can be identified by comparative HPLC peptide mapping of an enzyme (i.e., no substrate) control that has been incubated in the same manner as the sample and by subjecting candidate HPLC peptide peaks to matrix-assisted laser desorption mass spectrometry prior to edman sequencing. The latter can be extremely beneficial both in identifying (via their mass) expected protease autolysis products and in ascertaining the purity of candidate peptide peaks prior to edman sequencing. For sequencing by LC-MS/MS analysis, it is not as critical to eliminate the trypsin/enzyme autolysis products since a database search will identify these peptides. To promote more extensive digestion, we have sometimes used enzyme:substrate mole ratios that approach unity.
5. One approach to identifying disulfide-linked peptides is to comparatively HPLC peptide map a digest that has been reduced/carboxymethylated vs one that has only been carboxymethylated (thus leaving disulfide-linked

peptides intact). In this instance, pepsin offers an advantage in that the digest can be carried out under acidic conditions where disulfide interchange is less likely to occur.

6. As in the case of in-solution digests, care must be exercised to guard against sample loss during final purification. Whenever possible, SDS (0.05%) should simply be added to the sample prior to drying in a SpeedVac and subjecting to SDS-PAGE. Oftentimes, however, if the latter procedure is followed, the final salt concentration in the sample will be too high (i.e., >1 *M*) to enable it to be directly subjected to SDS-PAGE. In this instance, the sample may either be concentrated in a SpeedVac and then precipitated with TCA (as described above) or it may first be dialyzed to lower the salt concentration. If dialysis is required, the dialysis tubing should be rinsed with 0.05% SDS prior to adding the sample, which should also be made 0.05% in SDS. After dialysis versus a few micromolar NH_4HCO_3 containing 0.05% SDS, the sample may be concentrated in a SpeedVac and then subjected to SDS PAGE (note that samples destined for SDS PAGE may contain several % SDS). Another approach that works extremely well is to use a SDS polyacrylamide gel containing a funnel-shaped well that allows samples to be loaded in volumes as large as 300 µL ***(10)***.
7. In general, the sample should be run in as few SDS-PAGE lanes as possible to maximize the substrate concentration and to minimize the total gel volume present during the digest. Whenever possible, a 0.5–0.75-mm thick gel should be used. In general, we recommend using 0.5 µg enzyme/15 mm^3 of gel with the only caveat being that we use a corresponding lower amount of enzyme if the mole ratio of protease/substrate protein would exceed unity.
8. Since high concentrations of Coomassie blue interfere with digestion, it is best to use the lowest Coomassie blue concentration possible and to stain for the minimum time necessary to visualize the bands of interest. In addition, the gel should be well destained so that the background is close to clear.
9. Although most estimates of protein amounts are based on relative staining intensities, our data suggest there is a 5–10-fold range in the relative staining intensity of different proteins. Obviously, when working in the low pmol/fmol levels, such a 5–10-fold range could well mean the difference between success and failure.
10. For edman sequencing, modification of cysteine residues with MNS provides the advantage that the resulting S-methyl cysteine phenylthiohydantoin derivative elutes in a favorable position (i.e., between PTH-Tyr and PTH-Pro) using an Applied Biosystems PTH C-18 column.
11. Due to the manner in which the robot operates, it is necessary to not digest too large a gel volume. Recommended gel volumes are 2mm discs.

Acknowledgments

On-PVDF Protein Digestions for N-terminal Sequencing and Peptide Mass Fingerprinting

Victoria Pham, William Henzel, and Jennie R. Lill

1. Introduction

Two common analytical techniques employed for the characterization of proteins are N-terminal sequencing and peptide mass fingerprinting (PMF). ***(1)*** N-terminal sequencing employing the chemistries first described by Pehr Edman ***(2)*** is routinely used in many laboratories for deciphering if correct translational and post-translational processing of a protein has occurred. Peptide mass fingerprinting on the other hand, is used to determine if the correct protein has been cloned and translated, to look for mutations within a known protein sequence, and to look for posttranslational modifications.

A typical format for the N-terminal sequencing of protein is to transfer the sample onto a PVDF membrane. This is achieved by first separating proteins by SDS-PAGE, followed by electro-blotting onto PVDF membrane where they remain immobilized and stable until analysis. Edman chemistries require a free α-amino group at the N-terminus of the protein in order for phenylisothiocyante (PITC) to couple with the amino group of the terminus. However, many proteins expressed in mammalian cell lines are N-terminally blocked with co- or post translational modifications such as pyroglutamyl, acetyl or formyl groups, which render Edman chemistry inaccessible. Several protocols are available to remove these N-terminal modifications for example (deacetylation and pyroglutamyl). However, in some cases, e.g. for proteins with a pyroglutamyl group followed by a proline residue, removal of the modified group is not possible due to hindered stereochemistry. Under such situations, PVDF-imbedded N-terminally blocked proteins can be identified from their internal fragments generated from on-PVDF chemical or proteolytic cleavage.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

Peptide mass fingerprinting (PMF) involves the enzymatic or chemical proteolytic digestion of a protein into constituent peptides. Each protein will produce a unique signature of resultant peptides that can be compared against a list of theoretical masses to identify the protein, and also to look for alterations in sequence such as mutations and post translational modifications ***(3)***.

For characterization purposes, depending on the availability of the protein and the information that one needs to obtain, both Edman degradation and PMF analysis can be utilized since the 2 techniques are complimentary with each other. Here we describe protocols for the rapid on-PVDF enzymatic cleavage of proteins which can subsequently be analyzed either by Edman degradation or by PMF.

2. Materials

2.1. SDS-Polyacrylamide Gel Electrophoresis (SDS-PAGE)

1. Running buffer (10X): 247 m*M* Tris, 1.92 *M* glycine, 34.7 m*M* SDS, store at room temperature (RT).
2. Precast 4-20% Tris-glycine (Invitrogen, Carlsbad, CA).
3. Sample buffer (2X): 0.5 *M* Tris-HCl, pH 8.0, 20% SDS, 0.5% bromophenol blue, 26 % glycerol (in-house), store at RT.
4. Dithiothreitol DTT (BioVectra, Oxford, CT).
5. N-isopropyl iodoacetamide (NIPIA) (synthesized in-house).

2.2. Electroblotting

1. CAPS buffer: 10 m*M*, pH 11.0 containing 10 m*M* thioglycolic acid and 20% methanol, store at RT.
2. Problott PVDF membrane (Applied Biosystems, Foster City, CA).
3. Methanol at HPLC-grade (Burdick & Jackson, Muskegon, MI).

2.3. Staining/Destaining of PVDF Membrane

1. Staining solution: 0.1% Coomasie brilliant blue R250 in 50% methanol/10% acetic acid (in-house), store at RT.
2. Destaining solution: 50% methanol/10% acetic acid/MQ water (in-house), store at RT.

2.4. On-Membrane Chemical Cleavage for Edman Degradation

1. Mouse antihuman OX40 ligand antibody (R & D Systems, Minneapolis, MN).
2. Asp/Pro cleavage solution: 10% acetic acid containing 7 *M* guanidine, pH 2.5.

2.5. Rapid on-Membrane Digestion for Automated Edman Degradation

1. Human IL-20 receptor alpha poly his (purified in-house).
2. Clostripain (Calbiochem, San Diego, CA), trypsin (Promega, Madison, WI) store at −80 °C.
3. Zwittergent 3–16 (Calbiochem, San Diego, CA).
4. 0.1 *M* Tris-HCl, pH 8.0, 2 m*M* DTT, 1 m*M* $CaCl_2$.

2.6. On-Membrane Digestion for Peptide Mass Fingerprinting (PMF)

1. Recombinant human growth hormone (rec-HGH) (purified in-house), store at −80 °C.
2. Matrix α-cyano-4-hydroxycinnaminic acid (CHCA): nitrocellulose (NC) (20:5 w/w) in acetone: isopropyl alcohol at 1:1 ratio.
3. α-Cyano-4-hydroxycinnamic Acid (CHCA) (Sigma, St Louis, MO), NC (BioRad, Hercules, CA).
4. Acetone, isopropyl alcohol, acetonitrile at HPLC-grade (Burdick & Jackson, Muskegon, MI).

2.7. Instrumentation

1. Procise N-terminal sequencer, model 494 (Applied Biosystems, Foster City, CA).
2. Voyager-DE-STR MALDI-TOF (Applied Biosystems, Foster City, CA).

3. Methods

On-PVDF chemical cleavage has been widely used without pretreatment of the membrane. However, when on-PVDF enzymatic digestion is performed, the unoccupied sites on the membrane must be blocked. If these sites are not blocked enzyme activity maybe hindered, and also the ratio of enzyme to analyte upon analysis will be overwhelming. PVP-360 has previously been reported as a blocking agent for on-membrane digestion ***(4)*** and more recently we reported the use of Zwittergent 3–16, a sulfobetaine type detergent, with a hydrophobic un-branched 16-C chain, which binds strongly to the PVDF membrane, as an alternative surfactant ***(3)***. Our results indicated that Zwittergent 3–16 is a better blocking agent than PVP-360, and as a consequence more efficient on-PVDF digestion for N-terminal sequencing or PMF was observed.

3.1. SDS-PAGE and Electroblotting

1. Proteins are reduced with DTT (10 m*M* in 2X sample buffer) at 95 °C for 10 min and alkylated with NIPIA at a final concentration of 20 mM at RT for 20 min.
2. Proteins are then separated on a precast 4–20% Tris-glycine gel for 120 min at 120 V.

3.2. Electroblotting

1. Following separation, equilibrate gel in CAPS buffer (*see* **Note 1**) at RT for 10 min.
2. Electro-blot gel onto a prewetted PVDF membrane in CAPS buffer for 45-60 min at 250 mA (*see* **Note 2**)

3.3. Staining & destaining

1. Visualize proteins by staining in coomasie blue R250 staining solution for 30–60 s.
2. Destain PVDF membrane with 50% MeOH/ 10% acetic acid/H_2O for 2 min and extensively rinse with MQ H_2O (10 × 1.0 mL).
3. Store membrane at RT until further analysis.

3.4. On-PVDF Chemical Cleavage for Edman Degradation

1. Excise the band of interest and wet with 1–2 µL of methanol, rinsed with MQ water (10 × 1.0 mL).
2. Add 30 µL of diluted acid **(2.4)** and incubate in a thermocycler tube at 90 °C for 1 h (*see* **Note 3**)
3. After incubation, wash the protein band with MQ water (10 × 1.0 mL) and dry in the Speed Vac.
4. Peptides can then be analyzed by N-terminal sequencing to identify the protein (*see* **Note 4**).

3.5. Rapid on-Membrane Digestion for Automated Edman Degradation

1. Protein bands are wetted with 1-2 µL of methanol, rinsed with MQ water (10 × 1.0 mL).
2. Treat PVDF membranes with 100 µL of Zwittergent 3-16, 0.5% in Tris (0.1 *M*, pH 8.0) and incubate on a shaker at RT for 5 min to block the unoccupied sites on the membrane.
3. Wash membranes extensively with MQ water (10 × 1.0 mL).
4. After blocking the membranes, add appropriate digestion buffer (20 µL) and enzyme of choice (0.2 µg) and start digestion at 37 °C for 5–60 min. **Table 1** lists the digestion conditions of different enzymes.
5. After incubation, add 3 µL of 4% TFA/water to quench the digestion.
6. Rinse membranes with MQ water (10 × 1.0 mL) and dry in the Speed Vac.

Table 1
Digestion conditions of various enzymes (*)

Enzymes	Buffers	Time (min)	Specificity
Trypsin	Tris (0.1 M, pH 8.0)	10	C-terminal side of K & R
Lys-C	Ammonium bicarbonate (50 mM, pH 8.0)	10–30	C-terminal side of K
Clostripain	Tris (0.1 M, pH 8.0) containing 2 mM DTT, 1 mM $CaCl_2$.	10–20	C-terminal side of R
Glu-C	Ammonium bicarbonate (0.1 M, pH 8.)	10–30	C-terminal side of E
Glu-C	Sodium phosphate (50 mM, pH 8.0)	10–30	C-terminal side of E & D
Lys-N	Sodium phosphate (50 mM, pH 8.0)	10–20	N-terminal side of K
Asp-N	Sodium phosphate (50 mM, pH 8.0)	10–20	N-terminal side of D
PGAP	Sodium phosphate (50 mM, pH 7.0) containing 10 mM DTT, 1mM EDTA	60	Removal of pyroglutamyl group

(*) Pyroglutamyl aminopeptidase (PGAP) digestion was performed at 90 °C and the rest was performed at 37 °C

7. Analyze the resultant mixture of peptides as mentioned in **Subheading 3.4** (*see* **Note 5**).

3.6 On-Membrane Digestion for Peptide Mass Fingerprinting (PMF)

1. Block protein bands with Zwittergent solution as described in **Subheading 3.5**.
2. Carefully remove Zwittergent solution and rinse the membrane thoroughly with MQ water (10 × 1.0 mL) (*see* **Note 6**).
3. Heat protein bands to 95 °C for 5-10 min in the appropriate digestion buffer in the presence of 10% acetonitrile (*see* **Notes 7** and **8**).
4. Add the enzyme of choice to the digestion buffer and incubate at 37 °C for 1-3 h.
5. After incubation, quench the reaction with 3 µL of 4% TFA/water.
6. Spot the resultant peptide mixture (0.2-1.0 µL) onto the MALDI target plate using a nitrocellulose-base method (*see* **Note 9**) and air dry.
7. After the organic matrix is dried, wash sample spots with 1 µL of 0.1% TFA/water prior to MALDI analysis to remove any trace amount of salt.
8. Perform PMF on a MALDI-TOF instrument in reflectron mode. (Note, typically we employ the following conditions: mass range is set to 600-6000 Da at a laser power of 1800-1900 AU, acceleration voltage is set to 25 kV.)
9. Mass spectral analysis may be performed using any search algorithm that can perform PMF, for example Mascot (Matrix Sciences, London, UK) or by generating an *in silico* proteolytic digest peak list and manually comparing.

4. Notes

1. If proteins being electroblotted from the gel onto PVDF membrane have a high molecular weight, (> 80 kDa), use CAPS buffer containing 10% of methanol to improve transfer efficiency.
2. When assembling the sandwich cassette, remove all air bubbles from the gel, paper and PVDF, to ensure proper transfer of proteins onto the membrane.
3. Digestion of proteins using dilute acid usually cleaves the bonds between Asp and Pro residues resulting in peptides with a Proline N-terminal residue. However, cleavage between Asp and Gly residues may also be observed. In order to simplify the mixture of generated peptides, especially for proteins with a molecular weight over 80 kDa, one can block peptides starting with a primary amino acid with 30 µL of sodium borate 0.1 M containing 30 mM o-phthaladehyde (OPA) and 57 mM β-mercaptoethanol at RT for 5 min *(5)*.
4. **Fig.1** represents an on-PVDF chemical digestion of anti-OX40 ligand heavy chain using dilute acid solution. Under mild acidic condition, proteins are cleaved at bonds between Asp/Pro residues as shown by proline residue in the first cycle. Treatment of the membrane prior to chemical

Fig.1. N-terminal sequence analysis of an on-PVDF Asp/Pro cleavage of anti-OX40 ligand heavy chain at 90 °C for 1h.

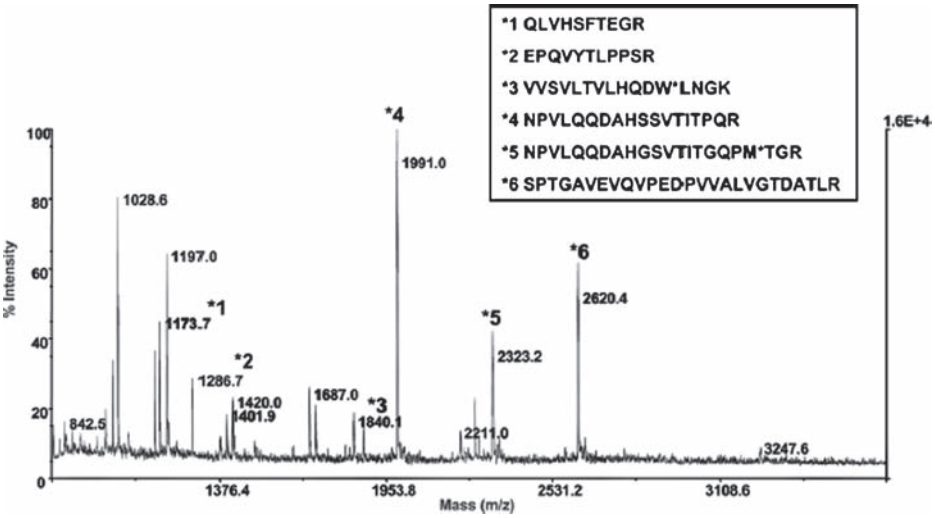

Fig. 2. On-PVDF clostripain digestion of human IL-20 receptor at 37 °C for 20 min. Underlined are peptides generated, which were identified by Edman degradation analysis.

cleavage is not needed. Sequencing data matches the variable and constant region of the heavy chain.

5. Human IL-12 receptor has part of an STII tag, a poly His tag and an enterokinase cleavage site at the N-terminus. Totally the tag consists of 21 amino acids. In order to confirm the identity of this protein by Edman sequencing, one needs to sequence out the first 30 residues in order to get pass the tag, i.e. it would take 10 h (20 min × 30 cycles). Using rapid clostripain digestion, one can confirm the presence of the tag as well as the identity of the protein in much less time (**Fig. 2**).
6. For peptide mass fingerprinting, it is necessary to remove Zwittergent solution as completely as possible in order to prevent signal suppression in MALDI-TOF analysis. This can be performed by taking a glass Pasteur pipette and repeatedly rinsing the membrane in MQ water.
7. Some researchers have shown that proteolysis of proteins in the presence of mixed organic-aqueous solvents, such as methanol or acetonitrile in

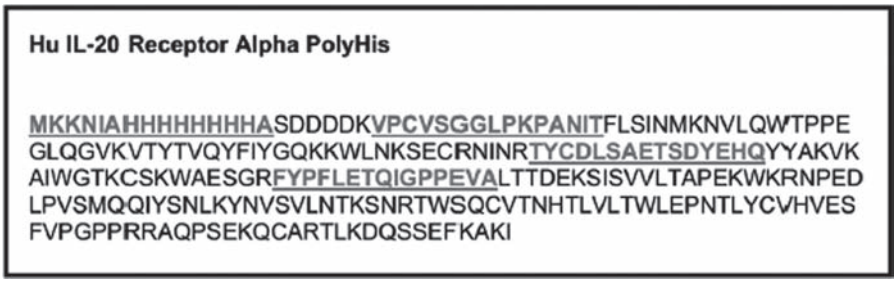

Fig. 3. PMF mass spectrum of B7H3 receptor after on-PVDF tryptic digestion at 37 °C for 1 h in Tris buffer (0.1 M, pH 8.0) containing 10% acetonitrile.

digestion buffer, helps denature the proteins, which allows more access of the enzyme to the substrate proteins. As a consequence digestion is more effective ***(6)***.

8. Acetonitrile is included in the digestion buffer to help extract generated peptides from the hydrophobic membrane into the solution which can be subsequently analyzed by mass spectrometry analysis without the further clean-up that is necessary if other detergents are used for the extraction step. (**Fig. 3**)
9. If the digestion buffer contains a high concentration of salt (i.e. Asp-N digestion), it is necessary to desalt using a C_{18} ziptip prior to loading the sample onto the MALDI plate for MALDI-TOF analysis. (High salt concentration leads to ion suppression during ionization).

Enzymatic Digestion of Membrane-Bound Proteins for Peptide Mapping and Internal Sequence Analysis

Joseph Fernandez and Sheenah M. Mische

1. Introduction

Enzymatic digestion of membrane-bound proteins is a sensitive procedure for obtaining internal sequence data of proteins that either have a blocked amino terminus or require two or more stretches of sequence data for DNA cloning or confirmation of protein identification. Since the final step of protein purification is usually SDS-PAGE, electroblotting to either PVDF or nitrocellulose is the simplest and most common procedure for recovering protein free of contaminants (SDS, acrylamide, and so forth) with a high yield. The first report for enzymatic digestion of a nitrocellulose-bound protein for internal sequence analysis was by Aebersold et al. in 1987, with a more detailed procedure later reported by Tempst et al. in 1990 ***(1, 2)***. Basically, these procedures first treated the nitrocellulose-bound protein with PVP-40 (polyvinyl pyrrolidone, M_r 40,000) to prevent enzyme adsorption to any remaining nonspecific protein binding sites on the membrane, washed extensively to remove excess PVP-40, and the sample was enzymatically digested at 37°C overnight. Attempts with PVDF-bound protein using the above procedures ***(3, 4)*** give poor results and generally require >25 µg of protein. PVDF is preferred over nitrocellulose because it can be used for a variety of other structural analysis procedures, such as amino-terminal sequence analysis and amino acid analysis. In addition, peptide recovery from PVDF-bound protein is higher, particularly from higher retention PVDF (ProBlott, Westran, Immobilon P^{sq}). Finally, PVDF-bound protein can be stored dry as opposed to nitrocellulose, which must remain wet during storage and work up to prevent losses during digestion.

Enzymatic digestion of both PVDF- and nitrocellulose-bound protein in the presence of 1% hydrogenated Triton X-100 (RTX-100) buffers as listed in

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

Table 1 was first performed after treating the protein band with PVP-40 ***(5)***. Unfortunately, the RTX-100 buffer also removes PVP-40 from the membrane, which can interfere with subsequent reverse-phase HPLC. Further studies ***(6, 7)*** demonstrate that treatment with PVP-40 is unnecessary when RTX-100 is used in the digestion buffer. It appears that RTX-100 acts as both a blocking reagent and a strong elution reagent.

PVDF-bound proteins are visualized by staining and subsequently excised from the blot. Protein bands are immersed in hydrogenated Triton X-100 (RTX-100), which acts as both a reagent for peptide extraction and a blocking reagent for preventing enzyme adsorption to the membrane during digestion. Remaining cystine bonds are reduced with dithiotreitol (DTT) and carboxyamidomethylated with iodoacetamide. After incubation with the enzyme of choice, the peptides are recovered in the digestion buffer. Further washes of the membrane remove the remaining peptides, which can be analyzed by microbore HPLC. Purified peptides can then be subjected to automated sequence analysis.

Additional studies have been reported that have enhanced this procedure. Best et al. ***(8)*** have reported that a second aliquot of enzyme several hours later improves the yield of peptides. Reduction and alkylation of cysteine is possible directly in the digestion buffer, allowing identification of cysteine during sequence analysis ***(9)***. Finally, octyl- or decylglucopyranoside can be substituted for RTX-100 in order to obtain cleaner mass spectrometric analysis of the digestion mixture ***(10)***.

2. Materials

The key to success with this procedure is cleanliness. Use of clean buffers, tubes, and staining/destaining solutions, as well as using only hydrogenated Triton X-100 as opposed to the nonhydrogenated form, greatly reduces contaminant peaks obscured during reverse-phase HPLC. A corresponding blank piece of membrane must always be analyzed at the same time as a sample is digested, as a negative control. Contaminants can occur from may sources and particularly protein contaminants are a cocnern. Human Kertain may contaminate samples if gloves are not worn. Proteins from Western blotting can contaminate the PVDF membrane if previously used dishes are used for staining. UV absorbing contaminants can arise from dirty tubes and sub quality detergents. All solutions should be prepared with either HPLC-grade water or double-glass-distilled water that has been filtered through an activated charcoal filter, and passed through a 0.22-µm filter ***(11)***.

2.1. Preparation of the Membrane-Bound Sample

Protein should be analyzed by SDS-PAGE or 2D-IEF using standard laboratory techniques. Electrophoretic transfer of proteins to the membrane should

Table 1 (continued)

Enzyme	Digestion buffer	Recipe (using RTX- 100)[a]	Recipe (using OGP)[c]	Comments
	100 m*M* Tris, pH 8.0	245 µL HPLC-grade water, and	345 µL HPLC-grade water, and	
		500 µL 200 m*M* Tris stock[b]	500 µL 200 m*M* Tris stock[b]	

[a]Hydrogenated Triton X-100 (RTX-100) as described in Tiller et al. ***(13)***.
[b]200 m*M* Tris stock (pH 8.0) is made up as follows: 157.6 mg Tris-HCl and 121.1 mg trizma base to a final volume of 10 mL with HPLC-grade water.
[c]Octyl glucopyranoside can be substituted for RTX-100.

be performed in a full immersion tank rather than a semidry transfer system to avoid sample loss and obtain efficient transfer ***(12)***. PVDF membranes with higher protein binding capacity such as Immobilon P^{sq} (Millipore, Bedford, MA), Problott (Applied Biosystems, Foster City, CA), and Westran (Bio-Rad, Hercules, CA), are preferred owing to greater protein recovery on the blot, although all types of PVDF and nitrocellulose can be used with this procedure. The following stains are compatible with the technique: Ponceau S, Amido black, india ink, and chromatographically pure Coomassie brilliant blue with a dye content >90%. **A blank region of the membrane should be excised to serve as a negative control**.

2.2. Enzymatic Digestion Buffers

Digestion buffer should be made as described in **Table 1**. Make up 1 mL of buffer at a time and store at −20°C for up to 1 wk. Hydrogenated Triton X-100 (RTX-100) (protein grade, Calbiochem, LaJolla, CA) is purchased as a 10% solution, which should be stored at −20°C. Note: Only hydrogenated Triton X-100 should be used since UV-absorbing contaminants are present in ordinary Triton X-100, making identification of peptides on subsequent HPLC impossible (*see* **Fig. 1**). Alternately, octyl glucopyranoside (OGP) (Ultrol-grade, Calbiochem) or decyl glucopyranoside (DGP) (Ultrol-grade, Calbiochem) can be substituted for RTX-100 as described in **Table 1**.

2.3. Reduction and Carboxyamidomethylation

1. 45 m*M* DTT: bring 3.5 mg DTT (Ultrol- grade, Calbiochem) up in 500 µL HPLC-grade water. This can be stored at −20°C for up to 3 mo.
2. 100 m*M* iodoacetamide solution: bring 9.25 mg iodoacetamide (reagent-grade) up in 500 µL HPLC-grade water. This solution must be made fresh just prior to use. Dry DTT and iodoacetamide should be stored at 4°C or −20°C.

2.4. Enzyme Solutions and Inhibitors

Enzymes should be stored as small aliquots at −20°C, and made up as 0.1 µg/µL solutions immediately before use. These aliquots can be stored for at least 1 mo at −20°C without significant loss of enzymatic activity.

1. Trypsin (25 µg, sequencing-grade, Boehringer Mannheim, Indianapolis, IN): Solubilize trypsin in 25 µL of 0.01% trifluoroacetic acid (TFA), and let stand ~10 min. Aliquot 5 µL (5 µg) quantities to clean microcentrifuge tubes, dry in a SpeedVac, and store at −20°C. Reconstitute the dry enzyme in 50 µL 0.01% TFA for a 0.1 µg/µL working solution, which is good for 1 d. **Trypsin cleaves at arginine and lysine residues**.
2. Endoproteinase Lys-C (3.57 mg, Wako Pure Chemicals, Osaka, Japan): Solubilize enzyme in 1000 µL HPLC- grade water, and let stand ~10 min. Make nine 100-µL

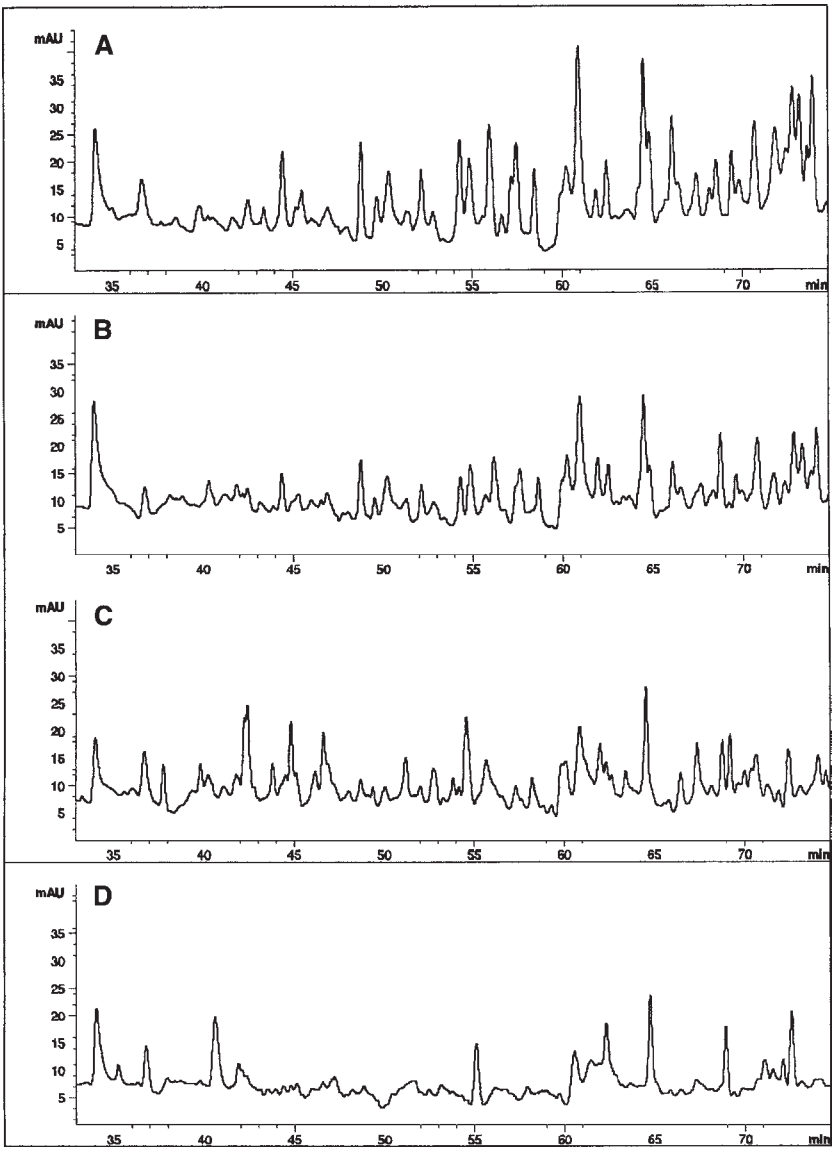

Fig. 1. Peptide maps of trypsin digestion of beta galactosidase bound to PVDF. Panels A–D represent varying amounts of proteins, 40 pmol, 20 pmol, 10 pmol, and 5 pmol respectively. Proteins were analyzed by SDS-PAGE, transferred to PVDF, and stained with Coomassie Brilliant Blue G-250.

quantities to clean tubes, and store at −20°C. Disperse remaining 100 µL into 20 × 5 µL aliquots (17.85 µg each), and store at −20°C. When needed, take one 5-µL aliquot and add 173 µL of HPLC-grade water to establish a 0.1 µg/µL working solution, which can be used for up to 1 wk if stored at −20°C between uses. When 5-µL aliquots are used up, disperse another 100-µL aliquot. **Endoptoteinase Lys-C cleaves only at lysine residues**.

3. Endoproteinase Glu-C (50 µg, sequencing- grade, Boehringer Mannheim) : Solubilize in 100 µL of HPLC- grade water, and let stand ~10 min. Aliquot 10-µL (5 µg) quantities to clean tubes, dry in a SpeedVac, and store at −20°C. Reconstitute the enzyme in 50 µL HPLC-grade water for a 0.1 µg/µL solution, which is good for only 1 d. **Under these conditions, endoproteinase Glu-C cleaves predominantly at glutamic acid residues, but can sometimes cleave at aspartic acid residues**.
4. Clostripain (20 µg, sequencing-grade, Promega, Madison, WI): Solubilize enzyme in 200 µL of manufacturer's supplied buffer for a concentration of 0.1 µg/µL. Enzyme solution can be stored at −20°C for 1 mo. **Clostripain cleaves at arginine residues only**.
5. 1% Diisopropyl fluorophosphate (DFP) solution: DFP is a dangerous neurotoxin that must be handled with double gloves in a chemical hood. Please follow all precautions listed with this chemical. Add 10 µL of DFP to 990 µL absolute ethanol in a capped microcentrifuge tube. Store at −20°C.

3. Method

3.1. Preparation of the Membrane-Bound Sample

Protein should be electrophoresed in one or two dimensions, followed by electrophoretic transfer to the membrane and visualization of the bands according to the following suggestions.

1. Electroblotting of proteins will be most efficient with a tank transfer system, rather than a semidry system. Concentrate as much protein into a lane as possible; however, if protein resolution is a concern, up to 5 cm^2 of membrane can be combined for digestion (*see* **Notes 3** and **5**).
2. Stain PVDF membrane with either Ponceau S, Amido black, india ink, or chromatographically pure Coomassie brilliant blue with a dye content of 90%. Destain the blot until the background is clean enough to visualize the stained protein. Complete destaining of the blot is unnecessary, but at least three washes (~5 min) with distilled water should be done to remove excess acetic acid, which is used during destaining (*see* **Note 5**).
3. Excise protein band(s), and place into a clean 1.5-mL microcentrifuge tube. In addition, excise a blank region of the membrane approximately the same size as the protein blot to serve as a negative control (*see* **Note 4**).
4. Air dry PVDF-bound protein dry at room temperature and store at −20°C or 4°C.

3.2. Digestion of the Membrane-Bound Protein

NOTE: Gloves should be worn during all steps to avoid contamination of sample with skin keratin.

1. Place ~100 µL of HPLC-grade water onto a clean glass plate, and submerge the membrane-bound protein into the water. Transfer the wet membrane to a dry region of the plate and with a clean razor blade, cut the membrane first lengthwise into 1-mm wide strips, and then perpendicular so that the membrane pieces are 1 × 1 mm. Treat the negative control under the same conditions as the sample. Keeping the membrane wet will simplify manipulation of the sample as well as minimize static charge, which could cause PVDF to "jump" off the plate. The 1 × 1 mm pieces of membrane will settle to the bottom of the tube and require less digestion buffer to immerse the membrane completely (*see* **Note 7**).
2. Slide the cut membrane onto the forceps with the razor blade, and return it to a clean 1.5-mL microcentrifuge tube. Use the cleanest tubes possible to minimize contamination during peptide mapping. Surprisingly, many UV-absorbing contaminants can be found in microcentrifuge tubes, and this appears to vary with supplier and lot number. Tubes can be cleaned by rinsing with 1 mL of HPLC-grade methanol followed by 2 rinses of 1 mL HPLC-grade water prior to adding the protein band.
3. Add 50 µL of the appropriate digestion buffer (**Table 1**), and vortex thoroughly for 10–20 s. Optionally, add 50 µL digestion buffer to an empty microcentrifuge tube to serve as a digestion blank for HPLC analysis. The amount of digestion buffer can be increased or decreased depending on the amount of membrane; however, the best results will be obtained with a minimum amount of digestion buffer. PVDF membrane will float in the solution at first, but will submerge after a short while, depending on the type and amount of PVDF.
4. Add 5 µL of 45 mM DTT, vortex thoroughly for 10–20 s, seal the tube cap with parafilm, and incubate at 55°C for 30 min. DTT will reduce any remaining cystine bonds. DTT should be of the highest grade to reduce uv absorbing contaminants that might interfere with subsequent peptide mapping.
5. Allow the sample to cool to room temperature. Add 5 µL of 100 mM iodoacetamide, vortex thoroughly for 10–20 s, and incubate at room temperature for 30 min in the dark. Iodoacetamide alkylates cysteine residues to generate carboxyamidomethyl cysteine, allowing identification of cysteine during sequence analysis. Allowing the sample to cool prior to adding iodoacetamide and incubating at room temperature are necessary to avoid side reaction to other amino acids.
6. Add enough of the required enzyme solution to obtain an estimated enzyme to substrate ratio of 1:10 (w/w) and vortex thoroughly for 10–20 s. Incubate the sample (including digestion buffer blank) at 37°C for 22–24 h. The amount of protein (substrate) can be estimated by comparison of staining intensity to that of known quantities of stained standard proteins. The 1:10 ratio is a general guideline. Ratios of 1:2 through 1:50 can be used without loss of enzyme efficiency or peptide recovery. An enzyme should be selected that would likely produce peptides of > 10 amino acids long. Amino acid analysis of the protein would be informative for estimating the number of cleavage sites. A second aliquot of enzyme can be added after 4–6 h (*see* **Note 6**).

3.3. Extraction of the Peptides

1. After digestion, vortex the sample for 5–10 s, sonicate for 5 min by holding in a sonicating water bath, spin in a centrifuge (~1800g) for 2 min, and transfer the supernatant to a separate vial that will be used directly for HPLC analysis.
2. Add a fresh 50 µL of digestion buffer to the sample, repeat **step 11**, and pool the supernatant with the original buffer supernatant.
3. Add 100 µL 0.1% TFA to the sample, and repeat **step 1**. The total volume for injection onto the HPLC is 200 µL. Most of the peptides (~80%) are recovered in the original digestion buffer; however, these additional washes will ensure maximum recovery of peptides from the membrane.
4. Terminate the enzymatic reaction by either analyzing immediately by HPLC or adding 2 µL of the DFP solution.

CAUTION: DFP is a dangerous neurotoxin and must be handled with double gloves under a chemical fume hood. Please follow all precautions listed for this chemical.

3.4. Analysis of Samples by Reverse-Phase HPLC and Storage of Peptide Fractions

1. Prior to reverse-phase HPLC, inspect the pooled supernatants for small pieces of membrane or particles that could clog the HPLC tubing. If membrane or particles are observed, either remove the membrane with a clean probe (such as thin tweezers, a thin wire, thin pipet tip, and so forth), or spin in a centrifuge for 2 min and transfer the sample to a clean vial. A precolumn filter will help increase the life of HPLC columns, which frequently have problems with clogged frits.
2. Sample is ready to be fractionated by HPLC (*see* Chapter 102). Fractions can be collected in capless 1.5-mL plastic tubes, capped, and stored at −20°C until sequenced (*see* **Note 9**). A typical fractionation is shown in **Fig. 1**.

4. Notes

1. This procedure is generally applicable to proteins that need to have their primary structure determined and offers a simple method for obtaining internal sequence data in addition to amino terminal sequence analysis data. The procedure is highly reproducible and is suitable to peptide mapping by reverse-phase HPLC. Proteins 12–300 kDa have been successfully digested with this procedure with the average size around 100 kDa. Types of proteins analyzed by this technique include DNA binding, cystolic, peripheral, and integral-membrane proteins, including glycosylated and phosphorylated species. The limits of the procedure appear to be dependent on the sensitivity of both the HPLC used for peptide isolation and the protein sequencer.
2. There are several clear advantages of this procedure over existing methods. First, it is applicable to PVDF (especially high-retention PVDF

membranes), which is the preferred membrane owing to higher recovery of peptides after digestion, as well as being applicable to other structural analysis. The earlier procedures ***(1,2)*** have not been successful with PVDF. Second, because of the RTX-100 buffer, recovery of peptides from nitrocellulose is higher than earlier nitrocellulose procedures ***(5)***. Third, the procedure is a onestep procedure and does not require pretreatment of the protein band with PVP-40. Fourth, since the procedure does not require all the washes that the PVP-40 procedures do, there is less chance of protein washout. Fifth, the time required is considerably less than with the other procedures. Overall, the protocol described here is the simplest and quickest method to obtain quantitative recovery of peptides.

3. The largest source of sample loss is generally not the digestion itself, but rather electroblotting of the sample. Protein electroblotting should be performed with the following considerations. Use PVDF (preferably a higher binding type, i.e., ProBlott, Immobilon P^{sq}) rather than nitrocellulose, since peptide recovery after digestion is usually higher with PVDF ***(5,8)***. If nitrocellulose must be used, e.g., protein is already bound to nitrocellulse before digestion is required, never allow the membrane to dry out since this will decrease yields. Always electroblot protein using a transfer tank system, since yields from semidry systems are not as high ***(12)***. Using stains such as Ponceau S, Amido black, or chromatographically pure Coomassie brilliant blue, with a dye content >90% will increase detection of peptide fragments during reverse-phase HPLC.

   Note: Most commercial sources of Coomassie brilliant blue are extremely dirty and should be avoided. Only chromatographically pure Coomassie brilliant blue with a dye content of 90% appears suitable for this procedure.

4. The greatest source of failure in obtaining internal sequence data is not enough protein on the blot, which results in the failure to detect peptide during HPLC analysis. An indication of insufficient protein is that either the intensity of the stain is weak, i.e., cannot be seen with Amido black even though observable with india ink (about 10-fold more sensitive), or possibly detectable by radioactivity or immunostaining, but not by protein stain. Amino acid analysis, amino-terminal sequence analysis, or at the very least, comparison with stained standard proteins on the blot should be performed to help determine if enough material is present. When <10 µg of protein is present, the most problematic item is misidentification of peptides on reverse-phase HPLC owing to artifact peaks and contaminants. Although elimination of every contaminant is usually impossible, there are several strategic points and steps that can be taken to help alleviate these

contaminants. A negative control of a blank region of the membrane blot (preferably from a blank lane) that is approximately the same size as the protein band will help to identify contaminants present that are associated with the membrane and digestion buffer (*see* **Fig. 1D**). The blank membrane should have gone through the same preparation steps as the sample, including electroblotting and staining, and should be analyzed by HPLC immediately before or after the sample. A positive control (membrane-bound standard protein) is generally unnecessary, but should be performed if the activity of the enzyme is in question or a new lot number of enzyme is to be used.

5. Major sources of contaminants are stains used to visualize the protein, the microcentrifuge tubes used for digestion, reagents used during digestion and extraction of peptides, and the HPLC itself. Stains are the greatest source of contaminants, and Coomassie brilliant blue in particular is a problem (*see* **Fig. 1A**). Amido black and Ponceau S are generally the cleanest, whereas chromatographically pure Coomassie brilliant blue with a dye content <90% does appear to generate less contaminants than most other commercially available Coomassie brilliant blue stains. Surprisingly, microcentrifuge tubes can produce significant artifact peaks, which seem to vary with supplier and lot number. A digestion blank of just the microcentrifuge tube should be done, since some contaminants only appear after incubation in the RTX-100 buffer. The major concern with the digestion buffer is the hydrogenated Triton X-100 (*see* **Fig. 1C**). Additional late-eluting peaks may be observed with certain lots of RTX-100, whereas other lots are completely free of UV-absorbing contaminants. HPLC-grade water or water prepared as described by Atherton ***(11)*** should be used for all solution preparation. An HPLC blank (gradient run with no injection) should always be performed to determine what peaks are related to the HPLC (*see* **Fig. 1E**).
6. The key to success of the procedure and quantitative recovery of peptides from both PVDF and nitrocellulose membranes is the use of hydrogenated Triton X-100 (RTX-100) in the buffer. This should be purchased from Calbiochem as a 10% stock solution, protein-grade (cat. no. 648464). **Figure 1C** demonstrates why hydrogenated Triton X-100 should be used, since nonhydrogenated Triton X-100 has several strong UV-absorbing contaminants ***(13)***. RTX-100 acts as a block to prevent enzyme adsorption to the membrane as well as a strong elution reagent of peptides ***(6,7)***. In addition, RTX-100 does not inhibit enzyme activity or interfere with peak resolution during HPLC, as do ionic detergents, such as SDS ***(5)***. The concentration of RTX-100 can be decreased to 0.1% ***(7)***. However, with a large amount of membrane, there could be a decrease in peptide recovery. Optionally,

octyl- or decylglucopyranoside can be substituted for RTX-100 with no loss in peptide recovery ***(10)***.

7. The membrane should be cut into 1 × 1 mm pieces while keeping it wet to avoid static charge buildup. The 1 × 1 mm pieces allow using the minimum volume of digestion buffer to cover the membrane. The volume of the digestion buffer should be enough to cover the membrane (~50 µL), but can be increased or decreased depending on the amount of membrane present. The enzyme solution should be selected based on additional knowledge of the protein, such as amino acid composition or whether the protein is basic or acidic. If the protein is a complete unknown, endoproteinase Lys-C or Glu-C would be a good choice. The enzyme-to-substrate ratio should be about 1:10; however, if the exact amount of protein is unknown, ratios of 1:2 through 1:50 will not affect the quantitative recovery of peptides. After digestion, most of the peptides are recovered in the original buffer (about 80%), and the additional washes are performed to ensure maximum peptide recovery. Microbore reverse-phase HPLC is the best isolation procedure for peptides.
8. As mentioned earlier, previous procedures ***(1–3, 5)*** require pretreatment with PVP-40 to prevent enzyme adsorption to the membrane. RTX-100 is essential for quantitative recovery of peptides from the membrane; however, RTX-100 also strips PVP-40 from the membrane, resulting in a broad, large UV-absorbing contaminant that can interfere with peptide identification. The PVP-40 contaminant is not dependent on the age or lot number of PVP-40, and making fresh solutions did not help as previously suggested ***(4)***. This appears to be more of a problem with nitrocellulose and higher binding PVDF (ProBlott and Immobilon P^{sq}) than lower binding PVDF (Immobilon P), and also is dependent on the amount of membrane. The PVP-40 contaminant also appears to elute earlier in the chromatogram as the HPLC column ages, becoming more of a nuisance in visualizing peptides. Therefore, using PVP-40 to prevent enzyme adsorbtion to the membrane should be avoided.
9. There are a few considerations that should be addressed regarding peptide mapping by HPLC using the protocol described here. A precolumn filter (Upchurch Scientific) must be used to prevent small membrane particles from reaching the HPLC column, thus decreasing its life. Inspection of the pooled supernatants for visible pieces of PVDF can prevent clogs in the microbore tubing, and can be removed either with a probe, or by spinning in a centrifuge and transferring the sample to a clean vial.

   Peptide mapping by reverse-phase HPLC after digestion of the membrane-bound protein should result in several peaks on the HPLC. Representative peptide maps from trypsin digestions of human transferrin bound

to PVDF and stained with Coomassie blue or amido black (Immobilon P^{sq}) is shown in Figs. 1A and B. Peptide maps should be reproducible under identical digestion and HPLC conditions. In addition, the peptide maps from proteins digested on membranes are comparable if not identical to those digested in solution, indicating that the same number of peptides are recovered from the membrane as from in solution. The average peptide recovery is generally 40–70% based on the amount analyzed by SDS-PAGE, and 70–100% based on the amount bound to PVDF as determined by amino acid analysis or radioactivity counting. The recovery of peptides from the membrane appears to be quantitative, and the greatest loss of sample tends to be in the electroblotting.

10. The entire procedure can be done in approx 24 h plus the time required for peptide mapping by reverse-phase HPLC. Cutting the membrane takes about 10 minutes, reduction with DTT takes 30 min, carboxyamidomethylation take another 30 min, digestion at 37°C takes 22–24 h, and extraction of the peptides requires about 20 min.

Reverse-Phase HPLC Separation of Enzymatic Digests of Proteins

Kathryn L. Stone and Kenneth R. Williams

1. Introduction

Reverse-phase HPLC is a powerful technique having the ability to resolve complex mixtures of peptides within a short amount of time, in volatile solvents and is compatible with mass spectrometric approaches. Recent technological advances in HPLC analysis include improved stationary phase packing materials for columns (moving from 10 µm to 3 µm and now 1.7 µm particle sizes) and next generation LC systems that have improved resolution, speed and sensitivity and operate at ultra high pressures of up to 10,000 psi ***(1)***. These LC systems are commonly referred to as ultra high pressure or ultra performance liquid chromatography (UPLC). In general, we find that peptides that are less than about 30 residues in length usually separate based on their content of hydrophobic amino acids and that their relative elution positions can be reasonably accurately predicted from published retention coefficients ***(2,3)***. Since proteins often retain some degree of folding under the conditions used for reverse-phase HPLC, the more relevant parameter in this instance is probably surface rather than total hydrophobicity. Although larger peptides and proteins may be separated on HPLC, sometimes their tight binding, slow kinetics of release, propensity to aggregate, and relative insolubility in the usual acetonitrile/0.05% trifluoroacetic acid mobile phase results in broad peaks and/or carryover to successive chromatograms. In our experience, these problems are seldom seen with peptides that are less than about 30 residues in length, which thus makes reverse-phase HPLC an ideal method for fractionating enzymatic digests of proteins. Although it is sometimes possible to improve a particular separation by lessening the gradient slope in that region of the chromatogram, generally, enzymatic digests from a wide variety of proteins can be reasonably well fractionated using a single

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

gradient that might extend over 1–2 h. Another advantage of reverse-phase HPLC is its excellent reproducibility which greatly facilitates using comparative HPLC peptide mapping to detect subtle alterations between otherwise identical proteins. Applications of this approach might include identifying point mutations as well as sites of chemical and posttranslational modification and demonstrating precursor/ product relationships. Finally, since peptides are isolated from reverse-phase HPLC in aqueous mixtures of acetonitrile and 0.05% to 0.1% of an acid (typically TFA, acetic acid, or formic acid) they are ideally suited for subsequent analysis by matrix-assisted laser desorption mass spectrometry (MALDI-MS, ***10***), on-line LC-MS/MS and automated Edman sequencing.

2. Materials

1. HPLC system: Digests of 1 pmol to 10 nmol amounts of proteins may be fractionated on a Hewlett Packard 1090M, 1100 or comparable analytical HPLC system (*see* **Note 1** for suggestions on evaluating HPLC systems and for a general discussion of important parameters that affect HPLC reproducibility, resolution, and sensitivity) capable of generating reproducible gradients in the flowrate range extending at least from about 50 to 500 µL/min. The HP 1090M HPLC used routinely in our lab for off line LC analysis, was equipped with an optical bench upgrade (HP #79891A), a 1.7-µL high-pressure microflow cell with a 0.6-cm path length, a diode array detector, a Waters Chromatography static mixer, and a 250-µL injection loop. The detector outlet was connected to an Isco Foxy fraction collector and Isco Model 2150 Peak Separator to permit collection by peaks into 1.5-mL Sarstedt capless Eppendorf tubes that were positioned in the tops of 13 × 100 mm test tubes. We have found that by applying a varying resistance in parallel to the input detector signal that enters the Model 2150 Peak Separator, it is possible to improve peak detection significantly in the <500 pmol range. This can be easily accomplished via a small "black box" that is equipped with a four-position switch and that contains four different resistors labeled and configured as follows: 50 pmol/2,000 Ω, 100 pmol/1000 Ω, 250 pmol/470 Ω, 500 pmol/220 Ω. With this arrangement, best peak detection is obtained with the following settings on the 2150 Peak Separator: input = 10 mV, peak duration = 1 min, slope sensitivity = high. To minimize the "transit time" during which a given peak is traveling from the flow cell to the fraction collector, these two components are connected with 91 cm of 75-µ id fused silica capillary tubing (*see* **Note 2**). With this configuration, the dead volume is equal to about 7.5 µL, which corresponds to a peak delay of about 9 s at a flowrate of 50 µL/min, and the drop size is sufficiently small that even extremely small peak volumes can be accurately fractionated.
2. A 5-µ particle size, 1 × 250 mm C18 microbore column is recommended for fractionating (off line) 1–250 pmol amounts of digests, whereas 250 pmol to 10 nmol amounts may be fractionated on 3.9–4.6 mm id analytical columns. Although many commercially available columns would undoubtedly be satisfactory (*see* **Note 3**), the column that is currently being used in our laboratory for off line HPLC analysis is the 300-Å Vydac C18 (cat. # 218TP51 for the 1-mm column, Separations

Group, Hesperia, CA) and the RP-300 Aquapore C8, 7 µm, 300-Å, 1 × 250 mm id Brownlee Microbore Column, (cat. # 07120097, PerkinElmer)

3. For on-line LC analysis, a capillary LC system such as the Waters cap LC, Dionex Ultimate or the Waters nanoAcquity UPLC is recommended. Normal HPLC systems as described above, can also be used if stream splitting is enabled so that the flow rate into the mass spectrometer is appropriate for the column and electrospray source used.
4. For the Waters capLC and the Dionex Ultimate systems, we use a Waters Atlantis™ dC18, 3 µm particle size, 100-Å pore size, 100 µm (or 75 µm) × 150 mm NanoEase™ column. The flow rate into the mass spectrometer is 300 nl/min for the 75 µm column and 500 nl/min for the 100 µm column. On the Waters nanoAcquity UPLC system, a 1.7 µm, 75 µm × 250 mm nanoAcquity UPLC column is used. Typical flow rate is 300 nl/min. (*see* **Note 4**)
5. pH 2.0 Buffer system off line analysis: *see* **Notes 5** and **6**. Buffer A: 0.06% trifluoroacetic acid (TFA) (3 mL 20% TFA/H_2O/L final volume HPLC-grade H_2O). Buffer B: 0.052% TFA/80% acetonitrile (2.7 mL 20% TFA/H_2O, 800 mL CH_3CN [HPLCgrade], HPLC-grade H_2O to a final volume of 1000 mL).
6. pH 6.0 Buffer system, off line analysis: *see* **Note 6**. Buffer A: 5 m*M* potassium phosphate, pH 6.0 (10 mL 0.5*M* KH_2PO_4 in a total volume of 1000 mL HPLC-grade H_2O). Buffer B: 80% (v/v) CH_3CN (200 mL HPLC-grade H_2O and 800 mL acetonitrile [HPLC-grade]).
7. CH_3COOH Buffer system for LC-MS analysis: Buffer A: 98% H_2O, 2%CH_3CN, 0.1% CH_3COOH (100 µl % CH_3COOH [HPLC grade], plus 2mL CH_3CN [HPLCgrade] diluted to 100 mL with HPLC grade H_2O) Buffer B: 20% H_2O, 80% CH_3CN, 0.09% CH_3COOH (100 µl % CH_3COOH [HPLC grade], plus 20mL H_2O [HPLC grade] diluted to 100mL with CH_3CN [HPLCgrade])
8. HCOOH Buffer system for Waters nanoAcquity UPLC: Buffer A: 100% H_2O, 0.1% HCOOH (100 µl 99+% HCOOH [Pierce], diluted to 100 mL with HPLC grade H_2O) Buffer B: 100% CH_3CN, 0.075% (75 µl HCOOH (100 µl 99+% HCOOH [Pierce], diluted to 100mL with CH_3CN [HPLCgrade])
9. Peptide dilution buffer: 2 *M* urea, 0.1 *M* NH_4HCO_3. Dissolve 1.2 g Pierce Sequanal Grade urea and 79 mg NH_4HCO_3 (Mallinckrodt Baker) in a final volume of 10 mL HPLC-grade H_2O. This solution should be made up at least weekly and stored at −20 °C.

3. Methods

3.1. HPLC Separation of Peptides

The TFA acetonitrile buffer system described in **Materials**, **item 5** is an almost universal reverse-phase solvent system owing to its low-UV absorbance, high resolution (minimizing peak broadening), and excellent peptide solubilizing properties. However, for HPLC analysis on line with an electrospray mass spectrometer, the TFA needs to be greatly minimized or removed. This is because the TFA has a suppressive effect on the analyte signal due to a combined effect of ion-pairing and surface tension modifications. ***(4)*** Newer generations of col-

umns (e.g. Waters Atlantis dC18 columns) no longer require TFA to maintain peak shape or retention, and formic acid or acetic acid can be used instead making these columns MS compatible. The gradients we generally use are:

Normal Gradient for HPLC Separations		Fast Gradient used on UPLC	
Time	% B	Time	%B
0–60 min	2–37.5%	0–1 min	1%
60–90 min	37.5–75%	1–50 min	1–50%
90–105 min	75–98%	50–51 min	50–85%

In the case of extremely complex digests (i.e., tryptic digests of proteins that are above about 100 kDa), the gradient times may be doubled. In general, we recommend using the lowest flowrates consistent with near-optimum resolution for the column diameter that is being used ***(5,6)***. Hence, we recommend a flowrate of 250–300 nl/min for 75 µm and 500nl/min for 100 µm capillary columns; 50 µL/min for 1mm Microbore columns; 75 µL/min for 2.0–2.1 mm Narrowbore columns; and a flowrate of 0.5 mL/min for 3.9–4.6 mm Analytical columns.

For digests analyzed off line from a mass spectrometer, the peptides can be collected for further analysis such as MALDI-MS or edman sequencing. For these samples, all fractions are immediately tightly capped (to prevent evaporation of the acetonitrile—*see* **Note 7**) and are then stored in plastic boxes (USA/Scientific Plastics, Part #2350–5000) at 5 °C. With the reduced flowrate of 50 µL/min, the average peak detected fraction volume is about 35 µL, which is sufficiently small that, if necessary, the entire fraction can be directly spotted onto support disks used for automated Edman degradation. For MALDI-MS analysis, 1 µL of the fraction can be removed and analyzed directly. To prevent adsorptive peptide losses onto the plastic tubes, fractions should not be concentrated prior to further analysis and, after spotting the peptide sample for edman sequencing, the empty tube should be rinsed with 50 µL 100% TFA, which is then overlaid on top of the sample. If <100% of the sample is to be sequenced, we recommend that the fraction that is to be saved be transferred to a second tube, so that the tube in which the sample was collected can be rinsed in the same manner as described with 100% TFA. Because one of the important applications of reverse-phase HPLC is comparative peptide mapping, we have included below (*see* **Note 8**) a brief discussion of the use of this approach to identifying subtle structural modifications between otherwise identical proteins.

3.2. HPLC Repurification of Peptides

Peptides from novel proteins whose absorbance profile and/or MALDI-MS spectrum indicate they are insufficiently pure for edman chemical sequencing, may be further purified by chromatography on a second (different) C18 column

developed with the same mobile phase and gradient as was used for the initial separation. Because of their differing selectivity ***(7)***, we recommend that (when necessary) peptides that are initially separated on a Vydac C-18 column be further purified by injection onto an Aquapore C8 that is eluted with the same mobile phase and gradient as was used for the initial separation. Peptides destined for repurification are mixed with a volume of 2 *M* urea, 0.1 *M* NH_4HCO_3 such that the volume of the 2 *M* urea, 0.1 *M* NH_4HCO_3 is equal to or greater than the volume of 0.05% TFA, acetonitrile in which the fraction was originally isolated (*see* **Note 9**). In this way, the acetonitrile concentration is diluted by at least 50%, which, in our experience, is sufficient to permit peptide binding to the second C-18 column.

In those few instances where the sequential use of Vydac C-18 and Aquapore C-8 columns fails to bring about sufficient purification, the sample may be further purified by chromatography at pH 6.0 on either of these columns (*see* **Note 10**). Again, the same gradient is used with the only difference being the change in mobile phase.

4. Notes

1. Although general suggestions for selecting suitable HPLC systems may be found in Stone et al. ***(6)***, three factors that critically impact on peptide HPLC and that will be briefly discussed are reproducibility, resolution, and sensitivity. Although reproducibility will not have a significant impact on the success of a single analytical HPLC separation, comparative peptide mapping requires that successive chromatograms of digests of the same protein be sufficiently similar that they can be overlaid onto one another with little or no detectable differences. In general, the latter requires that average peak retention times not vary by more than about ± 0.20% ***(6)***. Assuming the digests were carried out under identical conditions, problems with regard to reproducibility often relate to the inability of the HPLC pumps to deliver accurate flowrates at the extremes of the gradient range. That is, to accurately deliver a 99% buffer A/1% buffer B composition at an overall flowrate of 75 µL/min requires that pump B be able to accurately pump at a flowrate of only 0.75 µL/min. The latter is well beyond the capabilities of many conventional HPLC systems. Although reproducibility can be improved somewhat by restricting the gradient range to 2–98%, as opposed to 0–100% buffer B, the reproducibility of each HPLC system will be inherently limited in this regard by the ability of its pumps to deliver low flowrates accurately. Obviously, some HPLC systems that provide reproducible chromatograms at an overall flowrate of 0.5 mL/min might be unable to do so at 75 µL/min ***(6)***. Similarly, minor check valve, piston seal, and injection valve leaks that go unnoticed at 0.5 mL/min might well account for reproducibility problems at 75 µL/min. With the newer generation of ultra performance LC systems (e.g Waters Acquity and nanoAcquity UPLC) reproducibility is not an issue

with run to run variation at less than ±0.2% even when requested to run at 300 nl/min at 99% buffer A.

The ability of HPLC to discriminate between chemically similar peptides and to resolve adequately a reasonable number of peptides from a high-mol-wt protein, which might well produce 100 or more tryptic peptides, is critically dependent on resolution, which, in turn, depends on a large number of parameters, including the flowrate, gradient time, column packing, and dimensions as well as the mobile phase ***(5–7)***. Studies with tryptic digests of transferrin suggest that, within reasonable limits, gradient time is a more important determinant of resolution than is gradient volume. In general, a total gradient time of ~100 min seems to represent a reasonable compromise between optimizing resolution and maintaining reasonable gradient times ***(5)***. And, unless precautions are taken to minimize dead volumes, significant problems may be encountered in terms of automated peak detection/collection and postcolumn mixing as flowrates are lowered much below 0.15 mL/min ***(7)***. Typically, the use of flowrates in the 25–75 µL/min range require that fused silica tubing be used between the detector and the fraction collector, and that a low volume flow cell (i.e., 1–2 µL) be substituted for the standard flow cell in the UV detector.

Since peptide resolution appears to be directly related to column length ***(5–7)***, whenever possible, the 250-mm versions of these columns should be used. The caveat is that as the inner diameter of the column is reduced to 75 or 100 µm, the column length typically has to be shortened in order to keep the pressure at levels low enough to prevent a high pressure shut down. The new ultraperformance LC systems operate at much higher pressures and now, 75 µm × 250 mm columns can be run at 300 nl/min with pressures of approximately 6000 psi (*see* **Fig 1**). Although the low-UV absorbance, high resolution, and excellent solubilizing properties of the 0.05% TFA/acetonitrile, pH 2.0, buffer system have made it the almost universal mobile phase for reverse-phase HPLC, there are occasions when a different mobile phase might be advantageous. Hence, the differing selectivity of the 5 m*M,* pH 6.0, phosphate system ***(7)*** makes this a valuable mobile phase for detecting posttranslational modifications (such as deamidation) that may be more difficult to detect at the lower pH of the TFA system (where ionization of side-chain carboxyl groups would be suppressed). In addition, as noted in **Subheading 3.2**, changing the mobile phase provides another approach for further purifying peptides that were originally isolated in the TFA system. In our experience, however, the pH 2.0 mobile phase provides somewhat better resolution than the higher pH mobile phase ***(7)***. Hence, we recommend using the pH 2.0 system for the initial separation.

The sensitivity of detection of HPLC is dictated primarily by the volume in which each peak is eluted. Although sensitivity can be increased

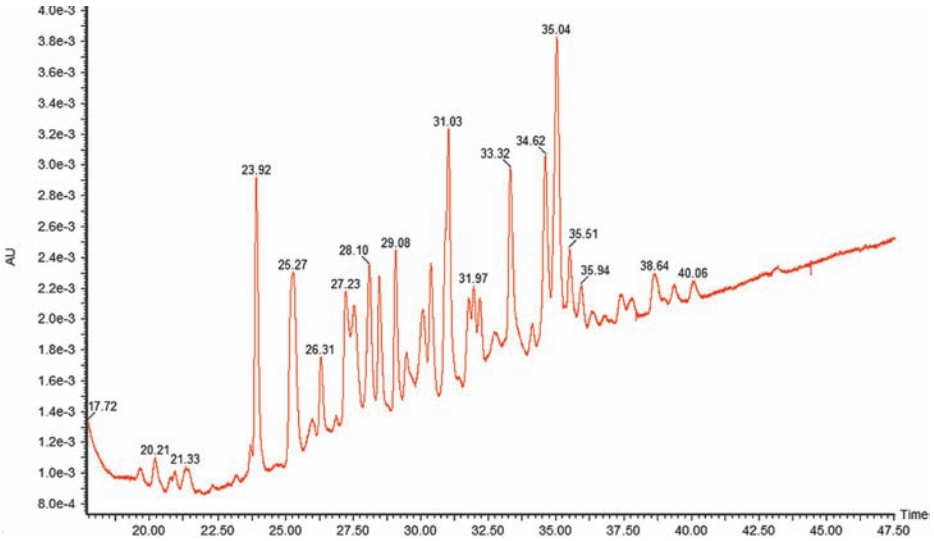

Fig. 1. Reverse-phase HPLC of a 250 fmol aliquot of a large scale, in solution digest of carbamidomethylated transferrin. 250 fmol of the transferrin digest was analyzed on a Waters nanoAcquity using a 75 µm × 250 mm nanoAcquity UPLC column that was eluted at a flow rate of 300 nL/min as described in **Subheading 3.1.** The fast gradient in **Subheading 3.1** was used and peak detection was at 210 nm.

by simply decreasing the flowrate (while maintaining a constant gradient time program) eventually, the linear flow velocity on the column will be reduced to such an extent that optimal resolution will be lost ***(5–7)***. At this point, the column diameter needs to be decreased so that a more optimal linear flow velocity can be maintained at a lower flowrate. In general, the sensitivity of detection is increased as the wavelength is decreased with the practical limit in 0.05% TFA being about 210 nm. Finally, an important determinant of sensitivity (that is often overlooked) is the path length of the flow cell. For instance, an HP1090 equipped with a 0.6-cm path length cell provides (at the same flowrate) a threefold increase in sensitivity over that afforded by a Michrom UMA System equipped with a 0.2-cm path length cell. The ultra performance LC systems have addressed the sensitivity issue by concentrating the analytes into a lower volume and thereby, yielding UV peaks that are narrower and taller.

2. If the transit time (i.e., peak delay) between the detector and the fraction collector is too long, closely eluting peaks will be pooled together. The reason is that if a second peak is detected by the Isco Model 2150 Peak Separator while it is "counting down" the peak delay for the first peak, the two peaks will be pooled together. Although our experience is this phenomenon seldom occurs with a peak delay of 9 s (at a flowrate of 50 µL/min),

which corresponds to a "dead volume" of about 7.5 µL, it often occurs if the peak delay exceeds about 15 s.

3. The procedure we use to evaluate C-18 reverse-phase columns is to determine the relative number of peaks that are detected at a given slope sensitivity during the fractionation of an aliquot of a large-scale tryptic digest of transferrin *(5–7)*.
4. The newer UPLC systems are capable of operating at up to 10,000 psi. This means that longer columns, which run at higher pressures at the same flow rates, can be run in order to increase the column peak capacity (i.e. the number of compounds that can be separated). Typical pressure on a 75 µm × 250 mm column running at 300 nl/min is 6100 psi.
5. For high-sensitivity work, the baseline may be "balanced" (after running the first blank run) by adding a small volume of 20% TFA (i.e., typically 10 to 100 µL) to either buffer A or B as needed *(7)*. For the acetic and formic acid buffers, small amounts of these acids can also be added to flatten the baseline. In figure 1, buffer A contains 0.1% HCOOH while buffer B only 0.075% HCOOH. By decreasing the amount of HCOOH in buffer B, it was possible to flatten the baseline sufficiently so that a wavelength of 210 nm (which is more sensitive than 214nm) could be used.
6. Because filtering HPLC solvents may result in their contamination *(7)*, we recommend they be made with HPLC-grade water and acetonitrile, and that they not be filtered prior to use.
7. Provided the fractions are tightly capped within a few hours of collection (to prevent loss of acetonitrile owing to evaporation), the acetonitrile is extremely effective at preventing microbial growth and peptide loss owing to adsorption. Under these conditions, we have often successfully sequenced peptide fractions that have been stored for longer than a year.
8. Provided that samples of both the modified and unmodified protein are available, comparative HPLC peptide mapping provides an extremely facile means of rapidly identifying peptides that contain posttranslational modifications. In the case of proteins that have been expressed in *E. coli*, the latter can often serve as the unmodified control, since relatively few posttranslational modifications occur in this organism. Certainly, the first attempt at comparative HPLC peptide mapping should be with enzymes, such as trypsin or lysyl endopeptidase, that have high specificity, and the digests should be separated using the acid/acetonitrile gradients. Although elution position (as detected by absorbance at 210 nm) provides a sensitive criterion to detect subtle alterations in structure, the value of comparative HPLC peptide mapping is further enhanced by multiwavelength monitoring and, especially, by on-line or off-line mass spectrometry of the resulting peptides. If comparative peptide mapping fails to reveal any significant changes, it is often worthwhile running the same digest in the pH 6.0 phosphate-buffered system (which may

not be compatible with on-line mass spectrometry). At this higher pH, some changes, such as deamidation of asparagine and glutamine, produce a larger effect on elution position than at pH 2.0, where ionization of the side-chain carboxyl groups would be suppressed. Another possible reason for failing to detect differences on comparative HPLC is that the peptide(s) containing the modifications are either too hydrophilic to bind or too hydrophobic to elute from reverse-phase supports. Hence, in addition to trying a different HPLC solvent system, another approach that may be taken to expand the capabilities of comparative HPLC peptide mapping is to try a different proteolytic enzyme, such as chymotrypsin or Protease V8. Finally, the failure to observe any difference on comparative HPLC peptide mapping may result from loss of the posttranslational modification during either the cleavage or the subsequent HPLC. Assignment of disulfide bonds is one example where this can be a problem in that disulfide interchange may occur during enzymatic cleavage, which is typically carried out at pH 8.0. This problem can be addressed by either going to shorter digestion times ***(9)*** or by carrying out the cleavage under acidic conditions, where disulfide interchange is less likely to occur. For this reason, pepsin (which is active in 5% formic acid) digests are often used for isolating disulfide bonded peptides. Providing that the control sample is reduced, comparative HPLC peptide mapping can be used to identify disulfide-linked peptides rapidly. If the sequence of the protein of interest is known, then comparison of the MALDI-MS spectra obtained before and after reduction of the disulfide-linked peptide can be used to identify the two peptides that are disulfide-bonded.

9. The purpose of the 2*M* urea is to minimize adsorptive losses on diluting the peptide fraction (which is accompanied by a 50% decrease in the acetonitrile concentration). We have found that provided the urea is made up (at least weekly) in NH_4HCO, no detectable NH_2-terminal blocking occurs as the result of cyanate formation.
10. The advantage of increasing the pH from 2.0, which is the approximate pH of the usual 0.05% TFA mobile phase, to pH 6.0 is that (as mentioned above) this change accentuates the separation of peptides based on their content of acidic amino acid residues. That is, since the P*Ka* of the acidic side chains of aspartic and glutamic acid is about 4, increasing the pH of the mobile phase from 2.0 to 6.0 results in ionization of their COOH side-chains. The increased charge that accompanies ionization greatly decreases retention of peptides on reverse-phase supports ***(2)***.

Peptide Mapping by Two-Dimensional Thin-Layer Electrophoresis-Thin-Layer Chromatography

Ralph C. Judd

1. Introduction

The principle behind peptide mapping is straightforward: If two proteins have the same primary structures, then cleavage of each protein with a specific protease or chemical cleavage reagent will yield identical peptide fragments. However, if the proteins have different primary structures, and then the cleavage will generate unrelated peptides. The similarity or dissimilarity of the proteins' primary structure is reflected in the similarity or dissimilarity of the peptide fragments. Separation of peptides by 2-D thin-layer electrophoresis–thin-layer chromatography (2-D TLE-TLC) results in very high resolution of the peptides, making subtle comparisons possible. There are four phases to the 2-D TLE-TLC peptide mapping process:

1. Identification and purification of the proteins to be compared;
2. Radiolabeling of the proteins, and thus the peptide fragments, to minimize the quantity of protein required;
3. Cleavage of the proteins with specific endopeptidic reagents, either chemical or enzymatic; and
4. Separation and visualization of the peptide fragments for comparison.

Each step can be accomplished in different ways depending on the amount of protein available, the technologies available, and the needs of the researcher. Basic procedures that have proven reliable are presented for each phase. Because peptide mapping is empirical by nature, reaction times, reagent concentrations, and amounts of proteins and peptides may need to be altered to accommodate different research requirements.

2. Materials

2.1. Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE)

See Chapter 21 for reagents and procedures for SDS-PAGE.

2.2. Electroblotting

1. Blotting chamber with cooling coil (e.g., Transblot chamber, Bio-Rad, Inc., Hercules, CA, or equivalent).
2. Power pack (e.g., EC 420, EC Apparatus Inc. [St. Petersburg, FL], or equivalent).
3. Nitrocellulose paper (NCP).
4. Polyvinylidene difluoride (PVDF) nylon membrane.
5. Ponceau S: 1–2 mL/100 mL H_2O.
6. Naphthol blue black (NBB): 1% in H_2O.
7. India ink (Pelikan, Hannover, Germany).
8. 0.05% Tween-20 in phosphate buffered saline (PBS), pH 7.4.
9. 20 m*M* phosphate buffer, pH 8.0: 89 mL 0.2 *M* Na_2HPO_4 stock, 11 mL 0.2*M* stock in 900 mL H_2O.

2.3. Radiolabeling

1. γ-Radiation detector.
2. Speed-Vac concentrator (Savant Inst. Inc., Farmingdale, NY) or any other drying system, such as heat lamps, warm air, and so forth, will suffice.
3. Carrier-free ^{125}I (*see* **Notes 1** and **2**).
4. 1,3,4,6-tetrachloro-3α,6α-glycouril (Iodogen). Iodogen-tubes are prepared by placing 10 µL of chloroform containing 1 mg/mL Iodogen in the bottom of 1.5-mL polypropylene microfuge tubes and allowing to air-dry. Iodogen tubes can be stored at −20°C for up to 6 mo.
5. PBS, pH 7.4 (any dilute, neutral buffer should work).
6. Dowex 1-X-8, 20–50 mesh, anion-exchange resin (Bio-Rad).
7. Twenty-four-well disposable microtiter plate.
8. Sephadex G-25 or G-50 (Pharmacia, Piscataway, NJ).
9. 15% Methanol in H_2O.
10. XAR-5 film (Kodak, Rochester, NY, or equivalent).
11. Lightening Plus intensifying screens (DuPont, Wilmington, DE, or equivalent).

2.4. Protein Cleavage

1. Enzymatic and chemical cleavage reagents and appropriate buffers as described in Chapter 94.
2. 88 or 70% Formic acid.
3. 50 m*M* NH_4HCO_3 adjusted to the appropriate pH with sodium hydroxide.
4. 50% Glacial acetic acid in H_2O.
5. Glacial acetic acid added to H_2O to bring pH to 3.0.

2.5. Peptide Separation

2.5.1. 2-D TLE-TLC

1. Forma 2095 refrigerated cooling bath (Forma Scientific, Marietta, OH) or equivalent.
2. Immersion TLE chamber (e.g., Savant TLE 20 electrophoresis chamber, or equivalent).
3. 1200-V Power pack.
4. Chromatography chambers.
5. "Varsol" (EC123, Savant, or equivalent).
6. 0.1-mm Mylar-backed cellulose sheets (E. Merck, MCB Reagents, Gibbstown, NJ, or equivalent).
7. TLE buffer: 2 L H_2O, 100 mL glacial acetic acid, 10 mL pyridine.
8. TLC buffer: 260 mL *n*-butanol, 200 mL pyridine, 160 mL H_2O, 40 mL glacial acetic acid.
9. H_2O containing Tyr, Ile, and Asp (1 mg/mL). These are 2-D TLC-TLE amino acid markers.
10. 1% Methyl green in H_2O (w/v).
11. Laboratory sprayer.
12. 0.25% Ninhydrin in acetone.
13. XAR-5 film (Kodak or equivalent).
14. Lightening Plus intensifying screens (DuPont or equivalent).

3. Methods

3.1. Protein Punfication

3.1.1. SDS-PAGE

Any protein purification procedure that results in 95–100% purity is suitable for peptide mapping. For analytical purposes, the discontinuous buffer, SDS-PAGE procedure is the best choice ***(1,2)***. SDS-PAGE provides apparent molecular-mass information, and the ability to probe SDS-PAGE-separated proteins by immunoblotting, helps ensure that the proper proteins are being studied.

If the proteins to be compared are abundant (>100 µg), peptide fragments can be visualized following 2-D TLE-TLC by ninhydrin staining. Much smaller amounts <0.05 µg) can be visualized by autoradiography if the proteins are extrinsically labeled with ^{125}I. Resolution of peptides increases as the amount of each peptide decreases. For these reasons, it is highly recommended that radiolabeled proteins be used ***(1,3–5)***. Proteins separated in SDS-PAGE gels can be labeled and cleaved directly in gel slices ***(3–7*** and *see* Chapter 99), but labeling and cleavage are much more efficient if the proteins are first electroblotted to NCP ***(4)***. Proteins can also be intrinsically or extrinsically labeled before SDS-PAGE separation ***(5)***. It is strongly recommended that even highly pure proteins be separated in SDS-PAGE gels and transferred to NCP because of the ease of labeling and cleavage using this system. Blotted proteins can be readily located by staining with Ponceau S in water (preferred), NBB in water, or India

ink-0.05% Tween-20-PBS ***(8)***. Proteins of interest can then be excised, labeled using ^{125}I, and cleaved directly on the NCP ***(4)***. The peptides are released into the supernatant and can then be separated using 2-D TLE-TLC ***(4)***.

A single SDS-PAGE separation is often adequate to purify proteins for peptide mapping. Occasionally, a second separation may be required. Alternately, 2-D isoelectric focusing-SDS-PAGE can be used to purify proteins. If ^{125}I-labeling is used, a single protein band from a single lane of a 24-tooth comb is ample material for numerous separations of peptide fragments. Again, labeling and cleavage are greatly facilitated by electroblotting the protein to NCP.

3.1.1.1. Single SDS-PAGE Separation

1. Samples to be compared can be separated in individual lanes of an SDS-PAGE gel; "preparative" gels, where each sample is loaded over the entire stacking gel ***(4)***, may also be used.
2. After electrophoresis, fixation, Coomassie brilliant blue (CBB) staining, and destaining (*see* Chapter 21), excise the protein bands of interest for use in the "gel slice" methods described below. The preferred method is to electroblot the protein to NCP, at 20 V constant current, 0.6 A for 16 h in degassed 20 m*M* phosphate buffer, pH 8.0 ***(9)*** (*see* Chapters 58 and 59).
3. To stain the proteins on NCP, shake the NCP in Ponceau S for 15 min, then destain with H_2O, or shake in 0.1% NBB in H_2O for 1 h, and then destain with H_2O. If the proteins cannot be located by using these stains, place the NCP in 100 mL of 0.05% Tween-20 PBS, and mix for 1 h. Then add three drops of India ink and mix for another hour. Protein bands will be black and the background white (*see* **Note 3**).
4. Excise the protein band from the NCP (a 1 × 5-mm band is more than ample), and place the excised strip in a 1.5-mL microfuge tube. Wash with H_2O until no stain is released into the supernatant. The protein is now ready for labeling and cleavage (*see* **Note 4**).

3.1.1.2. Double SDS-PAGE Separation

1. Separate the samples in individual lanes of an SDS-PAGE gel or in "preparative" SDS-PAGE gels. Fix, stain with CBB, and then destain (*see* Chapter 21).
2. Excise the protein bands of interest. Soak the bands in 50% ethanol–50% stacking buffer (1 *M* Tris-HC1, pH 6.8) for 30 min to shrink the gel strip to facilitate loading onto a second SDS-PAGE gel.
3. Push the excised band into contact with the stacking gel of a second SDS-PAGE gel of a different acrylamide concentration (generally use high concentration in the first gel and lower concentration in the second gel).
4. Separate proteins in a second gel (CBB runs just behind the dye front). Stain or electroblot the proteins as in **Subheading 3.1.1.** The protein is now ready for labeling and cleavage.

3.2. Protein Labeling

Proteins can be intrinsically labeled by growing organisms in the presence of a uniform mixture of ^{14}C-amino acids ***(5)***, but this is quite expensive. Intrin-

sic labeling with individual amino acids, such as ^{35}S-Met or ^{35}S-Cys, will not work, since many peptide fragments will not be labeled. Iodination with ^{125}I is inexpensive and reproducible. Iodinated peptides are readily visualized by autoradiography ***(1, 3, 4)***. Comparative cleavages of a 40,000-Dalton protein intrinsically labeled with ^{14}C-amino acids extrinsically labeled with ^{125}I showed that 61 of 66 α-chymotryptic peptides were labeled with ^{125}I, whereas all 22 *Staphylococcus aureus* V8 protease-generated peptides were labeled with ^{125}I, demonstrating the effectiveness of radioiodination ***(10)***. This demonstrates that tyrosine (Tyr) is not the only amino acid labeled using this procedure.

Iodination mediated by chloramine-T (CT) ***(11)*** produces extremely high specific activities, but the procedure requires an extra step to remove the CT and can cleave some proteins at tryptophan residues ***(12)***. This can be beneficial since it is specific and increases the number of peptides, thus increasing the sensitivity of the procedure (*see* **ref. *13***) for peptide maps of CT- vs Iodogen-labeled proteins). Unfortunately, small peptides generated by CT cleavage, followed by a second enzymatic or chemical cleavage, can be lost during the removal of the CT and unbound ^{125}I.

The 1,3,4,6-tetrachloro-3α,6α-glycouril (Iodogen) ***(13)*** procedure, where the oxidizing agent is bound to the reaction vessel, does not damage the protein and produces high specific activities. Aspiration of the reaction mixture stops the iodination and separates the protein from the oxidant in a single step. For these reasons, Iodogen-mediated labeling is the preferred method for radioiodination. (Radioemission of ^{125}I will be expressed as counts per minute [cpm]. This assumes a detector efficiency of 70%. If detector efficiency varies, multiply the cpm presented here by 1.43 to determine decays per minute (dpm), and then multiply the dpm by the efficiency of your detector.)

3.2.1. NCP Strip (Preferred Method)

1. Put the protein-containing NCP strip in an Iodogen-coated (10 µg) microfuge tube.
2. Add 50–100 µL PBS, pH 7.4 (any dilute, neutral buffer should work) and 50–100 µCi ^{125}I (as NaI, carrier-free, 25 µCi/µL) (*see* **Notes 1** and **2**).
3. Incubate at room temperature for 1 h. Aspirate the supernatant. (**Caution: supernatant is radioactive).**
4. Place the NCP strip in a fresh microfuge tube and wash three to five times with 1.5 mL H_2O (radioactivity released should stabilize at <10,000 cpm/wash).
5. The protein on the NCP strip is now ready for cleavage (*see* **Note 5**).

3.2.2. Gel Slice

1. Dry the gel slice containing protein using a Speed-Vac concentrator or other drying system, such as heat lamps, warm air, and so forth.
2. Put the slice in an Iodogen-coated (10-µg) microfuge tube.
3. Add 100 µL of PBS, pH 7.4 (any dilute, neutral buffer should work) plus 50–100 µCi ^{125}I (as NaI, carrier-free, 25 µCi/µL) (*see* **Notes 1** and **2**).

4. Incubate at room temperature for 1 h. Aspirate the supernatant. **(Caution: supernatant is radioactive)**.
5. Remove the gel slice and soak for 0.5 to 1 h in 1.5 mL of H_2O. Repeat three times.
6. Place 0.5 g Dowex 1-X-8, 20–50 mesh, anion-exchange resin and 1.5 mL of 15% methanol in H_2O in the wells of a 24-well microtiter plate.
7. Add the iodinated gel slice to a well with anion-exchange resin and incubate at room temperature for 16 h. The resin binds unreacted iodine, becoming **extremely** radioactive.
8. Remove the gel slice from the resin, and soak it in 1.5 mL of H_2O. Repeat several times, and dry the gel slice. The protein is now ready for cleavage (*see* **Note 6**).

3.2.3. Lyophilized/Soluble Protein

1. Suspend up to 1 mg/mL of protein in 100–200 µL of PBS, pH 7.4 (any dilute, neutral buffer should work), in a 1.5-mL microfuge tube containing 10 µg Iodogen.
2. Add 100–200 µCi ^{125}I (as NaI, carrier-free, 25 µCi/µL) (*see* **Notes 1** and **2**).
3. Incubate on ice for 1 h.
4. Remove the protein-containing supernatant and separate the protein from salts and unbound iodine by the following methods:
   a. (Preferred method) Separate on a Sephadex G-25 or G-50 desalting column using H_2O as the eluant and lyophilize.
   b. (Relatively easy) Solubilize the sample in 2X sample buffer (10–20 µg/lane), and separate in an SDS-PAGE gel. Stop the electrophoresis before the ion front reaches the bottom of the gel and cut the gel just above the dye front. Unbound iodine will be in this portion of the gel. Either fix, stain, and destain the gel to locate the protein band, or electroblot onto NCP and locate the protein by Ponceau S. NBB, or India ink staining (*see* **Subheading 3.1.1.1, step 3**). Excise the protein band from the gel or NCP.
   c. (Excellent if available) Separate the protein using reverse-phase or molecular-exclusion HPLC columns, and then dialyze and lyophilize.
   d. (Least preferred) Dialysis, followed by lyophilization, can be used, but it produces excessive radioactive liquid waste.
5. The protein is now ready for cleavage.

3.3. Protein Cleavage

The use of cleavage reagents (e.g., α-chymotrypsin) or combinations of cleavage reagents, which generate many fragments, tends to accentuate differences in primary structure, whereas cleavage reagents that produce small numbers of fragments (e.g., V8 protease, thermolysin, CNBr, BNPS-skatole) emphasize similarities in primary structure. Enzymatic reagents are often easiest to use, safest, and most reliable, but they can interfere with results, since they are themselves proteins. Chemical reagents are also easy to use and reliable, but can be toxic, requiring careful handling (*see* **Note 7**). Several practical cleavage reagents are presented in **Table 1**.

Table 1
Cleavage Reagents

Reagent	Site of cleavage	Buffer
Chemical		
Cyanogen bromide[a,d]	Carboxy side of Met	70% formate in H_2O
BNPS-skatole[a] (-bromo-methyl-2-(nitrophenylmercapto)-3H-indole)	Carboxy side of Trp	50% H_2O–50% glacial acetic acid
Formic acid	Between Asp and Pro	88% in H_2O
Chloramine T[b]	Carboxy side of Trp	H_2O
Enzymatic[c]		
α-chymotrypsin	Carboxy side of Tyr, Trp, Phe, Leu	50 m*M* NH_4HCO_3, pH 8.5
Pepsin A	Amino side of Phe>Leu	Acetate- H_2O, pH 3.0
Thermolysin	Carboxy side of Leu>Phe	50 m*M* NH_4HCO_3, pH 7.85
Trypsin	Carboxy side of Arg, Lys	50 m*M* NH_4HCO_3, pH 8.5
V8 protease	Carboxy side of Glu, Asp, or carboxy side of Glu	50 m*M* NH_4HCO_3, pH 8.5 pH 6–7 (H_2O)

[a]Cyanogen bromide and BNPS-skatole are used at 1 mg/mL. Room temperature incubation should proceed for 24–48 h under nitrogen in the dark.
[b]Chloramine T is used at 10 mg/mL in H_2O.
[c]All enzymes are used at 1 mg/mL in the appropriate buffer.
[d]**Caution:** CNBr is extremely toxic—handle with care in chemical hood.

Volatile buffers must be used when using 2-D TLE-TLC peptide separation, since this system is negatively affected by salts. For formate and CNBr cleavages, the acid is diluted in H_2O to 88 or 70%, respectively. BNPS-skatole works well in 50% glacial acetic acid-50% H_2O. Ammonium bicarbonate (50 m*M*), adjusted to the appropriate pH with sodium hydroxide, is excellent for enzymes requiring weak base environments (trypsin, α-chymotrypsin, thermolysin, V8 protease). The acid peptidase, Pepsin A, is active in H_2O adjusted to pH 3.0 with glacial acetic acid.

3.3.1. Protein on NCP Strip

1 Put the NCP strip containing the radiolabeled protein in a 1.5-mL microfuge tube, and measure the radioemission using a γ-radiation detector.

2. Add 90 µL of the appropriate buffer and 10 µL of chemical or enzymatic cleavage reagent in buffer (1 mg/mL) to the NCP strip.
3. Incubate with shaking at 37°C for 4 h (for enzymes) or at room temperature for 24–48 h in dark under nitrogen (for chemical reagents).
4. Aspirate the peptide-containing supernatant, and count the NCP strip and supernatant. Enzymes should release 60–70% of counts in the slice into the supernatant; CNBr should release >80%, BNPS-skatole rarely releases more than 50% (*see* **Notes 8** and **9**).
5. Completely dry the supernatant in a Speed- Vac, and wash the sample at least four times by adding 50 µL of H_2O, vortexing, and redrying in a Speed-Vac. Alternate drying systems will work.
6. The sample is now ready for peptide separation (*see* **Note 10**).

3.3.2. Protein in Gel Slice

1. Put the dry gel slice containing the radiolabeled protein in a 1.5-mL microfuge tube and measure the radioemission using a γ-radiation detector.
2. Add 10 µL of cleavage reagent in buffer (1 mg/mL) directly to the dry gel slice. Allow slice to absorb cleavage reagent, and then add 90 µL of appropriate buffer.
3. Continue as from **step 3, Subheading 3.3.1**. Release of peptides into the supernatant will be less efficient than with the NCP strip.
4. The sample is now ready for peptide separation (*see* **Note 10**).

3.3.3. Lyophilized/SolubleProteins

1. Rehydrate the lyophilized radiolabeled proteins in the appropriate buffer at 1 mg/mL (less concentrated samples can be used successfully).
2. Add up to 25 µL of the appropriate cleavage reagent (1 mg/mL) to 25 µL of suspended protein.
3. Continue as from **step 3, Subheading 3.3.1.,** except there is no strip to count.
4. The sample is now ready for peptide separation. Be aware that the sample will usually contain uncleared protein along with the peptide fragments (*see* **Note 10**).

3.4. 2-D TLE-TLC Peptide Separation

It is strongly recommended that iodinated samples be used in the 2-D TLE-TLC system. The technique described is precise enough that peptide maps can be overlaid to facilitate comparisons. Flat-bed electrophoresis can be used, but systems that cool by immersion of the thin-layer sheet in an inert coolant, such as "varsol" (such as the Savant TLE 20 electrophoresis chamber or equivalent), yield superior results. Cooling should be supplied by as large a refrigerated bath as possible, such as the Forma 2095 refrigerated cooling bath. Extra cooling coils, made by bending 1/4 in. aluminum tubing, are helpful. Peptides migrate based on charge, which is a function of pH, in an electric field. The buffer pH is a function of temperature. Therefore, maintenance of the running buffer temperature is crucial. Inconsistent cooling results in inconsistent peptide migration. For best results, use

only 0.1 mm Mylar backed cellulose sheets of E. Merck. Run two or three peptide maps per 20 × 20-cm sheet. If necessary, increased resolution can be obtained by running one sample/sheet and increasing running times (*see* **Note 11**).

1. Set the cooling bath at 8.5°C to keep the electrophoresis tank at 10–13.5°C. The temperature of the cooling tank should not increase more than 1.5°C during a run.
2. Rehydrate the peptide sample to 10^5 cpm/µL in H_2O containing Tyr, Ile, and Asp (1 mg/mL) as amino acid markers.
3. For two samples/run: draw a line down the center of the back of the sheet with a laboratory marker parallel to the machine lines (they can be subtle, but always electrophorese parallel to these lines). Mark two spots 2.5 cm from the end of the sheet and 1.5 cm from center line on the back of the sheet to indicate where to load samples. When the sheet is turned with the cellulose facing up, the marks will show through. For three samples/run: draw two lines of the back of the sheet (parallel to machine lines) 6.7 and 13.4 cm from left edge of sheet and mark three spots, each 8 cm from the end of the plate and 1 cm to the right of the left edge and each line (*see* **Note 12**).
4. Use a graduated, 1–5 µL capillary pipette to spot 2 µL (~ 2×10^5 cpm) if two samples are used, or 1.5 µL (~ 1.5×10^5 cpm) if three samples are used, 0.5 µL at a time (dry spot with hair-dryer each time) to one mark on the sheet. Repeat for each sample on the other mark(s). More sample can be run, but resolution will decrease. To verify proper electrophoresis, spot 1 µL of 1% methyl green on the center line. The methyl green should migrate rapidly toward the cathode in a straight line. Veering indicates a problem.
5. Spray the plate with TLE buffer using a laboratory sprayer. Do not over wet. Remove any standing buffer with one paper towel. Always blot TLE plates in exactly the same manner.
6. Place in the electrophoresis chamber with the samples toward the anode. Run the electrophoresis at 1200 V (about 20 W and 20 mA) for 45 min (two samples/run) or 31 min (three samples/run).
7. Remove the sheet from the chamber, and immediately dry with a hair-dryer. The "varsol" will dry first, and then the buffer. Cut along the lines on the back of the sheet. Score the cellulose 0.5 cm down from top edge of each piece (bottom is the edge closest to the sample) to form a moat.
8. Place the sheets in the chromatography chamber so that chromatography can proceed perpendicularly to the electrophoresis. The TLC buffer should be about 0.5-cm deep. Chromatograph until the buffer reaches the moat. Remove and dry with a hair-dryer (best done in hood).
9. Spray the sheet with 0.25% ninhydrin in acetone (do not saturate) and dry with a hair-dryer to locate amino acid markers. Ninhydrin can also be used to locate peptides if larger amounts of sample are separated (10–100 µg). Be sure to run enzyme controls to distinguish sample from enzyme. Markers should migrate identically in all separations.
10. Overlay the sheets with X-ray film, place Lightening Plus intensifying screen over film, and place in cassette. Expose for 16–24 h at −70°C or expose film without a screen for about 4 d at room temperature. Develop the film (*see* **Note 13**).

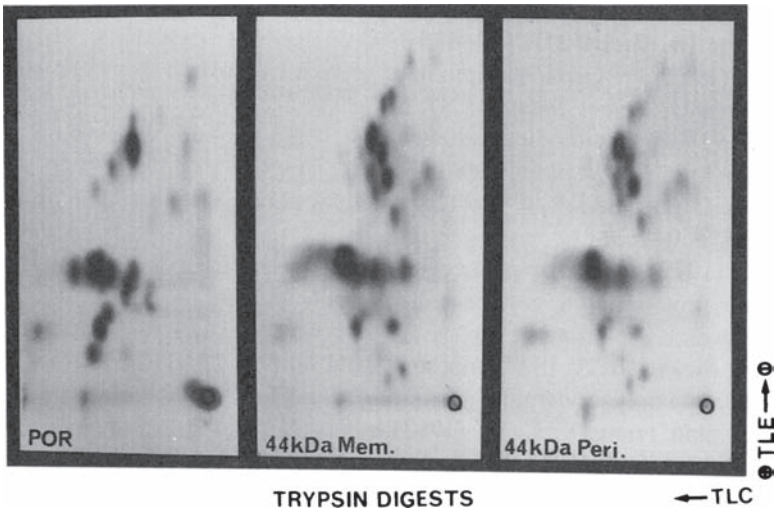

Fig. 1. Example of peptides separated by 2-D TLE-TLC. Proteins were radiolabeled on NCP strips as described in **Subheading 3.2.1.** and cleaved with trypsin as described in **Subheading 3.3.1.** The peptides (1×10^5 cpm) were spotted on a thin-layer cellulose sheet and subjected to 2-D TLE-TLC as described in **Subheading 3.4.** The origin (O) is at the lower right of each map. TLE-direction of thin- layer electrophoresis; TLC—direction of thin-layer chromatography. The ^{125}I-labeled peptides were visualized by autoradiography.

Figure 1 is presented to demonstrate the separation of peptides generated by cleavage with trypin by 2-D TLE-TLC. These peptide maps indicate that the porin protein (POR) of *Neisseria gonorrhoeae* is structurally unrelated to the 44-kDa proteins, whereas the 44-kDa protein from the sarkosyl insoluble (membrane) extract (44-kDa Mem.) is structurally indistinguishable from the 44-kDa protein from the periplasmic extract (44-kDa Peri.). Note the high resolution of the peptide fragments using this technique.

4. Notes

1. Regardless of the labeling procedure, never use ^{125}I that is over one half-life (60 d) old. Do not increase the amount of older ^{125}I to bring up the activity; it does not work.
2. Never use carrier-free ^{125}I in acid buffers. The iodine becomes volatile and could be inhaled.
3. Ponceau S can be completely removed with H_2O, but NBB or India ink cannot.
4. Do not compare proteins stained with Ponceau S with those stained with NBB or India ink. Use the same staining procedure for all proteins to be compared.

5. It is common to have between 3×10^6 and 6×10^6 cpm for a strip 1 × 5 mm. This provides enough material to run 15–30 peptide maps/strip.
6. It is common to have between 2×10^6 and 4×10^6 cpm in a gel slice (1 × 5 mm). This provides enough material to run 10–20 peptide maps/slice.
7. Chemical cleavage reagents are preferred when peptides are not radiolabeled since enzymes cleave themselves, resulting in confusing data. **CNBr is extremely toxic—handle with great care in a chemical hood**.
8. Repeated digestions will release about the same percentage of counts. Generally, one or two digestions are adequate. Only 1×10^5 cpm are necessary to produce a peptide map.
9. If >95% of counts are released in the first enzyme digestion, there may be excess, unbound iodine left in sample. This could cause serious problems, since the enzyme may become labeled. The resultant peptide maps will all be identical maps of the enzyme and not your sample.
10. Peptides prepared in this manner can also be separated by high-performance liquid chromatography (*see* Chapter 102).
11. CNBr should not be used to generate peptides for use in 2-D TLE-TLC, since it produces very hydrophobic peptides, which tend to compress at the top of the chromatogram. CNBr is excellent for generating peptides to be separated by SDS-PAGE or HPLC.
12. Always spot sample to be compared the same distance from the anode (positive) terminal, since peptides migrate more rapidly close to the anode and more slowly far from the anode.
13. Migration of peptides should be consistent enough to overlay peptide maps directly for comparisons. Coordinates of amino acid markers and peptides can be determined and used to compare migration. The labeling procedures described here are precise enough to use emission intensities as a criterion for comparison.

Peptide Mapping by Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis

Ralph C. Judd

1. Introduction

The comparison of the primary structure of proteins is an important facet in the characterization of families of proteins from the same organism, similar proteins from different organisms, and cloned gene products. There are many methods available to establish the sequence similarities of proteins. A relatively uncomplicated approach is to compare the peptide fragments of proteins generated by enzymatic or chemical cleavage, i.e., peptide mapping. The similarity or dissimilarity of the resultant peptides reflects the similarity or dissimilarity of the parent proteins.

One reliable method of peptide mapping is to separate peptide fragments by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Comparison of the separation patterns reveals the structural relationship of the proteins. Moderate separation of peptides can be accomplished using this procedure. The technique, first described by Cleveland et al. ***(1)***, is simple, inexpensive, requires no special equipment, and can be combined with Western blotting to locate epitopes (i.e., epitope mapping ***[1–3]***) or blotting to nylon membranes for microsequencing ***(4)***. Microgram amounts of peptide fragments can be visualized by in-gel staining, making this system fairly sensitive. Sensitivity can be greatly enhanced by radiolabeling (*see* Chapter 102).

2. Materials

2.1. SDS-PAGE

1. SDS-PAGE gel apparatus and power pack (e.g., EC 500, EC Apparatus, Inc., St. Petersburg, FL, or equivalent).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2. SDS-PAGE Solubilization buffer: 2 mL 10% SDS (w/v) in H_2O, 1.0 mL glycerol, 0.625 mL 1 *M* Tris-HCl, pH 6.8, 6 mL H_2O, bromophenol blue to color.
3. Enzyme buffer for Cleveland et al. ***(1)*** "in-gel" digestion: 1% SDS, 1 m*M* EDTA, 1% glycerol, 0.1 *M* Tris-HCl, pH 6.8.
4. All buffers and acrylamide solutions necessary for running SDS-PAGE (*see* Chapter 21).
5. Ethanol: 1 *M* Tris-HCl, pH 6.8 (50:50; [v/v]).
6. Fixer/destainer: 7% acetic acid, 25% isopropanol in H_2O (v/v/v).
7. Coomassie brilliant blue: 1% in fixer/destainer (w/v).
8. Mol-wt markers, e.g., low-mol-wt kit (Bio-Rad, Hercules, CA, or equivalent) or peptide mol-wt markers (Pharmacia, Piscataway, NJ, or equivalent).

2.2. Electroblotting (for Epitope or Sequence Analyses)

1. Blotting chamber with cooling coil (e.g., Transblot chamber, Bio-Rad, Inc. or equivalent).
2. Power pack (e.g., EC 420, EC Apparatus, Inc. or equivalent).
3. Nitrocellulose paper (NCP).
4. Polyvinylidene difluoride (PVDF) nylon membrane.
5. Ponceau S: 1–2 mL/100 mL H_2O.
6. 1% Naphthol blue black (NBB) in H_2O (w/v).
7. 0.05% Tween-20 in phosphate-buffered saline (PBS), pH 7.4.
8. India ink, three drops in 0.05% Tween-20 in PBS, pH 7.4.
9. 20 m*M* phosphate buffer, pH 8.0: 89 mL 0.2 *M* Na_2HPO_4 stock, 11 mL 0.2 *M* NaH_2PO_4 stock in 900 mL H_2O.

3. Methods

3.1. Protein Purification

Purification of the proteins to be compared is the first step in peptide mapping. Any protein purification procedure that results in 95–100% purity is suitable for peptide mapping. For analytical purposes, the discontinuous buffer, SDS-PAGE procedure is often the best choice (Chapter 21 and **refs. *2*** and ***5***). The advantages of SDS-PAGE are: Its resolving power generally can bring proteins to adequate purity in one separation, whereas a second SDS-PAGE separation almost always provides the required purity for even the most difficult proteins; the simple reliability of the procedure; both soluble and insoluble proteins can be purified; apparent molecular-mass information; and the ability to probe SDS-PAGE-separated proteins by immunoblotting help ensure that the proper proteins are being studied. If even greater separation is required, 2D isoelectric focusing-SDS-PAGE can be used.

Proteins separated in SDS-PAGE gels can be cleaved directly in gel slices ***(6)***. However, cleavage is more efficient if the proteins are first electroblotted to NCP ***(3)***. If required, proteins can also be intrinsically or extrinsically labeled before SDS-PAGE separation ***(6)*.**

3.2. Protein Cleavage

Cleavages of purified proteins can be accomplished in the stacking gel with the resultant peptides separated directly in the separating gel, or they can be performed prior to loading the gel (preferred). Several lanes, with increasing incubation time or increasing concentration of enzyme in each lane, should be run to determine optimal proteolysis conditions. Standard Laemmli SDS-PAGE *(5)* system is able to resolve peptide fragments >3000 Dalton. Smaller peptides are best separated in the tricine gel system of Schagger and von Jagow *(7)* (*see also* Chapter 23). The methods described in Chapter 97, **Subheading 3.3** can be used to generate peptides. Cleavage technique varies slightly depending on the form of the purified proteins to be compared.

3.2.1. In-Gel Cleavage/Separation

3.2.1.1. Lyophilized/Soluble Protein

1. Boil the purified protein (~1 mg/mL) for 5 min in enzyme buffer for Cleveland "in-gel" digestion.
2. Load 10–30 µL (10–30 µg) of each protein to be compared into three separate wells of an SDS-PAGE gel (*see* **Note 1**).
3. Overlay samples of each protein with 0.005, 0.05, and 0.5 µg enzyme in 10–20 µL of Cleveland "in-gel" digestion buffer to separate wells. V8 protease (endoproteinase Glu-C) works very well in this system (*see* **Note 2**). SDS hinders the activity of trypsin, α-chymotrypsin, and themolysin, so cleavage with these enzymes may be very slow. In-gel cleavage with chemical reagents is not generally recommended, since they can be inefficient in neutral, oxygenated environments. Gently fill wells and top chamber with running buffer.
4. Subject the samples to electrophoresis until the dye reaches the bottom of the stacking gel. Turn off the power, and incubate for 2 h at 37°C to allow the enzyme to digest the protein partially. Following incubation, continue electrophoresis until the dye reaches the bottom of the gel. Fix, stain, and destain, or electroblot onto NCP for immunoanalysis (*see* **Note 3**).

3.2.1.2. Protein In-Gel-Slice

Peptides of proteins purified by SDS-PAGE usually retain adequate SDS to migrate into a second gel without further treatment.

1. Run SDS-PAGE gels, fix, stain with Coomassie brilliant blue, and destain.
2. Excise protein bands to be compared with a razor blade.
3. Soak excised gel slices containing proteins to be compared in ethanol–1 *M* Tris-HCl, pH 6.8, for 30 min to shrink the gel, making loading on the second gel easier. Place the gel slices into the wells of a second gel.
4. Continue from **step 3, Subheading 3.2.1.1**.

3.2.1.3. Protein on NCP Strip

1. Run SDS-PAGE gels, and electroblot to NCP.
2. Stain blot with Ponceau S, NBB, or block with 0.05% Tween-20 in PBS for 30 min, and then add three drops India ink (*see* **Note 4**).
3. Excise protein bands to be compared with a razor blade.
4. Push NCP strips to bottom of the wells of a second SDS-PAGE gel.
5. Continue from **step 3, Subheading 3.2.1.1**.

Once the separation conditions, protein concentrations, and enzyme concentrations have been established, a single digestion lane for each sample can be used for comparative purposes.

3.2.2. Protein Cleavage Followed by SDS-PAGE

It is often preferable to cleave the proteins to be compared prior to loading onto an SDS-PAGE gel for separation. This generally gives more complete, reproducible cleavage and allows for the use of chemical cleavage reagents not suitable for in-gel cleavages.

3.2.2.1. Lyophilized/Soluble Protein

1. Rehydrate the lyophilized proteins in the appropriate buffer at 1 mg/mL (less concentrated samples can be used successfully). Soluble proteins may need to be dialyzed against the proper buffer.
2. Place 10–30 µL (10–30 µg) of each protein to be compared in 1.5-mL microfuge tubes.
3. Add up to 25 µL of the appropriate chemical cleavage reagent (1 mg/mL) to suspended protein. For enzymes, use only as much enzyme as needed to achieve complete digestion (1:50 enzyme to sample maximum) (*see* **Note 5**).
4. Incubate with shaking at 37°C for 4 h (for enzymes) or at room temperature for 24–48 h in dark under nitrogen (for chemical reagents).
5. Add equal volume of 2X SDS-PAGE solubilization buffer and boil for 5 min (*see* **Note 6**).
6. Load entire sample on SDS-PAGE gel and proceed with electrophoresis.

3.2.2.2. Protein In-Gel Slice

1. Run SDS-PAGE gels, fix, stain with Coomassie brilliant blue, and destain.
2. Excise protein bands to be compared with a razor blade.
3. Dry gel slices containing proteins using a Speed-Vac concentrator or other drying system, such as heat lamps, warm air, and so forth.
4. Put the dry gel slice containing the protein in a 1.5-mL microfuge tube.
5. Add up to 10 µL of the appropriate chemical cleavage reagent (1 mg/mL) directly to the gel slice protein, and then and 90 µL of appropriate buffer. For enzymes, use only as much enzyme as needed to achieve complete digestion (1:50 enzyme to sample maximum) (*see* **Note 5**).
6. Incubate with shaking at 37°C for 4 h (for enzymes) or at room temperature for 24–48 h in dark under nitrogen (for chemical reagents).

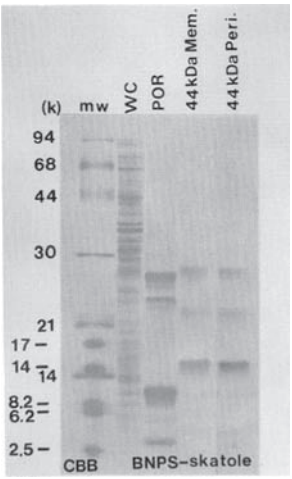

Fig. 1. Example of peptides separated in an SDS-PAGE gel. Whose cells (WC), a sarkosyl insoluble pellet, and a periplasmic extract of *Neisseria gonorrhoeae* were separated in "preparative" 15% SDS-PAGE gels and blotted to NCP as described in Chapter 103, **Subheading 3.1.1**. The 37,000-Dalton major outer membrane protein (POR) and two 44,000-Dalton (44-kDa) proteins, one isolated from a sarkosyl insoluble (membrane) extract (44-kDa Mem.), and the other isolated from a periplasmic extract (44-kDa Peri.), were located on the NCP by Ponceau S staining, excised, and cleaved with BNPS-skatole as described in Chapter 96, **Subheading 3.3.1**. Approximately 30 µg of peptides of each protein were solubilized and separated in an SDS-PAGE gel along with whole-cells (WC), Bio-Rad low-mol-wt markers, and Pharmacia peptide mol-wt markers (mw) (expressed in thousands of Dalton [k]). The gel was stained with Coomassie brilliant blue (CBB) to visualize peptides.

7. Aspirate peptide-containing supernatant.
8. Completely dry-down the supernatant in a Speed-Vac, and wash the sample several times by adding 50 µL of H_2O, vortexing, and redrying in a Speed-Vac. Alternate drying systems will work.
9. Add 10–20 µL SDS-PAGE solubilizing solution to samples and boil for 5 min (*see* **Note 6**).
10. Load samples onto SDS-PAGE gel and proceed with electrophoresis.

3.2.2.3. Protein on NCP Strip

1. Run SDS-PAGE gels, and electroblot to NCP.
2. Stain blot with Ponceau S, NBB, or block with 0.05% Tween-20 in PBS for 30 min, and then add three drops India ink (*see* **Note 3**).
3. Excise protein bands to be compared with a razor blade.
4. Put the NCP strip containing the protein in a 1.5-mL microfuge tube.
5. Continue from **step 5, Subheading 3.2.2.1**.

Figure 1 is presented to demonstrate the separation of peptides generated by cleavage with BNPS-skatole in an SDS-PAGE gel. These peptide maps indicate that the porin protein (POR) was structurally unrelated to the 44-kDa proteins, whereas the 44-kDa proteins from a sarkosyl insoluble (membrane) extract (44-kDa Mem.) and a periplasmic extract (44-kDa Peri.) appeared to have similar primary structures.

4. Notes

1. Between 5×10^4 cpm and 10^5 cpm should be loaded in each lane if radioiodinated samples are to be used. Autoradiography should be performed on unfixed gels. Fixation and staining may wash out small peptides. Place gel in a plastic bag and overlay with XAR-5 film, place in a cassette with a Lightening Plus intensifying screen, and expose for 16 h at −70°C.
2. Control lanes containing only enzyme must be run to distinguish enzyme bands from sample bands.
3. PVDF nylon membrane is preferable to NCP when blotting small peptides.
4. Do not compare proteins stained with Ponceau S with those stained with NBB or India ink. Use the same staining procedure for all proteins to be compared.
5. To ensure complete digestion, it is advisable to incubate the samples for increasing periods of time or to digest with increasing amounts of enzyme. Once optimal conditions are established, a single incubation time and enzyme concentration can be used.
6. It is often advisable to solubilize protein in SDS prior to cleavage, since some peptides do not bind SDS well.

Acknowledgments

Peptide Mapping for Protein Characterization

Peter Højrup

1. Introduction

Analysis of intact proteins is hampered by the fact that even when using high resolution techniques, like electrospray mass spectrometry; you will only be able to tell whether the protein has the expected mass. If you find a deviation from the expected you will in most cases be left wondering where (and perhaps what) the difference is. Recent methods, such as top-down sequencing ***(1,2)***, can give you invaluable information on terminal trimming or even simple posttranslational modifications, but generally works best for "simple" changes to the protein. Observations on intact proteins are compounded when using low-resolution techniques like gel filtration or SDS gel electrophoresis. Although 2-D gel electrophoresis is able to show a single charge difference, in the absence of additional information you are still left wondering where and what the differences are.

Performing Edman degradation on an intact protein will in most cases yield enough information for you to identify a protein and perhaps enable the construction of oligonucleotide probes, but many proteins are N-terminally blocked, and the need to purify enough protein is often prohibitive.

The solution is to perform peptide mapping. This approach is essential for the total characterization of a protein, and the approach also enables quick identification of a protein (if present in a protein database) and to locate differences between proteins.

The steps involved in peptide mapping can be listed as:

1. Purify the protein. Depending on the objective of the peptide mapping, it may be sufficient with a single spot from a 2-D gel, or you may have to purify several microgram of material using traditional protein chemical methods.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2. Cleave the protein using a suitable proteolytic enzyme or by chemical means. A software tool like GPMAW (*see* **Note 1**) greatly facilitates the selection of cleavage method and analysis of the resulting peptides.
3. Fractionate the resulting peptides, generally by reversed phase HPLC, but other methods may be applicable depending on the final method of analysis.
4. Analyze the purified peptide using mass spectrometry, Edman degradation, or amino acid analysis.

1.1. Peptide Mapping

Peptide mapping is usually carried out for two quite different reasons:

1.1.1. Protein Identification

Currently the most sensitive identification of an unknown protein is mass spectrometric peptide mapping (peptide mass fingerprinting, PMF). Using the rapidly expanding protein databases based on nucleotide sequencing, it is possible to identify a protein based on the molecular masses of its constituent (tryptic) peptides if they are determined with sufficient precision. The beauty of the method is that it is not necessary to determine the mass of all peptides; usually 6-7 peptides are sufficient for accurate protein identification. As it is not necessary to separate the peptides before analysis, the method is very sensitive; with routine determination of proteins in the low nanogram range (e.g. a single silver stained spot from an SDS gel).

Two alternative approaches are liquid chromatography coupled to electrospray mass spectrometry (LC-MS/MS) and Edman degradation. Both methods will generate a peptide sequence thus making it possible to do a homology search in case the protein is not present in the database. However, while the sensitivity of LC-MS/MS approaches that of MALDI-MS, the sensitivity of Edman degradation is 2-3 orders of magnitudes lower and further needs a purification step prior to analysis. The topic of LC-MS/MS is beyond the scope of this chapter and will not be treated further. For an introduction please see ***ref. (3)***.

1.1.2. Obtaining the Maximum Sequence Coverage

Unlike protein identification where even a limited number of peptides are able to identify the protein, you will try to cover the whole sequence when comparing proteins for identity/similarity or when performing complete chemical characterization.

1.1.2.1. Comparison of Proteins

Comparison of two proteins is done by performing an identical enzymatic digest on each protein followed by identification of each fragment. In some cases it may be sufficient to perform mass spectrometric mapping of the peptide mixture, but in most cases you will not be able to identify sufficient fragments to

cover the whole sequence. You will thus have to isolate each fragment by HPLC and perform peptide identification. Due to the high resolution of reversed phase HPLC it will in many cases be sufficient to compare the two chromatograms carefully in order to identify differences. When comparing proteins you should note that choosing an enzyme, which generates long peptide fragments, tends to emphasis similarities while short peptide fragments tends to emphasize differences (*see* **Note 2**).

1.1.2.2. Determine the Exact Chemical Structure of a Protein

Even though the number of known protein sequences increases exponentially over time through nucleotide sequence analysis, and you are thus likely to find your protein to be already known, the result of these analyses is the 'naked' amino acid sequence of the protein. However, the vast majority of proteins are post-translationally modified after synthesis, resulting in a structure that deviates from the nucleotide-derived sequence. The preferred strategy to solve the actual protein structure is to perform peptide mapping followed by an appropriate analytical techniques like mass spectrometry, Edman degradation and/or amino acid analysis. Here you always aim for total sequence coverage, and in order to obtain this you will in most cases have to perform at least two separate enzymatic digests.

The amount of material needed for maximum sequence coverage analysis is usually much higher than for PMF analysis, usually in the low to middle microgram range. In special cases where you search only for specific modifications using specific extraction of modified peptides (e.g. purification of phosphorylated peptides using titanium oxide), the sensitivity approach is similar to that of PMF ***(4)***.

2. Materials

2.1. Peptide Mapping for Protein Identification

1. Trypsin (modified trypsin, Promega,). This is most easily handled in aliquots of 1 µg trypsin in 10 µL 0.01 N HCl per tube at –20 °C. Dilute with 70 µL 50 m*M* ammonium bicarbonate before use (final concentration 12.5 ng /µL). Remember always to use UHQ (ultrahigh quality) water.
2. 50 m*M* ammonium bicarbonate. You can store aliquots of 100 m*M* ammonium bicarbonate at –20 °C, it is not necessary to adjust the pH. Dilute 1 : 1 for use.
3. Neat acetonitrile (HPLC quality).
4. 10 m*M* dithiothreitol (DTT). A 1 *M* DTT solution is stable for month at -20 °C. Store as 25 µL aliquots and dilute 1:100 with 100 mM ammonium bicarbonate for use.
5. 55 mM iodoacetamide (Sigma,) in 100 mM ammonium bicarbonate. Has to be prepared freshly (iodoacetamide: 10.2 µg / µL).
6. 0.5 mL polypropylene tubes.
7. Zip-tips (Waters) or homemade micro-purification tips based on Poros 50 R2 reversed phase material (Applied BioSystems, #1-1159-05) and Eppendorf GELoader tips (Eppendorf, #0030 001.222) (*see* **Note 3**).

8. Vacuum centrifuge.
9. Concentrated solution of alpha-cyano-4-hydroxycinnamic acid (Aldrich) in 70% acetonitrile, 0.1% TFA in water.
10. MALDI mass spectrometer.

2.2. Alkylation of Protein

1. 8 *M* urea, 100 m*M* ammonium bicarbonate (or Tris-HCl), pH 8.
2. Reduction agent: typically dithiothreitol (DTT) is used for reduction, but mercaptoethanol or tris(carboxyethyl)phosphine (TCEP – Sigma) may be used instead. Mercaptoethanol is volatile while TCEP is also active at low pH.
3. Alkylating reagent: iodoacetate, iodoacetamide, 4-vinylpyridine and N-isopropyliodoacetamide are all commonly used reagents. 4-vinylpyridine has the disadvantage of being prone to polymerization and thus has a limited shelf life.

2.3. Peptide Mapping with Purification of Peptides

1) Suitable enzyme or chemistry (*see* **Table 1**).
2) Buffer for digestion (*see* **Note 4**)
3) HPLC system capable of binary gradient formation (*see* **Note 5**) equipped with an in-line UV detector and a strip-chart recorder and/or computer integrator.
4) Acetonitrile (HPLC grade, UV cutoff < 210 nm). Neat trifluoroacetic acid (TFA) (analytical grade is acceptable, sequencing grade is optimal) (*see* **Note 6**).
5) Automatic or manual fraction collection into polypropylene tubes.
6) Vacuum centrifuge

As many of the solvents and reagents are used in very small quantities (e.g. ≤ 1 mL) it can be advantageous to prepare stock solutions that are stored at –20 °C, even of those that are not specifically mentioned in the text.

Most proteolytic enzymes are supplied freeze dried. When first opened you may dissolve the enzyme in pure water, make 0.5-2 µg aliquots in small polypropylene tubes, and lyophilize the aliquots. Endo Glu-C protease may be stored frozen in pure water.

3. Methods

3.1. Selection of Proteolytic Enzyme

The selection of an enzyme for digestion is one of the most important considerations when performing peptide mapping, and should be carefully considered in relation to the task you want to perform.

For peptide mass fingerprinting (PMF) the most common choice is trypsin. This is one of the most active enzymes, it is well characterized for PMF analysis (*see* **Notes 8** and **15**), and cleaves with high specificity (C-terminal to Lys and Arg). Most tryptic peptides will have molecular masses in the range 800–2500 Da, which is well suited for mass spectrometry, Furthermore, you are certain that

Table 1
Proteolytic Enzymes Suitable for Peptide Mapping.

Name	EC no.	Size Da.	Type	Organism	Accession number	pH optimum	pH range	Requirements	Tolerates detergents	Cleavage	Specificity	Manufacturer	Note
Trypsin	3.4.21.4	23,293	Serine	Bovine	P00760	8	5.5 – 10.5	Stabilized by small amounts of Ca^{++}	2 M urea >0.1% SDS 50% acetonitrile	Arg, Lys	High	R,W,S	16
Trypsin	3.4.21.4	23,463	Serine	Porcine modified	P00761	8	5.5 – 10.5	Stabilized by small amounts of Ca^{++}	2 M urea >0.1% SDS 50% acetonitrile	Arg, Lys	High	A,S R, P,W, S, PS	16
Chymotrypsin A B	3.4.21.1	25,600 25,700	Serine	Bovine	P00766 P00767	8	7–9		0.1% SDS 1 M urea 10–30% acetonitrile	Phe, Trp, Tyr	Medium to high	R,A, W,S, PS	17
Endo Glu-C	3.4.21.9	27,000	Serine	Staphylococcus aureus V8	P04188	7.8	4–9		2 M urea 0.2% SDS 10% acetonitrile	Glu (Asp) -Glu	High	R,A,P, W,S, PS	18

(continued)

Table 1 (continued)

Name	EC no.	Size Da.	Type	Organism	Accession number	pH optimum	pH range	Requirements	Tolerates detergents	Cleavage	Specificity	Manufacturer	Note
Endo Lys-N	3.4.24	22,000	Metallo	Grifola frondesa		10	6–10.5	Zn^{++} Avoid EDTA		N-terminal to Lys	High	SE	19
Lysyl endopeptidase	3.4.21.50	46.000	Serine	Achromabacter lyticus	P15636	8		Inhibited by ammonium salts	>0.1% SDS 4 M urea 40% acetonitrile	Lys	High	A	19
Endo Arg-C	3.4.21.40	30,000	Serine	Mouse submaxillary		8	7.5–8.5		2 M urea 10% acetonitrile	Arg	High	T,S,PS	19
Endo Asp-N	3.4.24.33	27.000	Metallo	Pseudomonas fragi		8	6.0–8.5	Avoid EDTA	0.1% SDS 1 M urea 10% acetonitrile	N-terminal to Asp	High	T,R,A,S, PS	19
Endo Asn-C		23.000	-SH	Jack Bean		5.0	4.5–6.5	1–10 mM dithiothreitol		Asn	High	T	19
Clostripain	3.4.22.8	50,000	-SH	Clostridium histolyticum	P09870	7.6		1–10 mM dithiothreitol	4 M urea 10% acetonitrile	Arg (Lys)	Medium	R,W,S	19

Pepsin	3.4.21.7	34,500	Acid	Pig gastric mucosa	P00791	2	1–5			N-terminal to hydrophobic Preferentially if preceded by Phe, Met, Leu, Trp	Low	R,A, W,S, PS	15
Thermo-lysin	3.4.24.4	37,500	Met-allo	Bacillus thermo-proteolyti-cus	P00800	8	7–9	Ca^{++} Avoid EDTA	8 M urea	N-terminal to hydrophobic Not if fol-lowed by Pro	Low	A,S	15
Elastase	3.4.21.36	25.900	Serine	Pig pan-creas	P00772	8.5	7–9		0.1% SDS 2 M urea	Uncharged (small) aliphatic	Low	R,A, W,S	15

Chemical cleavage procedures are not included in the table as experience shows that they tend to be rather unspecific for general peptide mapping, however, for those special hard to cleave proteins see relevant chapters in this book.
Accession number: Numbers refer to the Swiss-Prot/Uniprot database (http://www.ebi.ac.uk/).
Cleavage: All enzymes cleave C-terminal to the indicated residue except for except where noted. Minor, but still significant, secondary cleavages are listed in parenthesis. Cleavage does not take place if the cleavage position is followed by proline or a residue indicated by "-" (e.g. a -Lys-Pro- sequence is not cleaved by trypsin). See also notes for individual enzymes.
Specificity: Please *see* **Note 15** and notes for the individual enzymes.
Detergents: Even very small amounts of SDS is detrimental to mass spectrometric analysis, while reversed phase HPLC is capable of handling small amounts of SDS (*see* **Note 4**). When using urea you may dissolve the protein in a small amount of 8 M urea you can dilute to the required strength with buffer containing the relevant enzyme.
Manufacturer: R) Roche Biomolecular, S) Sigma Inc., P) Promega, T) Takara, W) Worthington, A) Wako, C) Calbiochem, PS) Princeton Separations

all peptides will contain a basic residue (except the C-terminal peptide), which means they will ionize better when analyzed by mass spectrometry in positive polarity mode. Endo-Lys and in particular lysyl endopeptidase (higher activity and specificity) are also well suited for PMF, but the peptides generated will, on average, be much larger, which may impede their identification. However, in many cases you will increase the sequence coverage, particularly in basic regions of the protein. Other potential enzymes are Endo Asp-N and Endo Glu-C, but the results are usually much more unpredictable.

If the protein sequence of your target protein is known, you should look at the distribution of residues when aiming for the largest sequence coverage before selecting an enzyme. Particularly the charged residues are important, as most of the specific enzymes will target these residues (**Table 1**). A few computer programs for this type of analysis are available (*see* **Note 1**).
Important aspects for enzyme selection are:

- *Short peptides*. Very short peptides are difficult to handle, both by MALDI mass spectrometry (< 7 residues) and HPLC (< 5 residues if they are hydrophilic).
- *Long peptides*. The mass resolution and sensitivity decreases on the mass spectrometer as you get above 30–35 residues. Likewise large, hydrophobic peptides can be difficult to purify by reversed phase HPLC (> 50 residues). If your prime objective is to obtain amino acid sequence by Edman degradation, long peptides are generally most informative.
- Hydrophobic peptides tend to stick to the wall of polypropylene tubes, particularly if the sample is dried completely (*see* **Note 7**).
- If you want to do protein comparison, you should note that small peptides tend to emphasize differences (e.g. making it easier to identify small differences between proteins) while large peptides will emphasize similarity (e.g. make it easier to identify similar regions).
- Enzyme specificity, activity and buffer compatibility (see table 1) should be chosen relative to the intended analysis method (mass spectrometry, HPLC separation, Edman degradation, amino acid analysis etc.).
- For most proteins you will need at least two different enzymes (digests) in order to get a good coverage (> 90%).

3.2. Peptide Mass Mapping

1. Cut out the stained gel band or gel spot using a sharp scalpel or a properly sized puncher (2–4 mm diameter). Cut the spot into smaller pieces (1 mm square) and place them in a small polypropylene tube. Try to cut as close as possible to the actual spot. A small concentrated spot yields better results than a large diffuse one. If you have a one-dimensional gel band, you may not need the whole band, but can reserve part of it for additional experiments.
2. Wash the gel pieces carefully in 50 µL, 50 m*M* ammonium bicarbonate. Discard the supernatant.

3. Add 50 µL neat acetonitrile. Let stand for 5 min until the gel pieces has fully shrunken and become white. Withdraw the acetonitrile and discard. Dry the gel pieces in a vacuum centrifuge for 20 min.
4. Add 50 µL 10 m*M* dithiothreitol and incubate for 30 min at 56 °C.
5. Cool to room temperature and remove excess solvent.
6. Add 55 m*M* iodoacetamide in 100 m*M* ammonium bicarbonate so the gel pieces are just covered.
7. Let stand for 30 min in the dark before discarding the supernatant.
8. Wash the gel pieces in 20 µL 50% acetonitrile in water.
9. Add 30 µL neat acetonitrile. Mix until the gel pieces are fully shrunken and white. Remove the acetonitrile.
10. Add 20 µL 100 m*M* ammonium bicarbonate and mix for 5 min.
11. Add additional 30 µL neat acetonitrile and mix until the gel pieces are shrunken and white.
12. Remove the supernatant and dry the gel pieces in a vacuum centrifuge.
13. Add 12.5 ng/µL modified trypsin until the gel pieces are just covered with solvent. If you are using a low sensitivity stain like coomassie blue, the trypsin concentration should be doubled (*see* **Note 8**). Let stand for 5 min before removing excess trypsin containing solvent.
14. Add 50 m*M* ammonium bicarbonate until the gel pieces are just covered.
15. Let the digestion proceed overnight at 37 °C.
16. Extract the excess solvent, which will contain the peptides. Purify the peptides on a Zip tip (Waters) or for higher sensitivity use a home-packed GelLoader tip ***(3)*** using the recommended procedures (*see* **Note 3**).
17. Run the peptide map on a MALDI mass spectrometer in alpha cyano hydroxy cinnamic acid.
18. Analysis of the resulting mass spectra can easily be carried out using World Wide Web based tools (*see* **Note 9**), but be careful to check the results (*see* **Note 8**).

3.3. Reduction and Carboxymethylation of Proteins in Solution

1. Dried sample (20–100 µg) is dissolved in 20 µL 8 *M* urea, 0.4 *M* ammonium bicarbonate buffer (*see* **Note 10**).
2. Add 5 µl 45 m*M* dithiothreitol.
3. Stand at 50 °C for 15 min. Cool to room temperature.
4. Add 5 µL 100 m*M* iodoacetamide.
5. Stand at room temperature for 15 min in the dark.

Purify the protein by reversed phase HPLC (a short Poros R1 column, PerSeptive Biosystems, is well suited), gel filtration or reversed phase solid phase extraction.

For digestion with trypsin, endo Glu-C or lysyl endoproteinase (**Table 1**) you can proceed as follows without prior purification:

1. Add 140 µL water to dilute the urea to less than 2 *M*.
2. Add 2–4 % w/w of the selected enzyme. For prolonged digestion you can add the enzyme in two equal portions with an interval of 4–6 h.

3. Stand for 16–24 h. at 37 °C.
4. Freeze the sample or inject directly onto reversed phase HPLC column. When programming the separation gradient you should start with 2–5 min of isocratic elution in order to let the urea elute from the column before starting the separation of the peptides.

3.4. Digesting in Solution

If your protein contains disulfide bridges you should reduce and alkylate the protein prior to digestion, see above.

1. Dissolve the protein in an appropriate buffer (50 m*M* ammonium bicarbonate, *see* **Note 4**) to a concentration of 1–5 µg/µL. If you have less than 20 µg, you should dissolve in 20 µL.
2. Add the enzyme of your choice (**Table 1**) to a final concentration of 2–4% w/w. Hard to digest proteins and dilute solutions will need a higher enzyme to substrate ratio. For limiting the cleavage to a single or a few positions you can try to lower the concentration to 1% or lower.
3. Most proteins will be digested in 6–8 hours at 37 °C, but conditions may have to be varied to suit each individual protein. For hard to digest proteins you can use extended digestion times (e.g. 24–48 hours or longer) (*see* **Note 4**). For long digestion times it is advantageous to add the enzyme in two equal portions separated by 4–8 hours.
4. Digestions may be stopped by lowering the pH with the addition a small amount of 2% TFA (raising the pH to above 5 in the case of pepsin), by injecting the sample onto the HPLC system or by adding an appropriate enzyme inhibitor.
5. Separate the peptide map by reversed phase HPLC. Prior to separation you may want to extract ½ µL of your sample for MALDI analysis in order to check the extent of proteolysis.

A control reaction run under identical conditions as the main digest should be run in parallel to show which peptides comes from the sample and which are autodigest products or other contaminants. A control digest of a known protein (e.g. beta-lactoglobulin, **Fig. 1**) can also be run to check the activity of the protease.

A special case of peptide mapping is when you want to determine the disulfide bridge structure of a protein.

1. Verify the complete protein structure using standard peptide mapping techniques
2. Use a software tool to determine the optimal cleavage pattern of the target protein (*see* **Note 1**). Remember that disulfide interchange is minimized at low pH. Enzymes like trypsin, Endo Glu-C, Endo Asp-N, Endo Asn-C and pepsin are all active below a pH of 7 and are thus to be preferred.
3. Digest your protein as described above and separate half the sample by reversed phase HPLC.
4. Make the other half of the sample 10 m*M* in dithiothreitol or TCEP (will reduce you sample even at low pH). Let stand for at least 30 min before separation the sample under conditions identical to the separation in step 3).

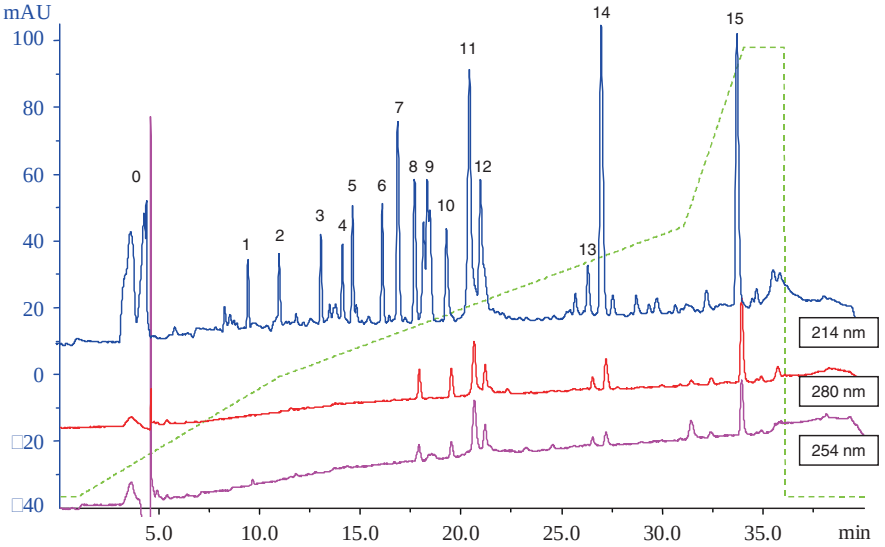

Fig. 1. Tryptic digest of 250 pmol bovine beta lactoglobulin. The traces of 214 nm, 254 nm and 280 nm are shown. The 254 nm and 280 nm traces are expanded x5 compared to the 214 nm trace. The stippled line show the gradient used. The identification of each peak is shown in figure 2. Peak 1 and peak 13 were not identified. Peak 13 is likely to be a partial digest product. The peaks at '0' are a mixture of small peptides and the buffer salts from the injection.

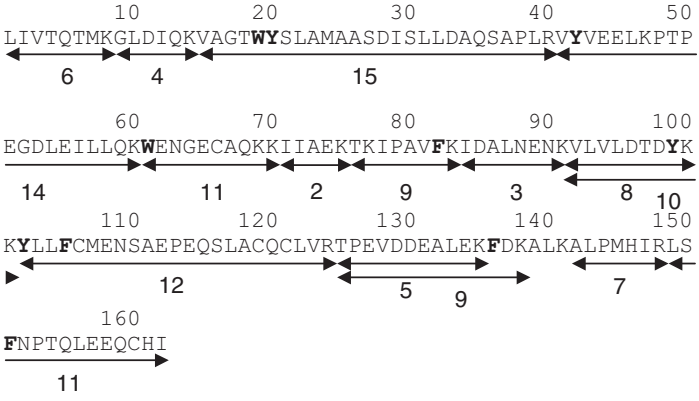

Fig. 2. Identification of the peaks separated in figure 1. Aromatic residues are shown in bold. The two peptides labeled 11 are linked by a disulphide bond (Cys66–Cys160). Peptide 12 has an internal disulphide bond. The peptides labeled 9 elute very close together (fig. 1).

5. Compare the two chromatograms. Peaks that disappear from the first chromatogram and appear in the second chromatogram must arise from Cys containing peptides and will thus have to be identified by mass spectrometry, Edman degradation or amino acid analysis (*see* **Note 10**).
6. Closely spaced Cys residues in the primary structure presents a special problem as you will have to cleave between them for a positive identification of the disulfide bridge. In this case you will often have to isolate a large peptide containing multiple disulfide bridges followed by subdigestion using a less specific enzyme (**Table 1**) ***(5)***.

Mass spectrometry is particularly suited to disulfide bridge determination and several methods have been developed ***(7)***.

3.5. Peptide Map Purification by HPLC

Other chapters in this book deals in detail with the purification of proteins and peptides by HPLC, so the following only emphasis the features relevant to peptide mapping. When purifying a peptide map by HPLC, the objective is usually to obtain the highest possible resolution, sensitivity and yield, but not to handle large amounts. The following description should be read in this context.

For general peptide mapping use a large pore (300 Å), reversed phase column packed with the smallest possible particle size and the longest column length. These parameters are conflicting as backpressure in the system rises with both smaller particle size and longer column length. A compromise is to use a long 250 mm column packed with 5 µm particles or a shorter 150 mm column packed with 3 µm particles. Backpressure in the running system should not exceed 100 bar (increasing the temperature to 45-50 °C using a column oven will lower the back pressure and will additionally increase the resolution slightly).

Using smaller diameter columns will increase the sensitivity of separation, if the HPLC system is optimized for the lower flow, at the cost of lower capacity (*see* **Note 5**). Furthermore, the peak volume from a 2.1 mm column is about 100 µL compared to 400-500 µL from a 4.6 mm column. This makes the volumes more compatible for further downstream processing (e.g. mass spectrometry or Edman degradation) and speeds up lyophilization (*see* **Note 7**).

An in-line UV detector is essential for separating peptide mixtures. As we cannot be certain that all peptides contain aromatic residues, detection has to be carried out at a wavelength low enough to observe the absorbance of the peptide bond. However, as solvents like 0.1% TFA and acetonitrile also absorbs at low wavelength we need to find the wavelength with the highest signal to noise ratio. On most systems this is at 214-215 nm. If you do not operate with the highest purity of solvents, you may have to increase the wavelength to 218-220 nm, but your sensitivity will be reduced by a factor of three.

Multiple wavelength detection (e.g. 254 nm and 280 nm) can greatly increase the confidence of peptide identification (*see* **Note 11**).

3.5.1. Separating a Peptide Map

1. Prepare 1 liter of A-solvent (5% acetonitrile/0.1% TFA in ultra high quality water) and ½ liter of B-solvent (90% acetonitrile in water, 0.85% TFA) (*see* **Notes 6** and **12**). Degas solvents carefully before use or, better, use in-line degassing, as degassed solvents will re-absorb oxygen from the air within a few hours.
2. Program your HPLC system to a gradient of 1%/min from 0% to 40% B-solvent, followed by 2%/min from 40 to 70% B-solvent. Finally step to 100% B-solvent for 2 min before equilibrating at 5% for at least 10 column volumes until you have a stable baseline. If your peptide map is not too complex, you may shorten the run time by increasing the gradient to 1½%/min between 0 and 40% and 2.5–3%/min between 40 and 70%.
3. Make a blind run each morning to equilibrate the column. The first run of a day is usually atypical with a rising or falling baseline that may not be present in subsequent analyses. You can most easily check the condition of your HPLC system and reversed phase column by making a separation run using a standard peptide mixture (e.g. a tryptic digest of β-lactoglobulin) (*see* **Note 13**).
4. Dissolve your sample in A-solvent and inject. Keep the injector in the "inject" position for two injection loop volumes before you switch back to "load" position. If your sample is already dissolved in a different solvent (i.e. urea, tris or phosphate) you should allow 2–3 min of isocratic elution before starting the gradient.
5. Collect the isolated peaks in polypropylene tubes. If you run at low flow rates, you may have to take a delay between the detector and the effluent from the capillary into account (*see* **Note 14**).
6. Dry down your collected fractions in a vacuum centrifuge (*see* **Note 7**). For several applications you may not have to dry the sample; just evaporate the major part of the organic modifier.

For problems in peptide map separations, *see* **Note 2.**

4. Notes

1. When the primary structure of the protein being analyzed is known, a couple of software tools are available for planning the peptide map. These tools can predict the peptides generated by various proteolytic enzymes or chemical cleavages. One freeware tool, PAWS, is available for download (http://bioinformatics.genomicsolutions.com/Paws.html), while a somewhat more advanced tool, GPMAW (http://www.gpmaw.com) *(7)*, will allow you to work with multiple sequences and, in addition to the prediction of peptides, provides additional physical/chemical characteristics of each peptide (e.g. charge, theoretical pI, hydrophobicity and size). GPMAW can even generate a simulated HPLC RP chromatogram. Although this chromatogram is only approximate (separation varies with column, system and

running conditions), it does give valuable indications for problems during separation.

The Expasy web site (http://www.expasy.ch/tools/) contains links to a large number of tools that are useful for peptide mapping (most are included in GPMAW).

2. If your peptide map contains small hydrophilic peptides they will elute very early in the reversed phase chromatogram, perhaps even as part of the solvent peak. Early eluting peaks may also have a bad peak shape, particularly if the column has not been equilibrated sufficiently before the start of the gradient. You may collect these early eluting peaks, dry them sufficiently to get rid of the organic solvent, and then re-separate on a 100–120Å pore size, high carbon load column (e.g. Hypersil ODS2 or equivalent) using 0.1%TFA / 90% methanol as a solvent system. The gradient should be a rather shallow 1%/min. gradient from 0 to 30%. An alternative is to separate hydrophilic peptides using HILIC (hydrophilic interaction chromatography), particularly glycopeptides can be efficiently separated in this way. Running HILIC chromatography is very similar to reversed phase chromatography, but the elution order of components is reversed. You dissolve your sample in high concentration of organic solvent and separate by running the gradient from high to low concentration of organic solvent.

   If on the other hand you have large, hydrophobic peptides you should use a 300Å, C4 or C8 column and elute with either acetonitrile or, for the really hydrophobic peptides, use 2-propanol.
3. The use of reversed phase purification as the last step before analysis of peptide mixtures is necessary to obtain the highest sensitivity and sequence coverage in mass spectrometric peptide mapping. You may use Zip-tips (Waters Inc.), but when analyzing peptide maps isolated from silver stained gel spots you can obtain considerable higher sensitivity by using homemade micro purification tips based on Eppendorf GELoader tips packed with Poros R2 50 µm reversed phase material (Applied BioSystems, Framingham, MA). For the purification of proteins you should use Poros R1 material. For details on how to construct these devices please see ***(8)***

   The GELoader tip is constricted at the end using the blunt end of a pair of tweezers or a pencil. Column material is dispersed in acetonitrile and sufficient material is applied to make a 3–5 mm length column. The GELoader tip is initially washed with 10–20 µL of neat acetonitrile, and then it is equilibrated in 2 × 10 µL of 0.1% TFA. The sample is added in 1–20 µL of solvent followed by washing with 2 × 10 µL of 0.1% TFA. Finally the sample is eluted with 0.8–1 µL of alpha-cyano-4-hydroxycinnamic acid in 70% acetonitrile/0.1% TFA (4 mg/mL to concentrated depending on instrument) directly onto the MALDI target.

4. Most buffers without an excessive amount of detergent or salt are suitable for proteolytic digestion. 50 m*M* ammonium bicarbonate is convenient because it can be removed by evaporation (do not use with lysyl endopeptidase). If you have large quantities or high concentrations of ammonium bicarbonate you may need to add a bit of acetic acid to help completely remove the ammonium bicarbonate. This buffer may be readily substituted for other buffers, e.g. 50 m*M* Tris-HCl, pH 8, or 50 m*M* phosphate buffer, pH 8.0. However, these buffers are not directly compatible with mass spectrometry.

   Hard to dissolve proteins can often be brought into solution by first dissolving the protein in small amount of 6–8 *M* urea (e.g. 5–10 µL) and then diluting the solution to the appropriate level (e.g. below 2 *M* for trypsin, *see* **Table 1**) with a buffer containing the enzyme for digestion. Another very efficient method is to use detergents, however, beware of downstream processing incompatibilities (e.g. SDS is incompatible with mass spectrometry and HPLC). RapiGest SF (Waters) and PPS Silent™ (Protein Discovery) are detergents that upon acidification degrade into smaller components which makes them compatible with both mass spectrometry and HPLC. Organic solvents (*see* **Table 1**) or heat denaturation may denature proteins, thus leading to faster, more efficient digestions ***(9)***.
5. The sensitivity of HPLC separations decreases with the square of the column diameter, thus a 2 mm column shows four times the sensitivity of a 4 mm column, if the HPLC system is built to handle the smaller diameter. As the column diameter decreases from 4 mm to 2 and 1 mm the optimal flow rate decreases from 1 mL/min to 0.25 mL/min and 0.06 mL/min. Unless you perform flow splitting you will need special HPLC pumps to be able to perform a gradient in 0.06 mL/min. In addition, the rest of the HPLC equipment has to be optimized for the lower flow rate in order to minimize extra column band broadening. The inner diameter of capillaries has to be decreased (*see* **Table 2**). You also need to make connections as short as possible, particularly after

Table 2
Parameters for HPLC System for Binary Gradient Formation

	Column diameter	Typical flow mL/min	Flow cell volume	Capillary diameter	Sensitivity increase
Normal	4–4.6 mm	1.0	< 12 µL	0.25 mm / 0.10”	× 1
Narrow	2–2.1 mm	0.2–0.25	< 8 µL	0.18 mm / 0.07”	× 4
Micro	1 mm	0.05–0.07	< 2 µL	0.12 mm / 0.05”	× 16

the column. The size of the detector flow cell is particularly important; as a standard flow cell with a volume of 10–12 µL will significantly decrease the resolution of a 2 mm column, even though the rest of the system is optimized (*see* **Table 2**). When changing to a smaller diameter column you may also have to replace the dynamic mixer as you may otherwise experience very long delay times.

For dual pump systems, each pump should have a minimum flow of no more than 5% of the running flow (e.g. a minimum flow of no more than 12.5 µL/min for a set total flow of 250 µL/min), and a minimum step of no more than 1% of the set flow rate. You may manage with slightly lower performance as the dynamic mixer will smooth out irregularities, but particularly at the beginning of the gradient you may observe irregular separation behavior.

6. TFA deteriorates over time. As the 0.1 % TFA used for buffer A ages you will see an increase in baseline during gradient runs. You may increase/decrease the content of TFA in the B-solvent to compensate. A ratio of 1:0.85 is usually a good starting point, but varies slightly from detector to detector. If you experience regular baseline noise, you can try to lower the content of TFA in buffer A to 0.06% and the content in buffer B correspondingly (0.05%).
7. For small amounts of peptide, the drying step can be critical for recovery as the peptides have a tendency to adhere to the walls of the polypropylene tube ***(10)***. For many analytical purposes it is not necessary to change solvent or you may only have to evaporate the organic solvent.
8. An accurate calibration of your mass spectra is essential for correct protein identification. The most accurate calibration is to use known peaks in each spectrum for internal calibration. When using Promega modified trypsin (porcine) you will find the following autolytic peptides (monoisotopic m/z) that are suited for internal calibration: 842.510, 1045.564 and 2211.105. If these peaks in general are too high or too low, you should adjust the concentration (not the volume) of trypsin added in step 13.

   When analyzing the results of a search, you should consider the following when differentiating between hits:

   How do the deviations between theoretical and experimental masses fit together (i.e. do the deviations lie on a straight line when plotted against the peptide mass you have a calibration error).

   If a peptide contains a methionine it is likely to have a +16 Da peak. The oxidized methionine seldomly occurs by itself.

   N-terminal glutamine containing peptides are always accompanied by a −17 Da satellite peak (deamidation to pyroglutamic acid).

   Multibasic sites often give rise to lysine/arginine ladders (tryptic cleavage).

Missed cleavages (i.e. peptides with an internal Lys or Arg residue) are much more likely to occur if there is a neighboring acidic residue (tryptic cleavage).

In a peptide mixture, (small) lysine-containing peptides are often suppressed relative to arginine containing peptides due to the more basic nature of arginine.

The GPMAW program (*see* **Note 1**) is also useful for checking the validity of a hit as you can perform detailed analysis of likely/unlikely peptide identifications as well as search for unusual enzyme cleavage sites.

9. Several Web sites cater for the analysis of peptide mass data. Some analyze MS data (PMF) others MS/MS data. The actual number changes over time, but you may want to check out the following:

   Mascot (http://www.matrixscience.com)

   ProteinProspector (MsFit) (http://prospector.ucsf.edu/).

   Aldente (http://www.expasy.org/tools/aldente/)

   PeptideSearch (http://www.mann.embl-heidelberg.de/GroupPages/pageLink/peptidesearchpage.html)

   XTandem (http://www.thegpm.org/)

   VEMS (http://yass.sdu.dk/)

   Phenyx (http://phenyx.vital-it.ch/pwi/login/login.jsp)

   You will have to read the accompanying help files for each search engine for detailed instructions.

10. You cannot usually identify reduced cysteine residues by Edman degradation or amino acid analysis, but the surrounding sequence will in most cases be sufficiently unique that positive identification of the peptide is no problem.

11. When separating a peptide map, it is advantageous to use multiple wavelengths. Modern in-line UV detectors can often be set up for three simultaneous wavelengths. You should use 214 nm for separating peptides, as you will get the highest response at this wavelength (you are measuring the absorbance of the peptide bond). Only the aromatic amino acid residues have any significant absorption at higher wavelength. Tryptophan and tyrosine have absorption maxima at 278 nm and 280 nm respectively while phenylalanine has maximum absorbance at 254 nm. You should thus set your detector at 214 nm, 254 nm and 280 nm, Tryptophan is usually recognized by having an absorbance several times that of tyrosine.

12. The inclusion of TFA in the B-solvent is in order to create a stable baseline as both acetonitrile and TFA absorbs at low wavelength. Depending on your system you may have to vary the concentration of TFA in the B-solvent between 0.75 and 0.85 % (*see* **Note 6**).

    Mixing a small amount of organic solvent in the A-solvent and some water in the B-solvent helps to give a better mixing of the solvents (mixing

water and acetonitrile is quite difficult), gives a better separation (helps to "wet" the hydrophobic surface, it may "collapse" in pure water) and helps to degas the A-solvent. If you have hydrophilic peptides that are eluted in the solvent front by the initial 5% organic content, you can use an A-solvent without organic content, but the first part of the chromatogram tend not to be so reproducible.

Column manufacturers recommend that you store the column in 50% methanol/water. However, experience has shown that most columns are stable for several years when stored in 0.1% TFA/acetonitrile (preferably with a high content of organic solvent).

13. Easy-to-make test mixture of peptides for checking reversed phase columns for peptide mapping: Dissolve 182 µg β-lactoglobulin (Sigma Inc, #L0130) in 100 µL, 50 m*M* ammoniumbicarbonate, pH 8.2. Add 3.6 µg trypsin (Roche Biochemicals, #109 819) and digest for 4 hours at 37 °C. Stop the digestion with 900 µL 0.1% TFA. Total solution is now 1000 µL at a concentration of 10 pmol /µL. Divide into 55 µL portions and store at –20 °C. Use 50 µL for 4 mm columns and 20 µL for 2 mm columns. The digest is also useful as calibrant/check for MALDI-MS.
14. If you use an automatic fraction collector you should be careful to calibrate the fraction collector for exact peak collection. In addition you should be careful that the collector adds a minimum of additional peak tubing to the separation system as this will result in delays and mixing of your sample resulting in a loss of resolution. Manual fraction collection is usually more precise but you may (initially) need an assistant to assist in tube handling and annotation. For manual collection a strip chart recorder is most convenient, as computer acquisition or integrators often have an unacceptable delay.
15. Most proteolytic enzymes do not have an absolute specificity, but are active toward several residues with varying activities. Activity towards a given type of residue is usually also dependent on the local environment (e.g. 3-D structure and neighboring residues). Excessive digestion times may thus lead to secondary cleavages that are not desired and may be difficult to predict.

    Most of the enzymes that have a single residue specificity (Lys, Arg, Glu, Asp, Asn) will show some level of activity towards "like" residues.

    While the selection of the specific enzymes can be clearly related to peptide predictions based on the primary structure (e.g. using the GPMAW program), the selection of unspecific enzymes like pepsin, thermolysin and elastase is usually based on other parameters like low solubility of the target protein. They have a difficult to predict, low specificity that is very dependent on the local structure of the substrate. Pepsin is active at pH 2.0, a pH where proteins often are more soluble than at neutral pH.

Thermolysin is active at temperatures as high as 80 °C (even in the presence of 8 *M* urea) where most proteins are denatured. Elastase targets a group of small hydrophilic residues not targeted by any of the "specific" enzymes. These enzymes are usually used either for an initial cleavage where you hope for few cleavage positions to either make a protein soluble or to cleave a large protein into smaller, more manageable pieces. In these cases you have to experiment with short digestion times and/or very dilute solutions. Alternatively the enzymes are used as a final cleavage to identify closely spaced disulfide bridges (see step 4).

16. During digestion, trypsin will autolyse and generate a small amount of ψ-trypsin, which has some chymotryptic activity. In certain cases, depending on the sequence or residual structure of the substrate, this may lead to complete cleavage at single or a few residues in a protein. The activity of trypsin is also affected by neighboring residues as acidic groups will slow cleavages and a following proline residue will in most cases completely inhibit cleavage. If you have neighboring basic residues (e.g. -Lys-Lys-) trypsin may cleave at either residue, but as the activity of trypsin towards terminal residues is considerably lower than towards internal residues, you may find all cleavage variants present in the peptide map even after prolonged digestion times.

    Porcine trypsin is usually preferred rather than bovine, due to less autolysis. Modified trypsin, which is even more resistant to autolysis, is available from a number of manufacturers (**Table 1**).
17. Chymotrypsin has a high activity towards the C-terminal side of aromatic residues, but other residues like Leu and Met can also be cleaved, particularly if they are situated in a hydrophobic environment (mostly -X-X↓Y where X is hydrophobic). Full digestions of intact proteins often give rise to unsuspected peptides, while the specificity when sub-digesting peptides is usually quite high.
18. Endoproteinase Glu-C, also called *S. aureus* protease V8, is a most useful enzyme in protein mapping. Its specificity nicely complements that of trypsin while still generating peptides of a suitable size. The main activity is directed towards the C-terminal of glutamic acid, but a reasonable activity towards aspartic acid means that you may have to control digestion times carefully in order to limit cleavage to Glu. In a few cases activity has also been seen towards Gly, but this is sequence dependent. If the following residue is Glu or Pro, cleavage will not take place (e.g. in a -Glu-Glu- sequence cleavage is only observed after the second Glu). Earlier reports that Endo Glu-C was specific towards Glu at pH 4.0 seem to be caused by the lower activity of the enzyme at this pH ***(11)***.
19. Lysyl endopeptidase, Endo Lys-C, Endo Asp-N, Endo Lys-N, and Endo Asn-C all tend to generate very clean peptide maps with a low amount of secondary cleavages. However, some of the peptides generated may be quite large

and difficult to handle. Endo Asp-N, Endo Lys-N, and Endo Asn-C are considerably more expensive than the other enzymes mentioned but a single optimal digest is more likely to succeed than multiple rounds of digestion and separation.

Endo Arg-C (submaxillary gland proteinase) and clostripain both target the C-terminal side of arginine, but with a significant amount of lysine cleavage. Furthermore, their activity is not very high making them problematic for digesting intact proteins.

Production of Protein Hydrolysates Using Enzymes

John M. Walker and Patricia J. Sweeney

1. Introduction

Traditionally, protein hydrolysates for amino acid analysis are produced by hydrolysis in 6 *N* HCl. However, this method has the disadvantage that tryptophan is totally destroyed, serine and threonine partially (5–10%) destroyed, and most importantly, asparagine and glutamine are hydrolyzed to the corresponding acids. Digestion of the protein/peptide with enzymes to produce protein hydrolysate overcomes these problems, and is particularly useful when the concentration of asparagine and glutamine is required. For peptides less than about 35 residues in size, complete digestion can be achieved by digestion with aminopeptidase M and prolidase. For larger polypeptides and proteins, an initial digestion with the non-specific protease Pronase is required, followed by treatment with aminopeptidase M and prolidase. Since it is important that all enzymes have maximum activity, the following sections will discuss the general characteristics of these enzymes.

1.1. Pronase

Pronase (EC 3.4.24.4) is the name given to a group of proteolytic enzymes that are produced in the culture supernatant of *Streptomyces griseus* K-1 ***(1–3)***. Pronase is known to contain at least ten proteolytic components: five serine-type proteases, two Zn^{2+} endopeptidases, two Zn^{2+}-leucine aminopeptidases, and one Zn^{2+} carboxypeptidase ***(4, 5)***. Pronase therefore has very broad specificity, hence its use in cases where extensive or complete degradation of protein is required. The enzyme has optimal activity at pH 7.0–8.0. However, individual components are reported to retain activity over a much wider pH range ***(6–9)***. The neutral components are stable in the pH range 5.0–9.0 in the presence of calcium, and have optimal activity at pH 7.0–8.0. The alkaline components are stable in the pH range

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3.0–9.0 in the presence of calcium, and have optimal activity at pH 9.0–10.0 ***(4)***. The aminopeptidase and carboxypeptidase components are stable at pH 5.0–8.0 in the presence of calcium ***(9)***. Calcium ion dependence for the stability of some of the components (mainly exopeptidases) was one of the earliest observations made of Pronase ***(2)***. Pronase is therefore normally used in the presence of 5–20 m*M* calcium. The addition of excess EDTA results in the irreversible loss of 70% of proteolytic activity ***(10)***. Two peptidase components are inactivated by EDTA, but activity is restored by the addition of Co^{2+} or Ca^{2+}. One of these components, the leucine aminopeptidase, is heat stable up to 70°C. All other components of Pronase lose 90% of their activity at this temperature ***(5)***. The leucine aminopeptidase is not inactivated by 9 *M* urea, but is labile on dialysis against distilled water ***(2)***. Some of the other components of Pronase are also reported to be stable in 8 *M* urea ***(2)***, and one of the serine proteases retains activity in 6 *M* guanidinium chloride ***(11)***. Pronase retains activity in 1% SDS (w/v) and 1% Triton (w/v) ***(12)***.

Among the alkaline proteases, there are at least three that are inhibited by diisopropyl phosphofluoridate (DFP) ***(10)***. In general, the neutral proteinases are inhibited by EDTA, and the alkaline proteinases are inhibited by DFP ***(4)***. No single enzyme inhibitor will inhibit all the proteolytic activity in a Pronase sample.

1.2. Aminopeptidase M

Aminopeptidase M (EC 3.4.11.2), a zinc-containing metalloprotease, from swine kidney microsomes ***(13–16)*** removes amino acids sequentially from the N-terminus of peptides and proteins. The enzyme cleaves N-terminal residues from all peptides having a free α-amino or α-imino group. However, in peptides containing an X-Pro sequence, where X is a bulky hydrophobic residue (Leu, Tyr, Trp, Met sulfone), or in the case of an N-blocked amino acid, cleavage does not occur. It is for this reason that prolidase is used in conjunction with aminopeptidase M to produce total hydrolysis of peptides. The enzyme is stable at pH 7.0 at temperatures up to 65°C, and is stable between pH 3.5 and 11.0 at room temperature for at least 3 h ***(15)***. It is not affected by sulfhydryl reagents, has no requirements for divalent metal ions, is stable in the presence of trypsin, and is active in 6 *M* urea. It is not inhibited by PMSF, DFP, or PCMB. It is, however, irreversibly denatured by alcohols and acetone, and 0.5 *M* guanidinium chloride, but cannot be precipitated by trichloroacetic acid ***(15)***. It is inhibited by 1,10-phenanthroline (10M) ***(16)***.

Alternative names for the enzyme are amino acid arylamidase, microsomal alanyl aminopeptidase, and α-aminoacyl peptide hydrolase.

1.3. Prolidase

Prolidase (EC 3.4.13.9) is highly specific, and cleaves dipeptides with a prolyl or hydroxyprolyl residue in the carboxyl-terminal position ***(17, 18)***. It has no

activity with tripeptides ***(19)***. The rate of release is inversely proportional to the size of the amino-terminal residue ***(19)***. The enzyme's activity depends on the nature of the amino acids bound to the imino acid. For optimal activity, amino acid side chains must be as small as possible and apolar to avoid steric competition with the enzyme receptor site. The enzyme has the best affinity for alanyl proline and glycyl proline. The enzyme has optimal activity at pH 6.0–8.0, but it is normally used at pH 7.8–8.0 ***(20)***. Manganous ions are essential for optimal catalytic activity. The enzyme is inhibited by 4-chloromercuribenzoic acid, iodoacetamide, EDTA, fluoride, and citrate. However, if Mn^{2+} is added before iodoacetamide, no inhibition is observed ***(21)***.

Alternative names for the enzyme are imidodipeptidase, proline dipeptidase, amino acyl L-proline hydrolyase, and peptidase D.

2. Materials

1. Buffer: 0.05 *M* ammonium bicarbonate, pH 8.0 (no pH adjustment needed) or 0.2 *M* sodium phosphate, pH 7.0 (*see* **Note 1**).
2. Pronase: The enzyme is stable at 4°C for at least 6 mo and is usually stored as a stock solution of 5–20 mg/mL in water at −20°C.
3. Aminopeptidase M: The lyophilized enzyme is stable for several years at −20°C. A working solution can be prepared by dissolving about 0.25 mg of protein in 1 mL of deionized water to give a solution of approx 6 U of activity/mL. This solution can be aliquoted and stored frozen for several months at −20°C.
4. Prolidase: The lyophilized enzyme is stable for many months when stored at −20°C and is stable for several weeks at 4°C if stored in the presence of 2 m*M* $MnCl_2$ and 2 m*M* β-mercaptoethanol ***(18)***.

3. Methods

3.1. Digestion of Proteins (22)

1. Dissolve 0.2-µmol of protein in 0.2 mL of 0.05*M* ammonium bicarbonate buffer, pH 8.0, or 0.2 *M* sodium phosphate, pH 7.0 (*see* **Note 1**).
2. Add Pronase to 1% (w/w), and incubate at 37°C for 24 h.
3. Add aminopeptidase M at 4% (w/w), and incubate at 37°C for a further 18 h.
4. Since in many cases the X-Pro- bond is not completely cleaved by these enzymes, to ensure complete cleavage of proline-containing polypeptides, the aminopeptidase M digest should be finally treated with 1 µg of prolidase for 2 h at 37°C.
5. The sample can now be lyophilized and is ready for amino acid analysis (*see* **Note 2**).

3.2. Digestion of Peptides (22)

This procedure is appropriate for polypeptides less than about 35 residues in length. For larger polypeptides, use the procedure described in **Subheading 3.1.**

1. Dissolve the polypeptides (1 nmol) in 24 µL of 0.2 *M* sodium phosphate buffer, pH 7.0, or 0.05 *M* ammonium bicarbonate buffer, pH 8.0 (*see* **Note 1**).

2. Add 1 µg of aminopeptidase M (1 µL), and incubate at 37°C.
3. For peptides containing 2–10 residues, 8 h are sufficient for complete digestion. For larger peptides (11–35 residues), a further addition of enzyme after 8 h is needed, followed by a further 16-h incubation.
4. To ensure complete cleavage at proline residues, finally treat the digest with 1 µg of prolidase for 2 h at 37°C.
5. The sample can now be lyophilized and is ready for amino acid analysis (*see* **Note 2**).

4. Notes

1. Sodium phosphate buffer should be used if ammonia interferes with the amino acid analysis.
2. When using two enzymes or more, there is often an increase in the background amino acids owing to hydrolysis of each enzyme. It is therefore important to carry out a digestion blank to correct for these background amino acids.

Amino Acid Analysis by Precolumn Derivatization with 1-Fluoro-2,4-Dinitrophenyl-5-L-Alanine Amide (Marfey's Reagent)

Sunil Kochhar and Philipp Christen

1. Introduction

Precolumn modification of amino acids and the subsequent resolution of their derivatives by reverse-phase high-performance liquid chromatography (RP-HPLC) is the preferred method for quantitative amino acid analysis. The derivatization step introduces covalently bound chromophores necessary not only for interactions with the apolar stationary phase for high resolution but also for photometric or fluorometric detection.

Marfey's reagent, 1-fluoro-2,4-dinitrophenyl-5-L-alanine amide or (*S*)-2-[(5-fluoro-2,4-dinitrophenyl)-amino]propanamide, is used to separate and to determine enantiomeric amino acids ***(1)***. The reagent reacts stoichiometrically with the amino group of enantiomeric amino acids to produce stable diastereomeric derivatives, which can readily be separated by reverse-phase HPLC (**Fig. 1**). The dinitrophenyl alanine amide moiety strongly absorbs at 340 nm (ε = 30,000 M^{-1} cm^{-1}), allowing detection in the subnanomolar range. With smaller columns, the sensitivity will correspondly increase.

Pre-column derivatization with the reagent can also be used to quantify the 19 commonly analyzed L-amino acids ***(2)***. Major advantages of Marfey's reagent over other pre-column derivatizations are: (1) possibility to carry out chromatography on any multipurpose HPLC instrument without column heating; (2) photometric detection at 340 nm that is insensitive to most solvent impurities; and (3) stable amino acid derivatives. For the occasional user, the simple methodology provides, an attractive and inexpensive alternative to the dedicated amino acid analyzer. Further development to on-line derivatization and microbore chromatography has been reported ***(3)***. The pre-column derivatization

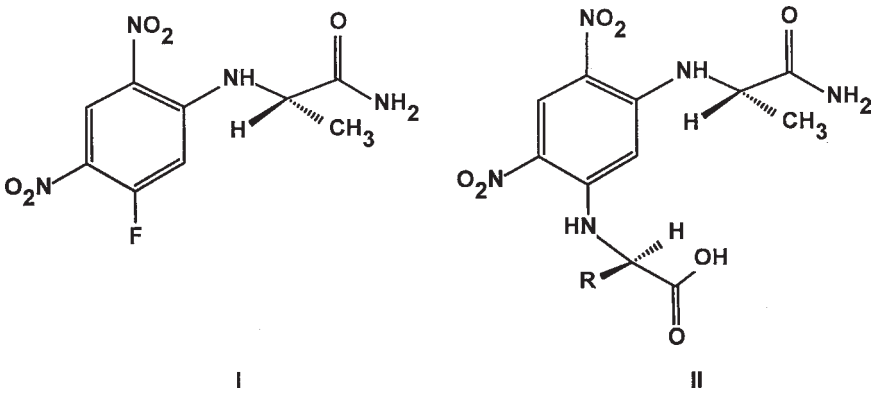

Fig. 1. Marfey's reagent (I) and L,L-diastereomer derivative from L-amino acid and the reagent (II).

with Marfey's reagent has found applications in many diverse areas of biochemical research ***(4–16;*** for recent reviews, see ***17, 18***), including determination of substrates and products in enzymic reactions of amino acids (*see* **Note 1**).

2. Materials

2.1. Vapor-Phase Protein Hydrolysis

1. Pyrex glass vials (25–50 × 5 mm) from Corning.
2. Screw-capped glass vials.
3. 6 *N* HCl 1.from Pierce.

2.2. Derivatization Reaction

1. Amino acid standard solution H from Pierce.
2. Marfey's reagent from Pierce. **Caution: Marfey's reagent is a derivative of 1- fluoro-2,4-dinitrobenzene, a suspected carcinogen.** Recommended precautions should be followed in its handling ***(19)***.
3. HPLC/spectroscopic grade triethylamine, methanol, acetone, and dimethyl sulfoxide (DMSO) from Fluka.

2.3. Chromatographic Analysis

1. Solvent delivery system: Any typical HPLC system available from a number of manufacturers can be used for resolution of derivatized amino acids. We have used an HPLC systems from Bio-Rad (HRLC 800 equipped with an autoinjector AST 100), Hewlett-Packard 1050 system and Waters system.
2. Column: A silica-based C_8 reverse-phase column, for example, LiChrospher 100 RP 8 (250 × 4.6 mm; 5 µm from Macherey-Nagel), Aquapore RP 300 (220 × 4.6 mm; 7 µm from Perkin-Elmer), Nucleosil 100-C_8 (250 × 4.6 mm; 5 µm from Macherey-Nagel), or Vydac C_8 (250 × 4.6 mm; 5 µm from The Sep/a/ra/tions group).
3. Detector: A UV/VIS HPLC detector equipped with a flow cell of lightpath 0.5–1 cm and a total volume of 3–10 µL (e.g., Bio-Rad 1790 UV/VIS monitor,

Hewlett-Packard Photodiode Array 1050, Waters Photodiode Array 996). The derivatized amino acids are detected at 340 nm.

4. Peak integration: Standard PC-based HPLC software with data analysis program can be employed to integrate and quantify the amino acid peaks (e.g., ValueChrom from Bio-Rad, Chemstation from Hewlett-Packard or Millennium from Waters).
5. Solvents: The solvents should be prepared with HPLC grade water and degassed.

a. Solvent A: 13 m*M* trifluoroacetic acid plus 4% (v/v) tetrahydrofuran in water.
b. Solvent B: Acetonitrile (50% v/v) in solvent A.

3. Methods

3.1. Vapor-Phase Protein Hydrolysis

1. Transfer 50–100 pmol of protein sample or 20 µL of amino acid standard solution H containing 2.5 µmol/mL each of 17 amino acids into glass vials and dry under reduced pressure in a SpeedVac concentrator.
2. Place the sample vials in a screw cap glass vial containing 200 µL of 6 *N* HCl.
3. Flush the vial with argon for 5–15 min and cap it airtight.
4. Incubate the glass vial at 110 °C for 24 h or 150 °C for 2 h in a dry-block heater.
5. After hydrolysis, remove the glass vials from the heater, cool to room temperature, and open them slowly.
6. Remove the insert vials, wipe their outside clean with a soft tissue paper, and dry under reduced pressure.

3.2. Derivatization Reaction

1. Add 50 µL of triethylamine/methanol/water (1:1:2) to the dried sample vials, mix vigorously by vortexing, and dry them under reduced pressure (*see* **Note 2**).
2. Prepare derivatization reagent solution (18.4 m*M*) by dissolving 5 mg of Marfey's reagent in 1 mL of acetone.
3. Dissolve the dried amino acid mixture or the hydrolyzed protein sample in 100 µL of 25% (v/v) triethylamine in water and add 100 µL of the Marfey's reagent solution and mix by vortexing (*see* **Note 3**).
4. Incubate the reaction vial at 40 °C for 60 min with gentle shaking protected from light (*see* **Note 4**).
5. After incubation, stop the reaction by adding 20 µL of 2 *N* HCl (*see* **Note 5**). Dry the reaction mixture under reduced pressure.
6. Store the dried samples at −20 °C in the dark until used (*see* **Note 6**).
7. Dissolve the dry sample in 50% (v/v) DMSO.

3.3. Chromatographic Analysis

1. Prime the HPLC system according to the manufacturer's instructions with solvent A and solvent B.
2. Equilibrate the column and detector with 90% solvent A and 10% solvent B.
3. Bring samples for analysis to room temperature; dilute, if necessary, with solvent A, and inject 20 µL (50–1000 pmol) onto the column (*see* **Note 7**).

4. Elute with gradient as described in **Table 1** (*see* **Note 8**). Resolution of 2,4-dinitrophenyl-5-L-alanine amide derivatives of 18 commonly occurring L-amino acids and of cysteic acid is achieved within 120 min (**Fig. 2**) (*see* **Note 9**).
5. Determine the response factor for each amino acid from the average peak area of standard amino acid chromatograms at 100, 250, 500, and 1000 pmol amounts.
6. When HPLC is completed, wash the column and fill the pumps with 20% (v/v) degassed methanol for storage of the system. Before re-use, purge with 100% methanol.

Table 1
HPLC Program for Resolution of Amino Acids Derivatized with Marfey's Reagent

Time (min)	% Solvent A	% Solvent B	Input
0	90	10	
15	90	10	Detector auto zero Inject
15.1	90	10	
115	50	50	
165	0	100	
170	0	100	

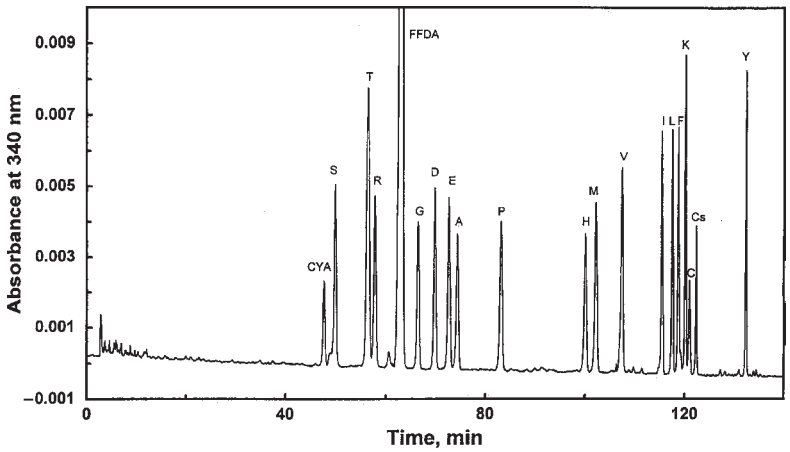

Fig. 2. Separation of 2,4-dinitrophenyl-5-L-alanine amide derivatives of L-amino acids by HPLC. A 20-µL aliquot from the amino acid standard mixture (standard H from Pierce Chemical Company) was derivatized with Marfey's reagent. Chromatographic conditions: Column, LiChrospher 100 RP 8 (250 × 4.6 mm; 5 µm from Macherey-Nagel); sample, 100 pmol of diastereomeric derivatives of 18 L-amino acids; solvent A, 13 m*M* trifluoroacetic acid plus 4% (v/v) tetrahydrofuran in water; solvent B, 50% (v/v) acetonitrile in solvent A; flow rate, 1 mL/min; detection at 340 nm; elution with a linear gradient of solvent B in solvent A (**Table 1**). The amino acid derivatives are denoted by single-letter code, cysteic acid as CYA and cystine as Cs. FFDA indicates the reagent peak; the peaks without denotations are reagent-related as shown in an independent chromatographic run of the reagent alone.

4. Notes

1. For analysis of amino acids as substrates or products in an enzymic reaction, deproteinization is required. Add 4 *M* perchloric acid to a final concentration of 1 *M* and incubate on ice for at least 15 min. Excess perchloric acid is precipitated as $KClO_4$ by adding an equal volume of ice-cold 2 *M* KOH. After centrifugation for 15 min at 4 °C, the supernatant is collected, dried, and used for derivatization.
2. Complete removal of HCl is absolutely essential for quantitative reaction between amino acids and Marfey's reagent.
3. The molar ratio of the Marfey's reagent to the total amino acids should not be more than 3:1.
4. During derivatization, the color of the reaction mixture turns from yellow to orange-red.
5. On acidification, the color of the reaction mixture turns to yellow.
6. The dried amino acids are stable for over one month when stored at −20 °C in the dark. In 50% (v/v) DMSO, derivatives are stable for 72 h at 4 °C and for > 6 wk at −20 °C.
7. To obtain good reproducibility, an HPLC autoinjector is highly recommended.
8. Silica-based C_8 columns from different commercial sources produce baseline resolution of the 19 amino acid derivatives; nevertheless, the gradient slope of solvent B should be optimized for each column. *S*-carboxymethyl-L-cysteine and tryptophan, if included, are also separated in a single chromatographic run (*see* **ref. *2***).
9. The identity of each peak is established by adding a threefold molar excess of the amino acid in question. A reagent blank should be run with each batch of the Marfey's reagent to identify reagent-related peaks. Excess reagent interferes with baseline separation of the arginine and glycine peaks. Lysine and tyrosine are separated as disubstituted derivatives.

Amino Acid Analysis of Protein Hydrolysates Using Anion Exchange Chromatography and IPAD Detection

Petr Jandik, Jun Cheng, and Nebojsa Avdalovic

1. Introduction

Following the commercial introduction as "AAA Direct," amino acid analysis by anion exchange chromatography and integrated pulsed amperometric detection (IPAD) ***(1)*** has been applied in many different types of amino acid assays ***(1–16)***. The new method does not require any derivatization. It is thus easier to use and less costly than derivatizaton-based methods. Additional savings are achieved by the relatively inexpensive single-component mobile phases and by the low flow rate (0.25 mL/min).

The limits of detection are in the femtomol range and linear calibration plots extend over three orders of magnitude for the most amino acids ***(1)***.

Various protocols for analyzing protein and peptide hydrolysates are outlined in the literature ***(1,9–11)***. The results obtained for a collagen hydrolysate were compared with those generated by cation exchange / ninhydrin method ***(1)***. Simultaneous analysis of carbohydrates and amino acids was reported by several authors ***(12–16)***. The use of the technique for monitoring and control of metabolism in mammalian cell has been discussed ***(16)***.

In this chapter, we provide suitable protocols for the validation of reproducibility and accuracy. Such validation should be performed not only during a start up but also in regular intervals during the routine use. Evaluation of reproducibility is made easier by a new report format of Dionex software.

We expect many of the new users of AAA Direct to be experienced in one of the post- or pre-column derivatization techniques. In anticipation, we include guidelines for the selection of compatible buffers, surfactants and reagents.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

Several of the compounds that are not compatible or difficult to use with the older methods do not cause any problems when utilized in conjunction with the AAA Direct (i.e. Triton X100, urea, ammonia from the hydrolysis of polyacrylamide, sodium hydroxide). On the other hand, some chemicals that are in widespread use in the pre- or post-column derivatization-based protocols do interfere, if utilized with our method. The most important examples of the latter category are tris(hydroxymethyl)aminomethane (Tris) or carbohydrates when present in high concentrations. However, both Tris and carbohydrates interfere only within the simplest format of AAA Direct. Recently, the authors have reported a modified version of AAA Direct overcoming Tris and carbohydrate interference ***(17,18)***.

2. Materials

2.1. Chromatography

1. Water 18 megohm (Millipore, Bedford, MA, Milli Q or equivalent, *see* **Note 1**)
2. Sodium hydroxide solution 50% w/w (Certified Grade, Fisher Scientific, Pittsburgh, PA)
3. Sodium acetate, anhydrous (Microselect Grade, FLUKA, Milwaukee, MI)
4. Helium or argon gas cylinder, pressure regulation valve, Tygon tubing connecting cylinder to eluent containers.
5. Sterile filtration units from Nalge (0.2 µm Nylon filter in covered funnels, vol = 1 L, VWR, West Chester, PA)
6. Serological glass pipets, vol =10 mL (Fisher Scientific)
7. Eluent A: Water 18 megohm filtered through a 0.2 µm Nylon filter (*see* **Notes 2** and **3**)
8. Eluent B: Filter 1 L of water through a 0.2 µm Nylon filter; using the serological pipets (see **Note 4**), add 13.1 mL of 50% sodium hydroxide to the filtered 1L-volume of water (see **Note 3**).
9. Eluent C: Dissolve 82 g of anhydrous sodium acetate in ca. 500 mL of water. Fill up to 1L and filter through the 0.2 µm Nylon filter.
10. AminoPac PA10 Guard Column (2 × 50mm) and AminoPac PA10 analytical column (2 × 250mm).
11. Ternary low-pressure gradient, microbore, HPLC system, Dionex BioLC or comparable with an autosampler (e.g. Dionex AS50) and column thermostat. The system must include Dionex ED40 electrochemical detector.
12. AAA certified gold cell for use with the ED40 detector.
13. PC with installed copy of Dionex PeakNet 6.1 or equivalent (*see* **Note 5**).

2.2. Reproducibility Testing Using Injections of Standards

1. Amino Acids in 0.1 *M* HCl, Standard Reference Material 2389 (National Institute of Standards and Technology, Gaithersburg, MD)
2. Norleucine (Sigma, St. Louis, MO)
3. Sodium azide (Sigma)
4. 0.1 *M* HCl (reagent grade)

5. Diluent containing norleucine and sodium azide: Prepare 4 m*M* stock solution of norleucine (524.8 mg/L) in 0.1 *M* HCl. Dilute 500x with a solution of azide (20mg/L).
6. Reproducibility Standard: pipet 320 µL of SRM 2389 into a 100 mL volumetric flask and fill up to volume with the norleucine diluent. If stored in a refrigerator, the Reproducibility Standard is stable for up to 30 days. If used at room temperature, the Reproducibility Standard remains stable for up to three days (i.e. over a weekend).
7. The Reproducibility Standard from **item 6** does not contain all of the standard compounds that are required for the analysis of certain types of hydrolysate samples. These standards can be purchased from Sigma and are listed below: δ-hydroxylysine, D(+)-galactosamine hydrochloride, D(+)-glucosamine hydrochloride, hydroxy-L-proline, phospho-L-arginine sodium salt, o-phospho-D,L-serine, o-phospho-D,L-threonine, o-phospho-D,L-tyrosine, L-cysteic acid hydrate and L-tryptophan.
8. Prepare 1 mM, single component solutions of all standards from step 7 in 0.1 M HCl and store them in a refrigerator. As required, add 100 µL of one or more of the above single-component stock solution to the Reproducibility Standard (step 6).
9. Disposable transfer pipets (glass or polyethylene)

2.3. Accuracy of Amino Acid Analysis in a BSA Hydrolysate

1. Bovine serum albumin (7% solution) Standard Reference Material 927c (National Institute of Standards and Technology, Gaithersburg, MD)
2. Hydrolysate glass tubes with Teflon Plugs (Pierce, Rockford, IL)
3. Speedvac (Savant, Farmingdale, NY)
4. Heating Module with aluminum heating block (Pierce)
5. Constant Boiling HCl (Pierce)

2.4. Selecting Suitable Buffers, Surfactants and Reagents (see Note 6)

1. Buffers, surfactants, and reagents found to be compatible with AAA Direct: ACES (*see* **Note 7**); ADA; AMPSO; CAPS (*see* **Note 7**); CAPSO; CHES (*see* **Note 7**); citric acid (Fluka); EDTA (Aldrich); MES (Boehringer Manheim); MOBS; MOPS; MOPSO; n-octyl-β-glucoside (*see* **Note 8**); phenol; PIPES (*see* **Note 7**) sodium diphosphate; sodium monophosphate; sodium triphosphate; sodium azide; TES; TRITON X 100 (Aldrich).
2. Buffers, surfactants, and reagents producing *interfering* peaks in AAA Direct: BES (BDH Chemicals, Poole England); Bicine; BISTRIS (*see* **Note 9**); CHAPS; CHAPSO; DTE; EPPS; HEPES; imidazole; TEA (*see* **Note 8**); Tricine (*see* **Note 9**); TRIS (*see* **Note 9**).

3. Methods

3.1. Chromatography (see Note 10)

The chromatogram in **Fig. 1** was generated using the gradient conditions in **Table 1** and detection conditions in **Table 2**. We recommend using those conditions for all reproducibility and accuracy testing described below.

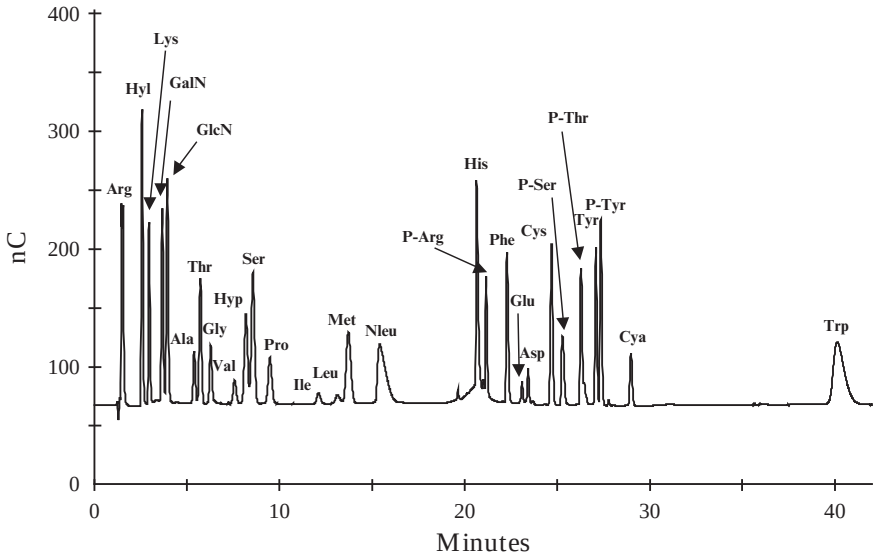

Fig. 1. Simultaneous separation of amino acids (including hydroxy-proline and hydroxy-lysine, or Hyp and Hyl, respectively), amino sugars (GalN and GlcN), phospho amino acids (P-Arg, P-Ser and P-Thr) and cysteic acid (Cya) under the conditions of standard AAA Direct gradient.

Fig. 1 illustrates the capability of AAA Direct for protein and peptide hydrolysates. All common types of hydrolysates (HCl, HCl /propionic acid, MSA, NaOH,) can be analyzed under identical gradient and detection conditions. An important exception is the separation of methionine sulfone, that can be achieved only at the column temperature of 35 °C (See **ref *9***). In contrast, the correct column temperature for all other separations (including that in **Fig. 1**) is 30 °C.

1. Connect the fully assembled ED40 cell directly to the injector outlet. Running the initial gradient conditions (76%A, 24%B at 0.25 mL/min) switch the cell voltage on (Specify "Integrated Amperometry" and apply Waveform from **Table 2**). Verify that the signal is lower than 80 nC.
2. Install the AminoPac PA10 column set and check again that the signal background is at less than 80 nC.
3. Allow the column oven to reach 30 °C and run a blank gradient (*see* **Table 1**) injecting 25 µL of water. Verify that gradient rise is not exceeding 30 nC.
4. Prepare an aliquot of Reproducibility Standard (**Subheading 2.2, item 6**) and place it into the autosampler. Follow proper procedures in executing the first standard injection (vol = 25 µL) by not allowing any delay between the end of the blank gradient run and first injection of standard.
5. Verify the absence of extraneous peaks in the blank gradient and a correct value of peak height for arginine (>100 nC). Verify the presence of peaks for all amino

acids. P-amino acids, hydroxylysine, hydroxyproline, amino sugars, cysteic acid and tryptophan are not present in the Reproducibilty Standard. Verify that the separation between alanine and threonine in the Reproducibility Standard chromatogram is comparable to that in **Fig. 1**.

3.2. Reproducibility Testing Using Injections of Standards

1. Verify the system status by carrying out steps 1-5, **Subheading 3.1**.
2. Transfer 1.5 mL of Reproducibility Standard (**Subheading 2.2, step 6**) into a glass autosampler vial. Place the full vial into the autosampler. Make sure there is also a vial with water inside the autosampler.
3. Create a "PeakNet Sequence" for running a blank gradient (vol = 25 µL injection of water, **Table 1** gradient, **Table 2** waveform) followed by nine injections of Reproducibility Standard (vol = 25 µL "Full Loop," **Table 1, Table 2**). Do not perform more than nine vol =25 µL Full-Loop-injections out of a single 1.5 mL-vial.
4. Create or update a quantitation method (.qnt) and include it in the PeakNet sequence. A meaningful evaluation of reproducibility relies on correct identification and integration of all peaks of interest. The correct identification and integration is dependent on a correct user input of retention times and integration parameters (*see* **Note 11**). The retention times can be updated and integration parameters optimized during the

Table 1

first standard run. It is not necessary to input pmol amounts for amino acids and to carry out a calibration at this stage as reproducibility is evaluated from the relative standard deviations of peak areas.

5. Following the completion of all standard runs, verify correct identification and integration of all peaks by inspecting all nine standard chromatograms separately. Close the files you opened for identification and integration verification.
6. Select all nine standard chromatograms simultaneously (press Ctrl. and click on corresponding row numbers). In the menu that opens up by rightclicking on one of the selected rows, choose "compare>ECD1" and an overlay of all selected chromatograms appears on the screen.
7. Rightclick anywhere in the upper-right portion of the chromatographic overlay. In the menu that now appears choose "Load Report Format>%RSD Peak Areas" (*see* **Note 12**) to generate a similar report as the one shown in **Fig. 2**.
8. Rightclick in the upper-right portion of the screen, go to "Load Report Format" again and switch to %RSD Retention Times (actual report not shown).

3.3. Accuracy of Amino Acid Analysis in a BSA Hydrolysate

The following protocol utilizes a data reduction procedure producing three numerical QC values, "Average % Error," Recovery [g],"and "% Recovery," characterizing the accuracy of results for a protein of known amino acid composition.

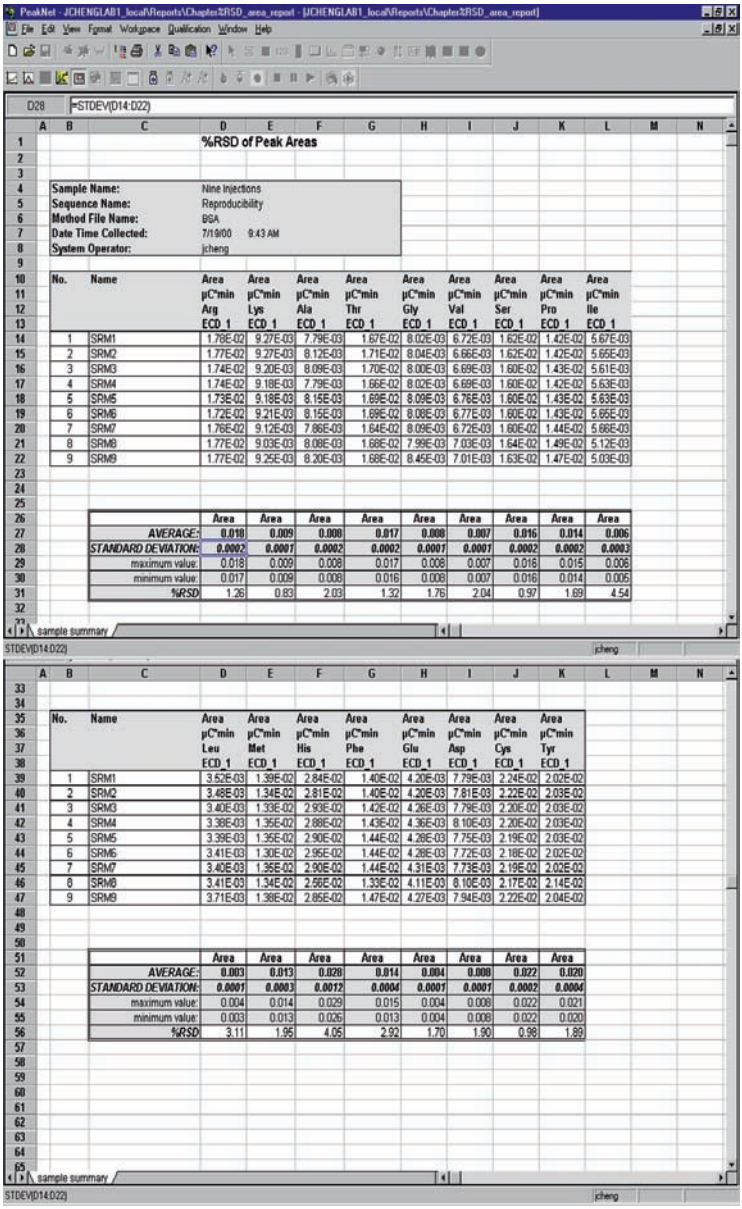

Fig. 2. Reproducibility Report. Relative standard deviations for each amino acid are listed in the bottom row. The report is linked to all data files in a given PeakNet Sequence. Any change of integration parameters produces instant updates of the corresponding area, average, and %RSD values.

$$\textbf{Average \% Error} = (\Sigma\ \%\ \textit{Error}\ \text{of 16 amino acids}) / 16 \quad (1)$$

Where:
% Error = 100* ABS (analytical result for *n* – true value for *n*)/true value for *n*
ABS (x): absolute value of x
n = number of each amino acid per molecule

$$\textbf{Recovery [g]} = \{(\textit{Corrected Average Ratio}) * \text{molecular weight of protein}\} \quad (2)$$

Where:
Corrected Average Ratio: mean value of those *First Ratios* values deviating by less than 20% from the Average of *First Ratios* (*Corrected Average Ratio* represents the analytical result for the mol-amount of protein injected)
First Ratio = analytical result in pmol of amino acid/ true value of *n*

$$\textbf{\% Recovery} = \{(\textbf{Recovery [g]} * \textbf{8}\}/\ \text{g of Protein in 200 µL of hydrolysate}) \quad (3)$$

This data reduction approach has been used, for example, in the "multicenter" (round robin) studies organized by the Association of Biomolecular Resource Facilities or ABRF ***(19)***. Evaluation of accuracy is simplified in AAA Direct by an automatic calculation of QC parameters from pmol results after calibration. As in the reproducibility evaluation (**Subheading 3.2**), the parameters are cal culated directly within the HPLC software. It is not necessary to export area or pmol results into another application such as Excel first (*see* **Note 14**).

As a protein of known amino acid composition, we have chosen the 7 % BSA solution from the National Institute of Standard and Technology (**Subheading 2.3**, **item 1**). The amino acid composition of BSA can be obtained in the literature ***(20)***. The NIST documentation certifies that the SRM 927c is from bovine blood and has the correct molecular weight and spectral properties for BSA. It also states that the SRM 927c may be used for calibration in amino acid analysis. The SRM 927c documentation, however, does not certify the amino acid composition of the actual protein sample used to prepare the 7% solution.

1. Prepare a 500fold dilution of SRM 927c in water containing 20 mg/L sodium azide.
2. Transfer 33.6 µL of 500x dilute SRM 927c into a clean microvial (vol=1.5 mL) and carry out evaporative centrifugation (Speedvac) to dryness.
3. Add to the dry residue 100 µL of constant boiling HCl and vortex thoroughly.
4. Using glass Pasteur pipets transfer the solution to a clean hydrolysis tube (**Subheading 2.3, step 2**).
5. To the microvial emptied in step 4, add a new 50 µL aliquot of constant boiling HCl, vortex and subsequently transfer as much as possible of the 50 µL aliquot to the sample in the hydrolysis tube from step 4. Use the same transfer pipet as in **step 4**.

6. Alternate vacuum and inert gas inside the hydrolysis tube three times. Place fully evacuated tube into a heating module (**Subheading 2.3, item 4**). Carry out hydrolysis for 16–24 hours at 110 °C.
7. Remove the hydrolysis tube from the heating module and allow it to cool down to the ambient temperature.
8. Using a clean glass Pasteur pipet transfer the hydrolyzed sample from the hydrolysis tube into a clean microvial.
9. Pipet another 50 µL aliquot of constant boiling HCl into the hydrolysis tube from **step 8**. Rinse and subsequently transfer as much as possible of the 50 µL aliquot to the first aliquot of hydrolysate in the microvial. Use the same transfer pipet for steps 8 and 9.
10. Carry out evaporative centrifugation of the combined hydrolysate aliquots from steps 8 and 9.
11. To the completely dry residue from step 10, add 200 µL of norleucine/azide diluent (**Subheading 2.2, item 5**) and vortex thoroughly.
12. Transfer an aliqot of the reconstituted hydrolysate into an autosampler vial (Polyethylene vial, (vol=0.3 mL, with a split septum, Dionex). Make sure that vials with water and calibration standard have also been placed into the autosampler tray.
13. Create a "PeakNet Sequence" starting with an injection of water blank and followed by at least three injections of both, the calibration standard (**Subheading 2.2, item 6**) and hydrolyzed sample. Use a program file (.pgm) that includes the gradient and waveform from **Tables 1** and **2**, respectively. Input correct pmol amounts (*see* **Note 15**) into the Amount Table of the quantitation method (.qnt, **Subheading 3.2, step 4**). Use 25 µL Fool-Loop injections for all samples and standards. In the quantitation method, specify the sequence line containing the calibration standard. Start the automatic execution of the entire sequence.
14. After executing all runs, inspect each standard and sample chromatogram. Verify correct identification and integration of all amino acid peaks.

In a hydrolysate chromatogram, rightclick in the upper-right portion of the chromatogram. In the menu that now appears choose "Load Report Format>QCBSA (see **Note 14**)." A similar report as the one in **Fig. 3** appears on the screen.

15. Make sure to input the actual concentration of BSA in the hydrolysate as specified in the report subtitle (line 3). Switch to "Layout Mode" (Edit>Layout Mode) to enable input of BSA concentration. The calculated values of Average % Error, Protein Recovery [g] and % Protein Recovery appear instantaneously in the lower half of the report page. The BSA QC report is now ready to be saved or printed out.
16. Additional QC Reports for the other BSA hydrolysate injections can be generated by moving from one sample file to another using the corresponding two icons on the screen (left and right arrow, top bar, third row). To complete the documentation, it is also possible to generate the %RSD Area , %RSD Retention Times reports for the standard injections of the same sequence by carrying out the steps 6 to 8 of the **Subheading 3.2.**

Fig. 3. Accuracy Report. The upper table is the usual "Amount Table" of PeakNet HPLC software. The pmol amounts in the sample are calculated from the pmol/area coefficients in the calibration file. The lower of the two tables evaluates equations (*1–3*) in the **Subheading 3.3**. This report is also linked to all data files of a given sequence. Any change of integration parameters produces an instant change of all calculated results.

3.4. Selecting Suitable Buffers, Surfactants, and Reagents

1. Generate chromatograms of 1 m*M* solutions of all buffers, surfactants and reagents present in your protein or peptide samples.
2. Hydrolyse (**Subheading 3.3.,** steps 6–12) 20 µL aliquots of 10 mM solutions of all buffers, surfactants and reagents in 180 µL of constant boiling HCl.
3. Generate chromatograms of hydrolyzed and reconstituted (azide/norleucine diluent) samples from steps 1 and 2 using the chromatographic conditions of **Subheadings 3.2 and 3.3**.
4. Avoid using chemicals causing peaks interfering with amino acids or carry out desalting prior to hydrolysis of protein solutions containing such additives. See **Subheading 2.4**. for guidelines in the selection of new additives.
5. Repeat steps 1-4 for all new batches of additives.

4. Notes

1. Minimize extraneous plastic tubing connected to the laboratory water unit and use only filters supplied by the manufacturers. Polymeric surfaces support bacterial growth. Bacterial contamination of water used in preparation of eluents causes high backgrounds and spurious peaks in amino acid analysis.
2. The main purpose of eluent filtration is to eliminate bacterial contamination stemming from the water purification unit and from the atmosphere. Wear powder-free gloves whenever preparing or replenishing mobile phases to avoid contamination by skin contact.
3. Minimize carbonate contamination of the eluents. Follow the guidelines in the Installation Instructions and Troubleshooting Guide for AAA Direct Amino Acid Analysis System (Dionex Document No. 031481).
4. Most vol=10 mL pipets can be used for the prescribed volume of 13.1 mL. Usually this larger volume is at or near the markings for the maximum possible volume. Verify the correct height of 13.1 mL by pipeting and weighing out water. Do not re-use serological pipets.
5. Make sure that the "Report Publisher" option is part of the installed software and it is switched on. (In the Pull-down menu: Help/About PeakNet)
6. Except where indicated otherwise, all of the buffers, reagents and surfactants were purchased from Sigma.
7. Four of the buffers that we evaluated (ACES, CAPS, CHES, PIPES) gave well-defined peaks, sufficiently separated from those of hydrolysate amino acids under the gradient conditions in **Table 1**. Users are advised to run control blanks when planning to utilize those buffers. Some of the peaks appear to be impurities unrelated to the actual buffer compound and may vary depending on the source and age of the chemical.
8. Glucoside-based surfactants produce a large interference peak when injected directly. However, they are completely hydrolyzed after 16–24 hours and

110 °C in constant boiling HCl and do not thus interfere in a completely hydrolysed sample.

9. Several of the non-anionic buffers (BISTRIS, TEA, TricineTRIS) produce a large peak interfering with arginine. This interference can be resolved using the modified AAA Direct technique described in **ref.** ***(17)***.
10. A copy of the Installation Instructions and Troubleshooting Guide for the AAA Direct Amino Acid Analysis (Dionex Document No. 031481) is included with each AminoPac PA10 column shipped by Dionex. The text under Heading 3 describes only a subset of AAA Direct methodology used for reproducibility and accuracy testing.
11. Optimization of integration parameters and other general guidelines for reproducible quantitation are described in "PekNet 6 User's Guide." (Dionex Document No. 031630). Specify the version of PeakNet you are running when ordering the document from Dionex.
12. The "Excel-like" environment in the report part of Dionex HPLC software makes it possible for a user to create many different report formats executing simple or complex mathematical formulas. However, the user has to purchase the "Report Publisher" option to be able to generate a custom report format (*see* **Note 5** for verification of presence of Report Publisher in the installed software). The electronic files for reproducibility evaluation without installing the Report Publisher can be obtained from Dionex Customer Support. Specify "Reproducibility Evaluation of AAA Direct" when ordering the report format file.
13. A comprehensive evaluation of AAA Direct in conjunction with hydrolysis of peptides in HCl and MSA is presented in **ref.** ***(10)***. **Reference** ***(9)*** contains detailed protocols for HCl, MSA (with and without performic acid oxidation) and NaOH hydrolysates. Also described in **ref.** ***(9)*** is a new method for using the same set of chromatographic conditions for automatic analysis of carbohydrates, amino sugars and amino acids in different types of TFA and HCl hydrolysates of glycoproteins.
14. As in the reproducibility evaluation (**Subheading 3.2** and **Note 12**), it is possible for a user to create highly customized report formats for the QC parameters of accuracy evaluation. The user has to have either the "Report Publisher" option installed on the PC (see **Note 5**) or obtain a suitable report format file from Dionex customer support. Specify "Accuracy of Amino Acid Analysis" when ordering the report format file from Dionex.
15. For a 321.5-fold dilution of SRM 2389 and 25 µL injection, divide all values in **Table 1** of SRM 2389 by 0.0125. For example: the original concentration of 2.50 mmol/L of aspartic acid yields 200 pmol amount to be entered into the Amount Table.

Validation of Amino Acid Analysis Methods

Andrew J. Reason

1. Introduction (*see* Notes 1–4)

This chapter presents a discussion of the points to consider during the validation of analytical methods and more specifically amino acid analysis. Amino acid analyses are utilised in various areas of research for free amino acids (in, for example, foodstuffs) and for analysis of products and components of interest comprising peptides, polypeptides and peptide/protein conjugates. In this Chapter, I have concentrated on the validation of amino acid analyses that are to be submitted in a package to obtain a regulatory authority licence for a peptide, protein, or conjugate product. In such studies, amino acid analyses can be used to provide various pieces of information generally required for biotechnological and/or biological products. For example quantitative amino acid analysis can be used to determine protein quality and quantity. Such data, combined with Optical Density (OD) measurements, can be used to determine the extinction coefficient for a protein.

Analyses that are to be submitted in a package to obtain a regulatory authority licence for a particular product should be validated in accordance with the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) Harmonised Tripartite Guidelines "Validation of Analytical Procedures: Text and Methodology" ***(1)*** except where there are specific issues for unique tests used for analyzing biotechnological and biological products ***(2)***. The terms and definitions within these documents are meant to bridge the differences that often exist between the regulators in Europe, Japan and USA. The validation criteria discussed below can be assessed using both precolumn and postcolumn amino acid analysis derivatization methods. The available techniques are described in detail in other chapters of this book ***(10–15)***. Requirements of speed and sensitivity have led

M-Scan to utilize a method involving acid hydrolysis followed by precolumn derivatization using phenylisothiocyanate and separation by reverse-phase high-performance liquid chromatography (RP-HPLC) for amino acid analysis. This method is used as a background to the discussion of validation of amino acid analysis methods.

2. Materials

2.1. Equipment for Hydrolysis of Proteins and Precolumn Derivatization of the Released Amino Acids (See Note 5)

1. An RP-HPLC system equipped with a Supelcosil LC-18-DB (250 × 4.6 mm, 5 µm; Supelco, Poole, UK) HPLC column, and capable of tertiary solvent/buffer supply, gradient control, autoinjection, UV detection at 254 nm and data acquisition (*see* **Note 6**).
2. Vacuum hydrolysis tubes (Pierce, Rockford, IL) 5 mL internal volume.
3. Vacuum pump system capable of evacuating hydrolysis tubes to 1–2 Torr.
4. Oven or dry heating block capable of heating vacuum hydrolysis tubes to hydrolysis temperature (usually 110°C).

2.2. Chemicals (see Note 5)

2.2.1. Hydrolysis of Proteins and for Precolumn Derivatization of the Released Amino Acids

1. Constant boiling 6 *M* HCl (Pierce).
2. Coupling buffer, acetonitrile:pyridine:water:triethylamine (10:5:3:2 v/v).
3. Phenylisothiocyanate (Pierce).
4. Amino Acid Standard H (Pierce), containing a mixture of 17 amino acids at 2.5 m*M* (cystine at 1.25 *M*) in 0.1 *M* HC1 (*see* **Note 7**).
5. Internal standard, L-Norleucine (Pierce).

2.2.2. RP-HPLC Separationof Derivatized Amino Acids

1. Solvent A: Ultra High Quality (UHQ) water (1 L).
2. Solvent B: Acetonitrile (HPLC grade):UHQ water (80:20 v/v), 1 L.
3. Buffer C, Weigh out 28.7g of anhydrous sodium acetate and dissolve in 500 mL of UHQ water ensuring that all the solid dissolves. Add 1.25 mL of triethylamine and adjust the pH of the buffer to 6.4 using glacial acetic acid.
4. Sample loading solvent, Solvent A:Solvent B:Buffer C (75:5:20 v/v).

3. Methods

3.1. Preparation of Amino Acid Standard Mixture

1. Weigh out a known amount of norleucine internal standard (~1 mg).
2. Dissolve the weighed internal standard (Norleucine) in 5% (v/v) acetic acid in water to generate a 1 nanomole/µL solution. This solution is stable for up to 12 mo at −20° C ± 5°C and can be used as the internal standard bulk solution.

3. An aliquot (50 µL) of the resulting solution, i.e., 50 nmoles is added to each sample being prepared for amino acid analysis and to the tube to be used for the amino acid standard mixture.
4. Add 20 µL of Amino Acid Standard H to 50nmoles of the norleucine (internal standard) in the tube set aside for the standard mixture.
5. The standard mixture of amino acids including the internal standard (norleucine) is derivatized in parallel with the samples to be studied (*see* **Subheading 3.3**).

3.2. Hydrolysis (see Notes 8 and 9)

1. Aliquot the desired amount of peptide, protein or conjugate (ideally 50–100 µg) to be hydrolyzed into a clean vacuum hydrolysis tube and label the tube(s) to identify the sample.
2. Add a known amount (ideally 50 nmoles) of norleucine (internal standard) to the sample tube.
3. Lyophilize resulting sample under vacuum using a Savant or similar drying device.
4. Add 200 µL of 6 *M* (constant boiling) hydrochloric acid.
5. Evacuate the vacuum hydolysis tube(s) for 2 min with agitation.
6. Incubate samples in a heating block or oven at 110°C for 24 h.
7. Allow samples to cool and lyophilize the products.
8. Derivatize released amino acids with phenylisothiocyanate.

3.3. Derivatization of Released Amino Acids and Amino Acid Standard Mixture

1. Add 100 µL of coupling reagent to the dried hydrolyzed or amino acid standard sample (*see* **Note 10**).
2. Lyophilize (*see* **Note 10**).
3. Add a further 100 µL of coupling reagent and 5 µL of phenylisothiocyanate (PITC) to the dried sample.
4. Incubate the mixture at room temperature for 5 min.
5. Lyophilize the products.
7. Add 100 µL UHQ water to the dried products (*see* **Note 11**).
8. Lyophilize (*see* **Note 11**).
9. Resuspend products in 200 µL of sample loading buffer and analyze an aliquot by RP-HPLC as described in **Subheading 3.4**.

3.4. RP-HPLC Separation of Derivatized Amino Acids

1. Connect the flow to the Supelcosil LC-18-DB HPLC column within the column heater compartment equilibrated at 45°C.
2. Wash the column with solvent B until a stable baseline is observed (*see* **Note 12**).
3. Load the amino acid analysis gradient parameters and allow the system to equilibrate at the initial conditions (*see* **Table 1** and **Note 13**).
4. Once the baseline has stabilized inject 10 µL of the sample loading buffer and run the gradient shown in **Table 1**.

Table 1
Reversed Phase-High Performance Liquid Chromatography Conditions for Separation of PTC-Derivatized Amino Acids

Time (min)	% Solvent A	% Solvent B	% Solvent C	Flow rate (mL/min)
0	75	5	20	1.0
25	30	50	20	1.0
28	20	80	0	1.0
33	20	80	0	1.0
34	75	5	20	1.0

5. Visually examine the chromatogram obtained and ensure that there is no significant UV absorption in the region of interest (between 5 and 25 min following injection; *see* **Fig. 1**). If the chromatogram contains no significant absorbance in the region of interest proceed to **step 6.** If UV peaks are observed the column should be cleaned or a new column used and a second aliquot of sample loading buffer should be analyzed.
6. Inject sequentially six separate 10 µL aliquots of the derivatized amino acid standard mixture.
7. Examine the resulting chromatograms for peak area variation, elution time variation, peak resolution, and tailing to determine that the system is suitable for use. Peak resolution should be calculated using the equation:

$$R=2(t_2-t_1)$$

W_2+W_1 Where, t_2 and t_1 are the corresponding widths at the bases of the peaks obtained by extrapolating the relatively straight sides of the peaks to the baseline (*see* **Fig. 2**). Peak tailing should be calculated using the equation:

$$W0.05$$

2f Where $W_{0.05}$ is the width of the peak at 5% height and, f is the distance from the peak front to the peak center at 5% peak height (*see* **Fig. 3**). If the system is suitable for use (*see* **Note 14**) analysis of samples may continue. If the data do not pass the set criteria, a test regime must be established to determine the reason for the failure (*see* **Note 15**).

8. Inject sequentially duplicate aliquots (10 µL) of the samples of interest.
9. Following each run sample peaks should be integrated taking into account the internal standard. The response ratio for each amino acid in each sample run is calculated by dividing the peak area for each amino acid by the peak area obtained for the internal standard (norleucine) in the same run.

Fig. 3.

Calculated by dividing the peak area for each amino acid by the peak area obtained for the internal standard (norleucine) in the same run.

The response ratio is in turn divided by the response ratio for the same amino acid in the amino acid standard mixture. The figure generated is multiplied by the known amount of the relative amino acid present in the standard mixture (i.e., 50 nmoles) to produce the molar amount of that amino acid in the sample. This may be summarized in the equations,

Rr = Rs/Ris (in the sample data)
Rm = Rs/Ris (in the standard mixture data)
Rc = Rr/Rm

nmoles of amino acid = Rc × 50 Where R_r is the response ratio for a particular amino acid in the sample or standard run of interest having a peak area R_s and an internal standard peak area (in the same run) R_{is} and, R_m is the response ratio for the same amino acid in the relevant standard mixture having a peak area R_s and an internal standard peak area (in the same run) R_{is}. and, R_c is the overall response ratio.

3.5. Validation Parameters (see Note 16)

The validation parameters that should be assessed during a full validation to ICH guidelines are outlined in **Subheadings 3.5.1.–3.5.9**. Samples should be prepared as outlined in **Subheadings 3.1.–3.4**. or using another suitable amino acid analysis procedure.

3.5.1. Specificity

Specificity is defined as the ability to assess unequivocally the analyte(s) in the presence of other components.

A suitable study should be designed to establish retention times and responses of known amino acids released from the study sample and the data obtained should be compared to that obtained from a standard mixture containing derivatized amino acids.

Generally, a standard aliquot of the peptide, protein, or conjugate for which the validation is being carried out is hydrolyzed and analyzed in duplicate and the data generated is compared with the data obtained from derivatized phenylthiocarbamyl (PTC)-amino acid standards.

The retention time of each of the PTC-amino acids released from the peptide, protein, or conjugate sample should normally be within ±3% of the same PTC-amino acid present in the standard mixture analyzed in the same session.

3.5.2. System Suitability Test (see Note 17)

System suitability is a test designed to ascertain the effectiveness of the operating system.

System suitability can be determined in a number of ways. Generally a series of replicate injections (n = 6) of the derivatized amino acid standards is performed to assess the relative standard deviations for peak area measurements and retention times. In addition, peak tailing (T) and peak resolution (R) can be determined (*see* **Subheading 3.3**).

The retention time variance should normally be within 3% and the relative standard deviation of peak areas taken from the six sets of data should normally be less than 5%. The peak tailing factor (T) should be less than or equal to two and the resolution factor (R) should be greater than one for the amino acids of interest.

3.5.3. Linearity

Linearity is defined as the ability (within a given range) of the analytical method to obtain results that are directly proportional to the concentration of analyte(s) in the sample.

Linearity may be demonstrated on the peptide, protein, or conjugate and standard mixture of amino acids via dilution of a standard stock solution or on separate weighings out of the peptide, protein, or conjugate.

Linearity of response of the amino acid standard mixture can be demonstrated by choosing at least 5 points in duplicate in a range to cover that anticipated for the peptide, protein, or conjugate.

This study should be repeated with aliquots of the peptide, protein, or conjugate (5 points in duplicate; 0, 50, 75, 100, and 150% of the usual aliquot analyzed).

Linearity should initially be determined using a visual inspection of a plot of peak area ratio (area of amino acid signal over the area of internal standard signal) against relative amount of the peptide, protein, or conjugate taken. If a linear relationship exists the plot obtained should be statistically evaluated. For example the sum of least squares around the regression line (r^2) should be calculated.

From the final plot, the correlation coefficient, y-intercept, slope of the regression line, and residual sum of squares should be determined and entered in the validation document.

The linearity data obtained should obey the equation $y = mx + C$, where C is zero within 95% confidence limits, and the sum of least squares around the regression line (r^2) is greater than 0.98.

3.5.4. Range

The range is derived from the linearity study and is established by confirming that the analytical procedure provides an acceptable degree of linearity, accuracy, and precision when applied to samples containing amounts of peptide, protein, or conjugate within or at the extremes of the specified range of the analytical procedure.

Following the linearity procedure described above, the working range for the analysis would be 50–150% of the concentration of the batch used for the analysis.

If the working range required is likely to be wider, additional concentrations may be added to the linearity study to take into account the future expected concentration range.

3.5.5. Accuracy/Recovery

An assay method should provide a true (accurate) result for a test peptide, protein, or conjugate sample.

Accuracy should be established across the specified range of the analytical procedure and can often be inferred once precision, linearity, and specificity have been established.

Generally percentage recoveries for the amino acids of interest should fall within the range of 90–110% and the percentage correlation of variance (%CV; standard deviation ◆ 100 / mean) for multiple measurements should normally be less than 10%.

3.5.6. Repeatability

Repeatability is measured by carrying out analysis (in six replicates) in one laboratory by one operator, using one instrument over a relatively short time span.

A standard aliquot of the peptide, protein or conjugate is hydrolyzed and the derivatized products are injected six times onto the RP-HPLC system. In general, the percentage correlation of variance (%CV) for the released amino acids should be less than or equal to 5%.

3.5.7. Intermediate Precision

Intermediate Precision is defined as long term variability of the measurement process, which may be determined for a method run on different days and or by different operators.

Six separate aliquots of the peptide, protein, or conjugate should be hydrolyzed, derivatized and analyzed by RP-HPLC on different days. The analyses should be carried out using different operators and different instruments in the same facility (*see* **Note 18**).

In general, the percentage correlation of variance (%CV) for the released amino acids should be less than or equal to 10%.

3.5.8. Reproducibility

Reproducibility expresses the precision between laboratories and can be assessed using an extension of the intermediate precision study described in **Subheading 3.5.7** to include analyses at different laboratories.

Ideally, the percentage correlation of variance (%CV) for the released amino acids should be less than or equal to 10%.

3.5.9. Robustness/Ruggedness

Robustness/ruggedness is defined as a review of the critical parameters in the method and the steps taken to minimise method variability. Generally experiments should be designed to assess the following criteria:

1. Stability of analytical solutions and derivatized products.
2. Influence of variations of pH in a mobile phase.
3. Influence of variations in mobile-phase composition.
4. Different columns (different lots and/or suppliers).
5. Temperature.
6. Flow rate.

For most validation studies it is impractical to carry out analyses to study all the factors previously outlined. The use of experimental matrix software can often be used to design a set of experiments to test the robustness/ruggeddness of the method being validated. Acceptance criteria are set prior to the start of the analyses and should adhere to the criteria set for linearity and percentage correlation of variance (%CV) described earlier. Unfortunately there are no actual in-depth guidelines to aid us in designing robustness/ruggeddness analyses.

3.5.10. Detection and Quantification Limit (i.e., Minimum Amount of Amino Acid Needed for Reliable Detection and Quantification)

Several approaches for determining the detection limit are possible ***(2)***. However, during a validation of amino acid analysis detection limits for each amino acid can be most easily determined based on the standard deviation of the response and the slope of the linearity plot.

The detection limit *(DL)* may be expressed as:

$$DL = {}^{3.3}\alpha S$$

Where ◆ ◆ the standard deviation of the response about the line of best fit S ◆ the slope of the calibration curve The quantification limit (QL) may be determined in the same way and is expressed as:

$$QL = {}^{10}\alpha S$$

where ◆ ◆ the standard deviation of the response, and *S* ◆ the slope of the calibration curve.

4. Notes

For other methods of amino acid analysis some details may differ, according to equilibration times, column lifetime, sensitivity (e.g., the amount of standard

required), and so forth, but the general principles of validation outlined above apply. Ideally, the HPLC system used should meet the basic criteria specified in the liquid chromatography Pharmacopoeias ***(3–5)***.

1. It is important to remember that the main objective of validation of an analytical procedure is to demonstrate that the procedure is suitable for its intended purpose.
2. All of the analytical data collected during a validation and any calculations made should be discussed in the resulting validation document as appropriate.
3. Well-characterized reference materials, with documented purity, should be used throughout a validation study.
4. The experimental work should be designed so that the appropriate validation characteristics can be considered simultaneously to provide a sound, overall knowledge of the capabilities of the analytical procedure.
5. Analyst information, performance validation, and/or calibration certificates for the equipment used should also be recorded and stored along with the raw data. All reagents should be approved for use prior to any validation study that is to be included in a regulatory authority application and their details (supplier, catalog number, lot number and expiry dates) recorded.
6. A Hewlett-Packard HP 1100 or HP 1200 with quaternary switching pump is ideal. Reagents of the highest quality should be used during these analyses.
7. If validation is being carried out for a protein or amino acid mixture that contains unusual amino acids or amino acids that are not present in the standard mixture, the unusual amino acid should be purchased, accurately weighed, and added to the standard mixture. If the amino acid is not commercially available, the amino acid can either be synthesized, rigorously characterized, accurately weighed, and added to the standard mixture or quantitated relative to a similar amino acid.
8. Ideally prior to hydrolysis peptide, protein and conjugate samples should be salt-, amine-, and detergent-free, because these may interfere with hydrolysis or subsequent chromatography.
9. Inter-amino acid bonds differ in their susceptibility to acid hydrolysis. For example, longer acid hydrolyses are more likely to yield accurate results for hydrophobic amino acid residues, such as Valine, Isoleucine, and Phenylalanine. Other factors also have to be taken into account when utilizing amino acid analysis data. Asparagine and Glutamine are converted to their corresponding acids, Aspartic acid and Glutamic acid, and therefore cannot be directly quantified. Losses of Serine, Threonine, and to an extent Tyrosine, can be expected during acid hydrolysis through hydrolytic breakdown. More accurate estimates of Serine and Threonine can often be determined

either by assuming 10% and 5% losses, respectively, over 24 h at 110°C, or by performing a series of hydrolyses for various times and extrapolating the amounts of these amino acids detected back to zero time. Determination of Cysteine is also problematic when using standard hydrolysis conditions, due to oxidation. Tryptophan is completely destroyed during normal hydrolyses and is not detected. Also, the quantitation of Aspartic and Glutamic acid, in precolumn derivatization methods, can also be compromised by the presence of buffer salts. Proteins are routinely hydrolyzed at 110°C for 24 h. Higher recoveries of more hydrophobic amino acids from membrane proteins can be achieved using higher-tempera-ture hydrolyses for example 160°C for 6 h. This matter is discussed further in Chapter 10.

10. Addition of coupling buffer and subsequent lyophilization ensures neutralization of the hydrolysed sample and the amino acid standard mixture.
11. The addition of UHQ water to the derivatized amino acids and subsequent lyophilization ensures optimal removal of derivatizing reagents and prevents variable chromatography.
12. The column routinely needs to be flushed for 30 min with solvent B to ensure that the column and UV lamp have equilibrated.
13. Equilibration at the initial conditions for amino acid analysis normally requires 5–10 min.
14. The system can be considered suitable if the retention time variance is ±3.0% and the relative standard deviation in peak areas for the six runs is < 5%. Peak tailing (T) should be less than or equal to two and Resolution (R) should be greater than one.
15. If the system fails a suitability test, the liquid chromatography system being used including hardware (pump, UV detector, switching valves, column, etc.) and solvents should be fully examined, for instance for leaks or partial blockages. Columns have a finite lifetime. For instance the type of RP-HPLC column used in the system described in **Subheading 2.1.1**. would normally be expected to allow 150–300 sample injections before peak broadening and loss of resolution result in excessively poor performance.
16. Validation of amino acid analysis for a particular sample should only be contemplated following optimization of the method or methods to be employed. In general the optimized method, the sample formulation and, of course, amino acid sequence for each peptide, protein, and conjugate will differ. Therefore, amino acid analysis should be validated for each product rather than using a generic validated method for analysis of various products.
17. Following validation the system suitability test should ideally be performed prior to each analysis of peptide, protein, or conjugate, providing that the

data obtained passes the criteria set the system is deemed to be suitable for analysis.

18. Precision across different instruments need only be assessed if more than one instrument is to be used for analysis of the sample of interest.

Molecular Weight Estimation for Native Proteins Using High-Performance Size-Exclusion Chromatography

G. Brent Irvine

1. Introduction

The chromatographic separation of proteins from small molecules on the basis of size was first described by Porath and Flodin, who called the process "gel filtration" ***(1)***. Moore applied a similar principle to the separation of polymers on crosslinked polystyrene gels in organic solvents, but named this "gel permeation chromatography" ***(2)***. Both terms came to be used by manufacturers of such supports for the separation of proteins, leading to some confusion. The term size-exclusion chromatography is more descriptive of the principle on which separation is based and has largely replaced the older names, although the expression "gel filtration" is still commonly used by biochemists to describe separation of proteins in aqueous mobile phases. Comprehensive reviews that cover both practical and theoretical aspects of the technique are available, with emphasis on both proteins ***(3,4)*** and peptides ***(5)***, and there is also much useful information in a technical booklet published by a leading manufacturer ***(6)***.

Conventional liquid chromatography is carried out on soft gels, with flow controlled by peristaltic pumps and run times on the order of several hours. These gels are too compressible for use in high-performance liquid chromatography (HPLC), but improvements in technology have led to the introduction of new supports with decreased particle size (5–13 μm) and improved rigidity. This technique is usually called high-performance size-exclusion chromatography (HPSEC), but is sometimes referred to as size-exclusion high-performance liquid chromatography (SE-HPLC). Columns (about 1 × 30 cm) are sold prepacked with the support, and typically have many thousands of theoretical plates. They

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

can be operated at flow rates of about 1 mL/min, giving run times of about 12 min, 10–100 times faster than conventional chromatography on soft gels. A medium pressure high-performance system called fast protein liquid chromatography (FPLC) that avoids the use of stainless steel components was developed by one major supplier (Amersham Pharmacia Biotech, now GE Healthcare Life Sciences). Prepacked columns of Superose and Superdex developed for this system can also be operated on ordinary HPLC systems.

As well as being a standard chromatographic mode for desalting and purifying proteins, size-exclusion chromatography can be used for estimation of molecular weights. This is true only for ideal size-exclusion chromatography, in which the support does not interact with solute molecules (*see* **Note 1**). Because the physical basis for discrimination in size-exclusion chromatography is size, one would expect that there would be some parameter related to the dimensions and shape of the solute molecule that would determine its K_d value (*see* **Note 2**). All molecules with the same value for this parameter should have identical K_d values on a size-exclusion chromatography column. Dimensional parameters that have been suggested for such a "universal calibration" include two terms related to the hydrodynamic properties of proteins, namely Stokes radius (R_S) and viscosity radius (R_h). Current evidence appears to indicate that R_h is more closely correlated to size-exclusion chromatography behavior than is R_S ***(7)***. However, even this parameter is not suitable for a universal calibration that includes globular proteins, random coils, and rods ***(8)***. Hence calibration curves prepared with globular proteins as standards cannot be used for the assignment of molecular weights to proteins with different shapes, such as the rodlike protein myosin. Several mathematical models that relate size-exclusion chromatography to the geometries of protein solutes and support pores have been proposed (*see* **Note 3**). However, in practical terms, for polymers of the same shape, plots of log molecular weight against K_d have been found to give straight lines within the range $0.1 < K_d < 0.9$ (*see* **Note 4**). It has been found that the most reliable measurements of molecular weight by HPSEC are obtained under denaturing conditions, when all proteins have the same random coil structure. Disulfide bonds must be reduced, usually with dithiothreitol, in a buffer that destroys secondary and tertiary structure. Buffers containing guanidine hydrochloride ***(9,10)*** or sodium dodecyl sulfate (SDS) ***(11)*** have been used for this purpose. However, the use of denaturants has many drawbacks, which are described in **Note 5**. In any case, polyacrylamide gel electrophoresis in SDS-containing buffers is widely used for determining the molecular weights of protein subunits. This technique can also accommodate multiple samples in the same run, although each run takes longer than for HPSEC. More recently SEC has been used in combination with other more absolute methods for molecular weight determination, particularly mass spectrometry ***(12)*** and multiangle laser light scattering ***(13)***.

The method described in this chapter is for the estimation of molecular weights of native proteins. The abilities to measure bioactivity, and to recover native protein in high yield, make this an important method, even though a number of very basic, acidic, or hydrophobic proteins will undergo non-ideal size exclusion under these conditions.

2. Materials

2.1. Apparatus

An HPLC system for isocratic elution is required. This comprises a pump, an injector, a size-exclusion column and a guard column (*see* **Note 6**), a UV-detector, and a data recorder. There are many size-exclusion columns based on surface-modified silica on the market. The results described here were obtained using a Zorbax Bioseries GF-250 column (0.94 × 25 cm), of particle size 4 µm, sold by Agilent Technologies. This column can withstand very high back pressures (up to 380 Bar or 5500 psi) and can be run at flow rates up to 2 mL/min with little loss of resolution ***(14)***. It has a molecular weight exclusion limit for globular proteins of several hundred thousand.

The exclusion limit for the related GF-450 column is about a million. Other suitable columns include TSK-GEL SW columns (Tosoh Biosep), and Superdex and Superose columns (Amersham Pharmacia Biotech).

2.2. Chemicals

1. 0.2 *M* Disodium hydrogen orthophosphate (Na_2HPO_4).
2. 0.2 *M* Sodium dihydrogen orthophosphate (NaH_2PO_4).
3. 0.2 *M* Sodium phosphate buffer, pH 7.0: Mix 610 mL of 0.2 *M* Na_2HPO_4 with 390 mL of 0.2 *M* NaH_2PO_4. Filter through a 0.22-µm filter (Millipore type GV).
4. Solutions of standard proteins: Dissolve each protein in 0.2 *M* sodium phosphate buffer, pH 7.0 at a concentration of about 0.5 mg/mL. Filter the samples through a 0.45-µm filter (Millipore type HV). Proteins suitable for use as standards are listed in **Table 1** (*see* **Note 7**).
5. Blue dextran, average molecular weight 2,000,000 (Sigma), 1 mg/mL in 0.2 *M* sodium phosphate buffer, pH 7.0. Filter through a 0.45-µm filter (Millipore type HV).
6. Glycine, 10 mg/mL in 0.2 *M* sodium phosphate buffer, pH 7.0. Filter through a 0.45-µm filter (Millipore type HV).

3. Method

1. Allow the column to equilibrate in the 0.2 *M* sodium phosphate buffer, pH 7.0, at a flow rate of 1 mL/min (*see* **Note 8**) until the absorbance at 214 nm is constant.
2. Inject a solution (20 µL) of a very large molecule, such as blue dextran (*see* **Note 9**) to determine V_0. Repeat with 20 µL of water (negative absorbance peak) or a solution of a small molecule, such as glycine, to determine V_t.

Table 1
Protein Standards

Protein	Molecular weight
Thyroglobulin	669,000
Apoferritin	443,000
β-Amylase	200,000
Immunoglobulin G	160,000
Alcohol dehydrogenase	150,000
Bovine serum albumin	66,000
Ovalbumin	42,700
β-Lactoglobulin	36,800
Carbonic anhydrase	29,000
Trypsinogen	24,000
Soybean trypsin inhibitor	20,100
Myoglobin	16,900
Ribonuclease A	13,690
Insulin	5900
Glucagon	3550

All proteins listed were obtained from Sigma, Poole, England.

3. Inject a solution (20 µL) of one of the standard proteins and determine its elution volume, V_e, from the time at which the absorbance peak is at a maximum. Repeat this procedure until all the standards have been injected. A chromatogram showing the separation of seven solutes during a single run on a Zorbax Bio-series GF-250 column is shown in **Fig. 1**. Calculate K_d (*see* **Note 2**) for each protein and plot K_d against log molecular weight. A typical plot is shown in **Fig. 2**.
4. Inject a solution (20 µL) of the protein of unknown molecular weight and measure its elution volume, V_e, from the absorbance profile. If the sample contains more than one protein, and the peaks cannot be assigned with certainty, collect fractions and assay each fraction for the relevant activity.
5. Calculate K_d for the unknown protein and use the calibration plot to obtain an estimate of its molecular weight.

4. Notes

1. Silica to which a hydrophilic phase such as a diol has been bonded still contains underivatized silanol groups. Above pH 3.0 these are largely anionic and will interact with ionic solutes, leading to non-ideal size-exclusion chromatography. Depending on the value of its isoelectric point, a protein can be cationic or anionic at pH 7.0. Proteins that are positively charged will undergo ion exchange, causing them to be retarded. Conversely, anionic proteins will experience electrostatic repulsion from the pores, referred to as "ion exclusion," and will be eluted earlier than

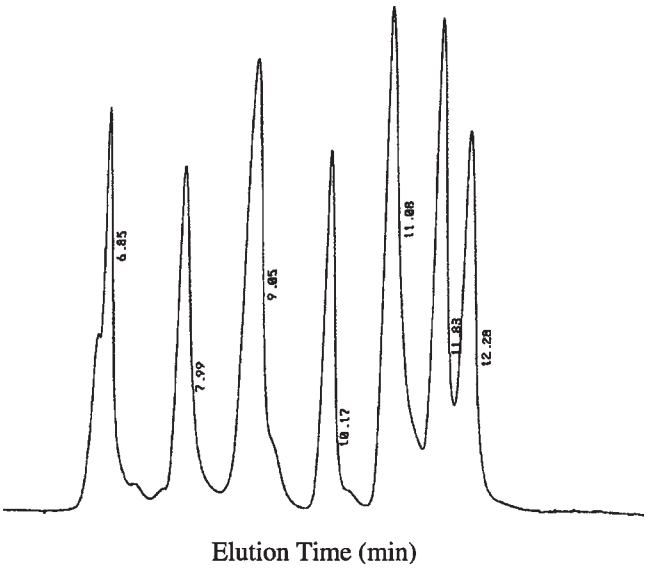

Fig. 1. Separation of a mixture of seven solutes on a Zorbax Bio-series GF-250 column. Twenty microliters of a mixture containing about 1.5 µg of each protein was injected. The solutes were, in order of elution, thyroglobulin, alcohol dehydrogenase, ovalbumin, myoglobin, insulin, glucagon, and sodium azide. The number beside each peak is the elution time in minutes. The absorbance of the highest peak, insulin, was 0.105. The equipment was a Model 501 Pump, a 441 Absorbance Detector operating at 214 nm, a 746 Data Module, all from Waters (Millipore, Milford, MA, USA) and a Rheodyne model 7125 injector (Rheodyne, Cotati, CA, USA) with 20-µL loop. The column was a Zorbax Bio-Series GF-250 with guard column (Aligent Technologies). The flow rate was 1 mL/min and the chart speed was 1 cm/min. The attenuation setting on the Data Module was 128.

expected on the basis of size alone. When size exclusion chromatography is carried out at a low pH, the opposite behavior is found, with highly cationic proteins being eluted early and anionic ones being retarded. To explain this behavior, it has been suggested that at pH 2.0 the column may have a net positive charge ***(15)***. To reduce ionic interactions it is necessary to use a mobile phase of high ionic strength. On the other hand, as ionic strength increases, this promotes the formation of hydrophobic interactions. To minimize both ionic and hydrophobic interactions, the mobile phase should have an ionic strength between 0.2 and 0.5 *M* ***(16)***.

2. The support used in size-exclusion chromatography consists of particles containing pores. The molecular size of a solute molecule determines the degree to which it can penetrate these pores. Molecules that are wholly excluded from the packing emerge from the column first, at the void volume, V_0. This represents the volume in the interstitial space (outside the

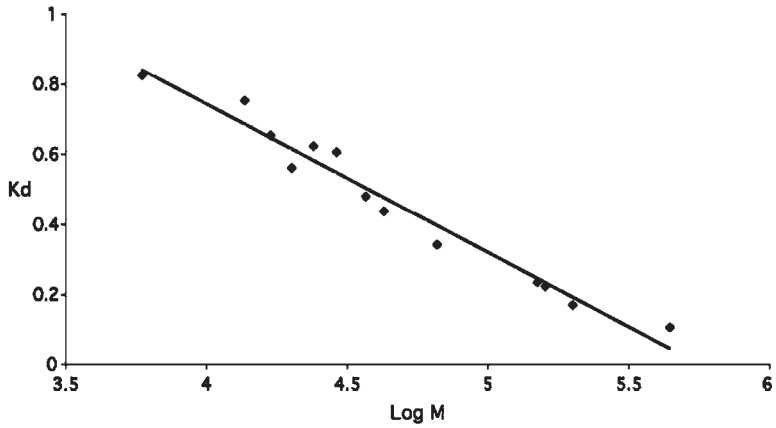

Fig. 2. Plot of K_d vs log molecular weight for those proteins listed in **Table 1** with K_d values between 0.1 and 0.9 (i.e., all except glucagon and thyroglobulin). Chromatography was carried out as described in the caption to **Fig. 1**. V_0 was determined to be 6.76 mL from the elution peak of blue dextran. *Vt* was determined from the elution peak of glycine and from the negative peak given by injecting water, both of which gave a value of 11.99 mL. The regression line $y = -0.4234x + 2.4378$, $r^2 = 0.9657$ was computed using all the points shown.

support particles) and is determined by chromatography of very large molecules, such as blue dextran or DNA. Molecules that can enter the pores freely have full access to an additional space, the internal pore volume, V_i. Such molecules emerge at V_t, the total volume available to the mobile phase, which can be determined from the elution volume of small molecules. Hence $V_t = V_0 + V_i$. A solute molecule that is partially restricted from the pores will emerge with elution volume, *Ve*, between the two extremes, V_0 and V_t. The distribution coefficient, K_d, for such a molecule represents the fraction of V_i available to it for diffusion. Hence

$$Ve = V0 + KdVi \text{ and } Kd = (V_e - V_0)/V_i = (V_e - V_0)/(V_t - V_0)$$

3. These models give rise to various plots that should result in a linear relationship between a function of solute radius, usually R_S, and some size-exclusion chromatography parameter, usually K_d ***(17)***. However, none has proven totally satisfactory. Recently it has been suggested that size-exclusion chromatography does not require pores at all, but rather that K_d can be calculated from a thermodynamic model for the free energy of mixing of the solute and the gel phase ***(18)***.
4. Manufacturers' catalogs often show plots of K_d against log molecular weight, *M*. For most globular proteins, this plot is a sigmoidal curve that is approximately linear in the middle section, where

$$Kd = a - b \log M$$

where a is the intercept on the ordinal axis, and b is the slope. From such plots one can estimate fractionation range (the working range lies in the linear portion, between about $0.9 > K_d > 0.1$) and the selectivity. This latter parameter depends on the slope of the plot and is a function of the pore size distribution. A support with average pore size distribution in a narrow band gives high selectivity (large value of b) but a restricted separation range (the larger the value of b, the lower the range of values for M). If no estimate is available for the size of the protein under investigation it is better to use a support with a broad fractionation range. A support of higher selectivity in a more restricted fractionation range can then be used later to give a more precise value for solute size.

5. Problems arising when size-exclusion chromatography is carried out under denaturing conditions include:

   a. For a particular column, the molecular weight range in which separation occurs is reduced. This is because the radius of gyration, and hence the hydrodynamic size, of a molecule increases when it changes from a sphere to a random coil. For example, the separation range of a TSK G3000SW column operating with denatured proteins is 2000–70,000, compared to 10,000–500,000 for native proteins ***(10,19)***. Of course this may actually be an advantage when working with small proteins or peptides.
   b. Proteins are broken down into their constituent subunits and polypeptide chains, so that the molecular weight of the intact protein is not obtained.
   c. Bioactivity is usually destroyed or reduced and it is not usually possible to monitor enzyme activity. This can be a serious disadvantage when trying to identify a protein in an impure preparation.
   d. The denaturants usually absorb light in the far UV range, so that monitoring the absorbance in the most sensitive region for proteins (200–220 nm) is no longer possible.
   e. Manufacturers often advise that once a column has been exposed to a mobile phase containing denaturants it should be dedicated to applications using that mobile phase, as the properties of the column may be irreversibly altered. In addition, the denaturant, especially if it is SDS, may be difficult to remove completely.
   f. Because these mobile phases have high viscosities, flow rates may have to be reduced to avoid high back pressures.
   g. High concentrations of salts, especially those containing halide ions, can adversely affect pumps and stainless steel.

6. Most manufacturers sell guard columns appropriate for use with their size-exclusion columns. To protect the expensive size-exclusion column it is strongly recommended that a guard column be used.
7. Even in the presence of high ionic strength buffers several proteins show nonideal behavior and are thus unsuitable as standards. For example, the basic proteins cytochrome c (pI ≅10) and lysozyme (pI ≅11) have K_d values > 1.0, under the conditions described for **Fig. 1**, because ion-exchange interactions are not totally suppressed. On the other hand, the very acidic protein pepsin (pI ≅1) emerges earlier than expected on the basis of size, because of ion exclusion. One should be aware that such behavior might also occur when interpreting results for proteins of unknown pI.
8. Columns are often stored in ethanol–water mixtures or in 0.02% sodium azide to prevent bacterial growth. Caution: Sodium azide is believed to be a mutagen. It should be handled with care (see suppliers' safety advice) and measures taken to avoid contact with solutions. It can also lead to explosions when disposed of via lead pipes. Solutions should be collected in waste bottles.

   When changing mobile phase some manufacturers recommend that the flow rate should not be greater than half the maximum flow rate.
9. Although V_0 is most commonly measured using blue dextran, Himmel and Squire suggested that it is not a suitable marker for the TSK G3000SW column, owing to tailing under nondenaturing conditions, and measured V_0 using glutamic dehydrogenase from bovine liver (Sigma Type II; mol. wt 998,000) ***(20)***. Calf thymus DNA is also a commonly used marker for V_0.

Detection of Disulfide-Linked Peptides by HPLC

Alastair Aitken and Michèle Learmonth

1. Introduction

Classical techniques for determining disulfide bond patterns usually require the fragmentation of proteins into peptides under low pH conditions to prevent disulfide exchange. Pepsin or cyanogen bromide are particularly useful (*see* Chapters 101 and 94 respectively).

Diagonal techniques to identify disulphide-linked peptides were developed by Brown and Hartley (*see* Chapter 113). A modern micromethod employing reverse-phase high-performance liquid chromatography (HPLC) is described here.

2. Materials

1. 1 *M* Dithiothreitol (DTT, good quality, e.g., Calbiochem).
2. 100 m*M* Tris-HCl, pH 8.5.
3. 4-Vinylpyridine.
4. 95% Ethanol.
5. Isopropanol.
6. 1 M triethylamine-acetic acid, pH 10.0.
7. Tri-n-butyl-phosphine (1% in isopropanol).
8. HPLC system such as Dionex UltiMate Micro HPLC systems for LC and LC/MS.
9. Reverse phase HPLC columns such as Vydac C_4, C_8, C_{18} microbore (1.0 mm I.D. columns) for the purification of low picomole amounts (< 5 pmol) of peptides. (*see* **Note 1**).

3. Method (*see* refs. 1 and 2)

1. Alkylate the protein (1–10 mg in 20–50 mL of buffer) without reduction to prevent possible disulfide exchange by dissolving in 100 m*M* Tris-HCl, pH 8.5, and adding 1 µL of 4-vinylpyridine (*see* **Note 2**).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2. Incubate for 1 h at room temperature and desalt by HPLC or precipitate with 95% ice-cold ethanol followed by bench centrifugation.
3. The pellet obtained after the latter treatment may be difficult to redissolve and may require addition of 10-fold concentrated acid (HCl, formic, or acetic acid) before digestion at low pH. It may be sufficient to resuspend the pellet with acid using a sonic bath if necessary, then commence the digestion. Vortex-mix the suspension during the initial period until the solution clarifies.
4. Fragment the protein under conditions of low pH (*see* **Note 3**) and subject the peptides from half the digest to reverse-phase HPLC. Vydac C_4, C_8, or C_{18} columns give particularly good resolution depending on the size range of fragments produced.

Typical separation conditions are;- column equilibrated with 0.1% (v/v) aqueous trifluoro acetic acid (TFA), elution with an acetonitrile–0.1% TFA gradient. A combination of different cleavages, both chemical and enzymatic, may be required if peptide fragments of interest remain large after one digestion method.

5. To the other half of the digest (dried and resuspended in 10 µL of isopropanol) add 5 µL of 1 *M* triethylamine-acetic acid pH 10.0; 5 µL of tri-*n*-butyl-phosphine (1% in isopropanol) and 5 µL of 4-vinylpyridine. Incubate for 30 min at 37 °C, and dry *in vacuo,* resuspending in 30 µL of isopropanol twice. This procedure cleaves the disulfides and modifies the resultant –SH groups.
6. Run the reduced and alkylated sample on the same column, under identical conditions on reverse-phase HPLC. Cysteine-linked peptides are identified by the differences between elution of peaks from reduced and unreduced samples.
7. Collection of the alkylated peptides (which can be identified by rechromatography on reverse-phase HPLC with detection at 254 nm) and a combination of sequence analysis and mass spectrometry *(see* **Note 1** and Chapter 112) will allow disulfide assignments to be made.

4. Notes

1. If the HPLC separation is combined with mass spectrometric characterization, the level of TFA required to produce sharp peaks and good resolution of peptide (approx 0.1% v/v) results in almost or complete suppression of signal. This does not permit true on-line HPLC-MS as the concentration of TFA in the eluted peptide must first be drastically reduced. However, the "low TFA," 218MS54, reverse-phase HPLC columns from Vydac (300 Å pore size) are available in C_4 and two forms of C_{18} chemistries. They are also supplied in 1 mm diameter columns that are ideal for low levels of sample eluted in minimal volume. We have used as little as 0.005% TFA without major loss of resolution and have observed minimal signal loss. There may be a difference in selectivity compared to "classical" reverse-phase columns; for example, we have observed phosphopeptides eluting approx. 1% acetonitrile later than their unphosphorylated counterparts (the

opposite to that conventionally seen). This is not a problem, but it is something of which one should be aware, and could be turned to advantage.

2. The iodoacetic acid used must be colorless. A yellow color indicates the presence of iodine; this will rapidly oxidize thiol groups, preventing alkylation and may also modify tyrosine residues. It is possible to recrystallize from hexane. Reductive alkylation may also be carried out using iodo-[^{14}C]-acetic acid or iodoacetamide (*see* Chapter 82). The radiolabelled material should be diluted to the desired specific activity before use with carrier iodoacetic acid or iodoacetamide to ensure an excess of this reagent over total thiol groups.
3. Fragmentation of proteins into peptides under low pH conditions to prevent disulfide exchange is important. Pepsin, Glu-C, or cyanogen bromide are particularly useful (*see* Chapters 99 and 94 respectively). Typical conditions for pepsin are 25 °C for 1–2 h at pH 2.0–3.0 (10 m*M* HCl, 5% acetic or formic acid) with an enzyme:substrate ratio of about 1:50. Endoproteinase Glu-C has a pH optimum at 4 as well as an optimum at pH 8.0. Digestion at the acid pH (typical conditions are 37 °C overnight in ammonium acetate at pH 4.0 with an enzyme/substrate ratio of about 1:50) will also help minimize disulfide exchange. CNBr digestion in guanidinium 6 *M* HCl/ 0.1–0.2 *M* HCl may be more suitable acid medium due to the inherent redox potential of formic acid which is the most commonly used protein solvent. When analyzing proteins that contain multiple disulfide bonds it may be appropriate to carry out an initial chemical cleavage (CNBr is particularly useful), followed by a suitable proteolytic digestion. The initial acid chemical treatment will cause sufficient denaturation and unfolding as well as peptide bond cleavage to assist the complete digestion by the protease. If a protein has two adjacent cysteine residues this peptide bond will not be readily cleaved by specific endopeptidases. For example, this problem was overcome during mass spectrometric analysis of the disulfide bonds in insulin by using a combination of an acid proteinase (pepsin) and carboxypeptidase A as well as Edman degradation ***(3)***.

112

Detection of Disulfide-Linked Peptides by Mass Spectrometry

Alastair Aitken and Michèle Learmonth

1. Introduction

Mass spectrometry is playing a rapidly increasing role in protein chemistry and sequencing and is particularly useful in determining sites of co- and post-translational modification ***(1,2)***, and application in locating disulfide bonds is no exception. This technique can of course readily analyze peptide mixtures; therefore it is not always necessary to isolate the constituent peptides. However, a cleanup step to remove interfering compounds such as salt and detergent may be necessary. Thus can be achieved using matrices such as 10-µm porous resins slurry-packed into columns 0.25 mm diameter. Polypeptides can be separated on stepwise gradients of 5–75% acetonitrile in 0.1% formic or acetic acid ***(3)***. On-line electrospray mass spectrometry (ES-MS) coupled to capillary electrophoresis or high-performance liquid chromatography (HPLC) has proved particularly valuable in the identification of modified peptides. If HPLC separation on conventional columns is attempted on-line with mass spectrometry, the level of trifluoroacetic acid (TFA) (0.1%) required to produce sharp peaks and good resolution of peptides results in almost or complete suppression of signal. In this case it is recommended to use the "low TFA," 218MS54, reverse-phase HPLC columns from Vydac (300 Å pore size) which can be used with as little as 0.005% TFA without major loss of resolution and minimal signal loss (*see* further details in Chapter 111).

Sequence information is readily obtained using triple quadrupole tandem mass spectrometry after collision-induced dissocation ***(4)***. Ion trap mass spectrometry technology (called LCQ) is now well established which also permits sequence information to be readily obtained. Not only can MS-MS analysis be

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

carried out, but owing to the high efficiency of each stage, further fragmentation of selected ions may be carried out to MS." The charge state of peptide ions is readily determined by a "zoom-scan" technique that resolves the isotopic envelopes of multiply charged peptide ions. The instrument still allows accurate molecular mass determination to 100,000 Da at 0.01% mass accuracy. The recent development of the Orbitrap mass spectrometer ***(5)*** allows very high resolution and sensitivity.

Selective detection of modified peptides is possible on ES-MS. For example, phosphopeptides can be identified from the production of phosphate-specific fragment ions of 63 Da (PO) and 79 Da (PO) by collision-induced dissociation during negative ion HPLC–ES-MS. This technique of selective detection of posttranslational modifications through collision-induced formation of low-mass fragment ions that serve as characteristic and selective markers for the modification of interest has been extended to identify other groups such as glycosylation, sulfation and acylation ***(6)***.

2. Materials

Materials for proteolytic and chemical cleavage of proteins are described in Chapters 94–99.

3. Method

3.1. Detection of Disulfide-Linked Peptides by Mass Spectrometry

1. Peptides generated by any suitable proteolytic or chemical method that minimizes disulfide exchange (i.e., acid pH, *see* **Note 1**). Partial acid hydrolysis, although nonspecific, has been successfully used in a number of instances. The peptides are then analyzed by a variety of mass spectrometry techniques ***(7)***. The use of thiol and related compounds should be avoided for obvious reasons. Despite this, it is possible that disulfide bonds will be partially reduced during the analysis and peaks corresponding to the individual components of the disulfide-linked peptides will be observed. Control samples with the above reagents are essential to avoid misleading results (*see* **Note 2**).
2. The peptide mixture is incubated with reducing agents, such as mercaptoethanol and dithiothreitol (DTT), and reanalyzed as before. Peptides that were disulfide linked disappear from the spectrum and reappear at the appropriate positions for the individual components. For example, in the positive ion mode the mass (M) of disulfide-linked peptides (of individual masses A and B) will be detected as the pseudomolecular ion at $(M+H)^+$, and after reduction this will be replaced by two additional peaks for each disulfide bond in the polypeptide at masses $(A+H)^+$ and $(B+H)^+$. Remember that A + B = M + 2, as reduction of the disulfide bond will be accompanied by a consistent increase in mass due to the conversion of cystine to two cysteine residues, that is, –S-S → –SH + HS- and peptides containing an intramolecular disulfide bond will appear at 2 amu higher. Such peptides, if they

are in the reduced state can normally be readily reoxidized to form intramolecular disulfide bonds by bubbling a stream of air through a solution of the peptide for a few minutes (*see* **Note 3**).

3. Computer programs are readily available on the Internet that are supplied with the mass spectrometer software package and will predict the cleavage position of any particular proteinase or chemical reagent. Simple knowledge of the mass of the fragment will, in most instances, give unequivocal answers as to which segments of the polypeptide chain are disulfide linked. If necessary, one cycle of Edman degradation can be carried out on the peptide mixture and the mass spectroometry analysis repeated. The shift in mass(es) that correlates with loss of specific residues will confirm the assignment.

4. Notes

1. Fragmentation of proteins into peptides under low pH conditions is important (e.g., with pepsin, Glu-C, or cyanogen bromide; *see* Chapter 99 and 94 respectively) to prevent disulfide exchange. Analysis can also be carried out by electrospray mass spectrometers (ES-MS), which will give an accurate molecular mass up to 80–100,000 Da (and in favorable cases up to 150,000 Da). The increased mass of 2 Da for each disulfide bond will be too small to obtain an accurate estimate for a polypeptide of mass Ca 10,000 (accuracy obtainable is >0.01%). There has been a recent marked increase in resolution obtained with both electrospray mass spectrometers and laser desorption time-of-flight mass spectrometers that could now permit a meaningful analysis. On the other hand, oxidation with performic acid will cause a mass increase of 48 Da for each cysteine and 49 Da for each half-cystine residue. Note that Met and Trp will also be oxidized. Met sulfoxide, the result of incomplete oxidation and that is often found after gel electrophoresis, has a mass identical to that of Phe. Met sulfone is identical in mass to Tyr. Orbitrap mass spectrometers have ppm accuracy that is well within the necessary range of resolution even for medium to large proteins ***(8)***.
2. Mass analysis by ES-MS ***(3,9)*** and matrix-assisted laser desorption mass spectrometry with time-of-flight detection (MALDI-TOF) ***(10)*** is affected, seriously in some cases, by the presence of particular salts, buffers, and detergents. In some cases, using nonionic saccharide detergents such as *n*-dodecyl-β-D-glucopyranoside, improvements in signal-to-noise ratios of peptides and proteins were observed ***(10)***. The effect on ES-MS sensitivity of different buffer salts, detergents, and tolerance to acid type may vary widely with the instrument and particularly with the ionization source. Critical micelle concentration is not a good predictor of how well a surfactant will perform ***(9)***.
3. The difference of 2 Da may allow satisfactory estimation of the number of intramolecular disulfide bonds by mass spectrometry. If necessary a larger

mass difference may be generated by oxidation with performic acid ***(11),*** and *see* Chapter 83). This will cause a mass increase of 48 Da for each cysteine and 49 Da for each half-cystine residue. (Remember that Met and Trp will also be oxidized.) ***(12)*** or by exopeptidase digestion from the N- and C-termini. This essentially a subtractive technique (one looks at the mass of the remaining fragment after each cycle). For example, when a phosphoserine residue is encountered, a loss of 167.1 Da is observed in place of 87.1 for a serine residue. This technique therefore avoids one of the major problems of analyzing posttranslational modifications. Although the majority of modifications are stable during the Edman chemistry, *O*- or *S*-linked esters, for example (which are very numerous), may be lost by β-elimination (e.g., *O*-phosphate) during the cleavage step to form the anilinothioazolidone or undergo *O*- (or *S*- in the case of palmitoylated cysteine) to *N*-acyl shifts which block further Edman degradation. Exopeptidase digestion may be difficult and the rate of release of amino acid may vary greatly.

Diagonal Electrophoresis for Detecting Disulfide Bridges

Alastair Aitken and Michèle Learmonth

1. Introduction

Methods for identifying disulfide bridges have routinely employed "diagonal" procedures using two-dimensional paper or thin-layer electrophoresis. This essentially utilizes the difference in electrophoretic mobility of peptides containing either cysteine or cystine in a disulfide link, before and after oxidation with performic acid. It was first described by Brown and Hartley ***(1)***. Peptides unaltered by the performic acid oxidation have the same mobility in both dimensions and, therefore, lie on a diagonal. After oxidation, peptides that contain cysteine or were previously covalently linked produce one or two spots off the diagonal, respectively. This method has also been adapted for HPLC methodology and is discussed in Chapter 111.

First the protein has to be fragmented into suitable peptides containing individual cysteine residues. It is preferable to carry out cleavages at low pH to prevent possible disulfide bond exchange. In this respect, pepsin (active at pH 3.0) and cyanogen bromide (CNBr) are particularly useful reagents. Proteases with active-site thiols should be avoided (e.g., papain, bromelain).

Before the advent of HPLC, paper electrophoresis was the most commonly used method for peptide separation ***(2)***. Laboratories with a history of involvement with protein characterization are likely to have retained the equipment, but it is no longer commercially available. Although it is possible to make a simple electrophoresis tank in house ***(3)***, thin-layer electrophoresis equipment is still commercially available, and it is advisable that this be used, owing to the safety implications.

For visualization of the peptides, ninhydrin is the classical amino group stain. However, if amino acid analysis or sequencing is to be carried out, fluorescamine is the reagent of choice.

2. Materials

2.1. Equipment

1. Electrophoresis tank.
2. Flat bed electrophoresis apparatus (e.g., Hunter thin-layer peptide-mapping apparatus (CBS Scientific, Del Mar, CA,. and VWR International Ltd, UK).
3. Whatman (Maidstone, UK) 3MM and Whatman No. 1 paper.
4. Cellulose TLC plates (Camlab [Cambridge, UK]

2.2. Reagents

1. Electrophoresis buffers (*see* **Note 1**): Commonly used volatile buffers are:

   pH 2.1 acetic acid/formic acid/water 15/5/80, v/v/v
   pH 3.5 pyridine/acetic acid/water 5/50/945 v/v/v
   pH 6.5 pyridine/acetic acid/water 25/1/225, v/v/v

2. Nonmiscible organic solvents: toluene, for use with pH 6.5 buffer: white spirit for use with pH 2.1 and 3.5 buffers.
3. Formic acid. **Care!**
4. 30% w/v Hydrogen peroxide. **Care!**
5. Fluorescamine: 1 mg/100 mL in acetone.
6. Marker dyes: 2% orange G, 1% acid fuschin, and 1% xylene cyanol dissolved in appropriate electrophoresis buffer.
7. 1% (v/v) Triethylamine in acetone.

3. Methods

3.1. First-Dimension Electrophoresis

3.1.1. Paper Electrophoresis

1. Dissolve the peptide digest from 0.1–0.3 µmol protein in 20–25 µL electrophoresis buffer.
2. Place the electrophoresis sheet on a clean glass sheet (use Whatman No. 1 for analytical work, Whatman 3MM for preparative work). Support the origin at which the sample is to be applied on glass rods. Where paper is used, multiple samples can be run side by side. Individual strips can then be cut out for running in the second dimension.
3. Apply the sample slowly without allowing to dry (covering an area of about 2 × 1 cm) perpendicular to the direction intended for electrophoresis. NB: for pH 6.5 buffer, apply near the center of the sheet, for acidic buffers, apply nearer the anode end.
4. Apply a small volume of marker dyes (2% orange G, 1% acid fuschin, 1% xylene cyanol, in electrophoresis buffer) on the origin and additionally in a position that will not overlap the peptides after the second dimension.
5. Once the sample is applied, wet the sheet with electrophoresis buffer slowly and uniformly on either side of the origin so that the sample concentrates in a thin line. Remove excess buffer from the rest of the sheet with blotting paper.
6. Place the wet sheet in the electrophoresis tank previously set up with electrophoresis buffer covering bottom electrode. An immiscible organic solvent (toluene

where pH 6.5 buffer is used, white spirit for acidic buffers) used to fill the tank to the top. Upper trough filled with electrophoresis buffer. **Care!**
7. Electrophorese at 3 kV for about 1 h, with cooling if necessary. The progress of the electrophoresis can be monitored by the movement of the marker dyes (*see* **Note 1**).
8. Dry sheet in a well-ventilated place overnight, at room temperature, secured from a glass rod with Bulldog clips.

3.1.2. Thin-Layer Electrophoresis

1. Dissolve the peptide digest from 0.1–0.3 µmol protein in at least 10 µL electrophoresis buffer.
2. Mark the sample and dye origins on the cellulose side of a TLC plate with a cross using an extrasoft blunt-ended pencil, or on the reverse side with a permanent marker.
3. Spot the sample on the origin. This can be done using a micropipet fitted with a disposable capillary tip. To keep the spot small, apply 0.5–1 µL spots and dry between applications.
4. Apply 0.5 µL marker dye to the dye origin.
5. Set up electrophoresis apparatus with electrophoresis buffer in both buffer tanks. Prepare electrophoresis wicks from Whatman 3MM paper, wet with buffer, and place in buffer tanks.
6. Prepare a blotter from a double sheet of Whatman 3MM, with holes cut at the positions of the sample and marker origins. Wet with buffer and place over TLC plate. Ensure concentration at the origins by pressing lightly around the holes.
7. Place TLC plate in apparatus.
8. Electrophorese at 1.5 kV for about 30–60 min.
9. Dry plate in a well-ventilated place at room temperature, overnight.

3.2. Performic Acid Oxidation (see Note 2)

1. Prepare performic acid by mixing 19 mL formic acid with 1 mL 30% (w/v) hydrogen peroxide. The reaction is spontaneous. **Care!**
2. Place the dry electrophoresis sheet/plate in a container where it can be supported without touching the sides.
3. Place the performic acid in a shallow dish inside the container. Close the container and leave to oxidize for 2–3 h. (Note the marker dyes change from blue to green.)
4. Dry sheet thoroughly at room temperature overnight.

3.3. Second Dimension Electrophoresis

3.3.1. Paper Electrophoresis

1. To prepare for the second dimension, individual strips from the first dimension can be machine zigzag stitched onto a second sheet. The overlap of the second sheet should be carefully excised with a razor blade/scalpel.
2. Wet the sheet with electrophoresis buffer, applying the buffer along both sides of the sample, thus concentrating the peptides in a straight line.
3. Repeat electrophoresis, at right angles to the original direction.
4. Thoroughly dry sheet, as before.

3.3.2. Thin-Layer Electrophoresis

1. Wet TLC plate with electrophoresis buffer using two sheets of prewetted Whatman 3 MM paper on either side of sample line.
2. Repeat electrophoresis at right angles to the original direction.
3. Thoroughly dry plate as before.

3.4. Visualization

Peptide spots can be seen after reaction with fluorescamine.

1. The reaction should be carried out under alkaline conditions. The sheet or plate should be dipped in a solution of triethylamine (1% [v/v]) in acetone. This should be carried out at least twice if the electrophoresis buffer employed was acidic. Dry the sheet well.
2. Dip the sheet in a solution of fluorescamine in acetone (1 mg/100 mL).
3. Allow most of the acetone to evaporate.
4. View the map under a UV lamp at 300–365 nm (**Care:** Goggles must be worn). Peptides and amino-containing compounds fluoresce. Encircle all fluorescent spots with a soft pencil.
5. Interpretation of diagonal maps: **Fig. 1** shows that peptides unaltered by the performic acid treatment have the same mobility in both dimensions and therefore lie

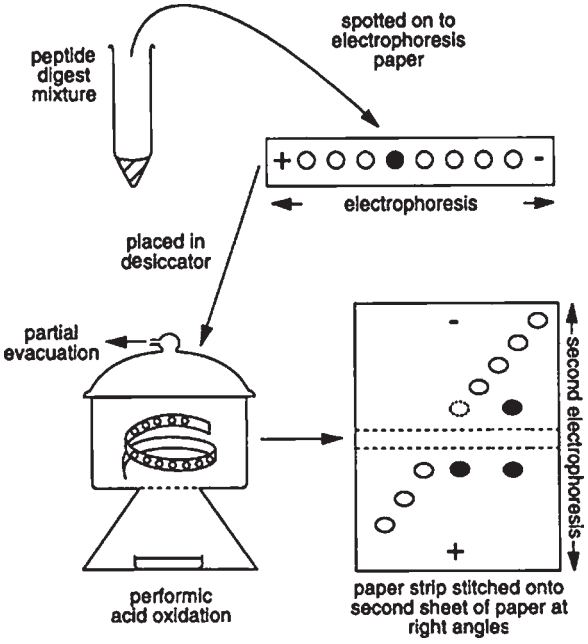

Fig. 1. Diagonal electrophoresis for identification and purification of peptides containing cysteine or disulfide bonds. This figure shows that peptides unaltered by the performic acid treatment (open circles) have the same mobility in both dimensions and therefore lie on a diagonal. Peptides that contain cysteine or were previously covalently linked (closed circles) produce one or two spots respectively, that lie off the diagonal after oxidation.

on a diagonal. Peptides that contain cysteine or were previously covalently linked produce one or two spots, respectively, that lie off the diagonal after oxidation.

3.5. Elution

Peptides may be eluted from the paper using, for example, 0.1 *M* NH_3 or 25% acetic acid. Peptides may be extracted from TLC plates by scraping off the spot into an Eppendorf tube containing elution buffer. This should be vortexed for 5 min and then centrifuged for 5 min. The cellulose can then be re-extracted once or twice with the same buffer to ensure optimal recovery of peptide.

4. Notes

1. The buffer of choice for the initial analysis is pH 6.5. However, if the cysteine residues have already been blocked with iodoacetate (*see* Chapter 82), the pH 3.5 buffer is very useful, since peptides containing these residues lie slightly off the diagonal, being slightly more acidic in the second dimension after the performic acid oxidation.
2. The movement of the marker dyes will enable progress of the electrophoresis to be followed to ensure that the samples do not run off the end of the paper.
3. It is important to exclude halide ions rigorously, since these are readily oxidized to halogens, which will react with histidine, tyrosine, and phenylalanine residues in the protein.

Estimation of Disulfide Bonds Using Ellman's Reagent

Alastair Aitken and Michèle Learmonth

1. Introduction

Ellman's reagent 5,5' -dithiobis(2-nitrobenzoic acid) (DTNB) was first introduced in 1959 for the estimation of free thiol groups ***(1)***. The procedure is based on the reaction of the thiol with DTNB to give the mixed disulfide and 2-nitro-5-thiobenzoic acid (TNB) which is quantified by the absorbance of the anion (TNB^{2-}) at 412 nm.

The reagent has been widely used for the quantitation of thiols in peptides and proteins. It has also been used to assay disulfides present after blocking any free thiols (e.g., by carboxymethylation) and reducing the disulfides prior to reaction with the reagent ***(2,3)***.

It is also commonly used to check the efficiency of conjugation ***(4)*** of sulfhydryl-containing peptides to carrier proteins (such as maleimide activated keyhole limpet haemocyanin, KLH) in the production of antibodies and to ensure that cysteine labeled sythetic peptides are coupled to affinity resins.

2. Materials

1. Reaction buffer: 0.1 *M* phosphate buffer, pH 8.0.
2. Denaturing buffer: 6 *M* guanidinium chloride, 0.1 *M* Na_2HPO_4, pH 8.0 (*see* **Note 1**).
3. Ellman's solution: 10 m*M* (4 mg/mL) DTNB (Pierce, Chester, UK) in 0.1 *M* phosphate buffer, pH 8.0 (*see* **Note 2**).
4. Dithiothreitol (DTT) (Boerhinger or Calbiochem) solution: 200 m*M* in distilled water.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Methods

3.1. Analysis of Free Thiols

1. It may be necessary to expose thiol groups, which may be buried in the interior of the protein. The sample may therefore be dissolved in reaction buffer or denaturing buffer. A solution of known concentration should be prepared with a reference mixture without protein. Sufficient protein should be used to ensure at least one thiol per protein molecule can be detected; in practice, at least 2 nmol of protein (in 100 µL) are usually required.
2. Sample and reference cuvets containing 3 mL of the reaction buffer or denaturing buffer should be prepared and should be read at 412 nm. The absorbance should be adjusted to zero (*A*buffer).
3. Add 100 µL of buffer to the reference cuvet.
4. Add 100 µL of Ellman's solution to the sample cuvet. Record the absorbance (A_{DTNB}).
5. Add 100 µL of protein solution to the reference cuvet.
6. Finally, add 100 µL protein solution to the sample cuvet, and after thorough mixing, record the absorbance until there is no further increase. This may take a few minutes. Record the final reading (A_{final}).
7. The concentration of thiols present may be calculated from the molar absorbance of the TNB anion. (*See* **Note 3**.)

$$\Delta \quad A_{412} = E_{412}TNB^{2-}[RSH] \tag{1}$$

Where $\Delta A_{412} = A_{final} - (3.1/3.2)\ (A\text{DTNB} - A\text{buffer}) - 1_M - 1$

and $E_{412}\ TNB^{2-} = 1.415 \times 10^4$ cm.

If using denaturing buffer, use the value $E_{412}\ TNB^{2-} = 1.415 \times 10^4$ cm $^{-1}M^{-1}$.

3.2. Analysis of Disulfide Thiols

1. Sample should be carboxymethylated (*see* Chapter 82) or pyridethylated (*see* Chapter 85) without prior reduction. This will derivatize any free thiols in the sample, but will leave intact any disulfide bonds.
2. The sample (at least 2 nmol of protein in 100 µL, is usually required) should be dissolved in 6 *M* guanidinium HCl, 0.1 *M* Tris-HCl, pH 8.0 or denaturing buffer, under a nitrogen atmosphere.
3. Add freshly prepared DTT solution to give a final concentration of 10–100 m*M*. Carry out reduction for 1–2 h at room temperature.
4. Remove sample from excess DTT by dialysis for a few hours each time, with two changes of a few hundred mL of the reaction buffer or denaturing buffer (*see* **Subheading 3.1**). Alternatively, gel filtration into the same buffer may be carried out.
5. Analysis of newly exposed disulfide thiols can thus be carried out as described in **Subheading 3.1.**

4. Notes

1. It is not recommended to use urea in place of guanidinium HCl, since this can readily degrade to form cyanates, which will react with thiol groups.
2. Unless newly purchased, it is usually recommended to recrystallize DTNB from aqueous ethanol.
3. Standard protocols for use of Ellman's reagent often give E_{412} TNB^{2-} = 1.36×10^4 cm $^{-1}M^{-1}$. A more recent examination of the chemistry of the reagent indicates that these are more suitable values ***(5)***, and these have been used in this chapter.

Quantitation of Cysteine Residues and Disulfide Bonds by Electrophoresis

Alastair Aitken and Michèle Learmonth

1. Introduction

Amino acid analysis quantifies the molar ratios of amino acids per mole of protein. This generally gives a nonintegral result, yet clearly there are integral numbers of the amino acids in each protein. A method was developed by Creighton ***(1)*** to count integral numbers of amino acid residues, and it is particularly useful for the determination of cysteine residues. Sulfhydryl and disulfide groups are of great structural, functional, and biological importance in protein molecules. For example, the Cys sulfhydryl is essential for the catalytic activity of some enzymes (e.g., thiol proteases) and the interconversion of Cys SH to Cystine S—S is directly involved in the activity of protein disulfide isomerase ***(2)***. The conformation of many proteins is stabilized by the presence of disulfide bonds ***(3)***, and the formation of disulfide bonds is an important posttranslational modification of secretory proteins ***(4)***.

Creighton's method exploits the charge differences introduced by specific chemical modifications of cysteine. A similar method was first used in the study of immunoglobulins by Feinstein in 1966 ***(5)***. Cys residues may be reacted with iodoacetic acid, which introduces acidic carboxymethyl (—O_2CCH_2S—) groups, or with iodoacetamide, which introduces the neutral carboxyamidomethyl (H_2NCOCH_2S—) groups. The reaction with either reagent is essentially irreversible, thereby producing a stable product for analysis. Using a varying ratio of iodoacetamide/iodoacetate, these acidic and neutral agents will compete for the available cysteines, and a spectrum of fully modified protein molecules having 0,1,2, … *n* acidic carboxymethyl residues per molecule is produced (where *n* is the number of cysteine residues in the protein). These species will

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

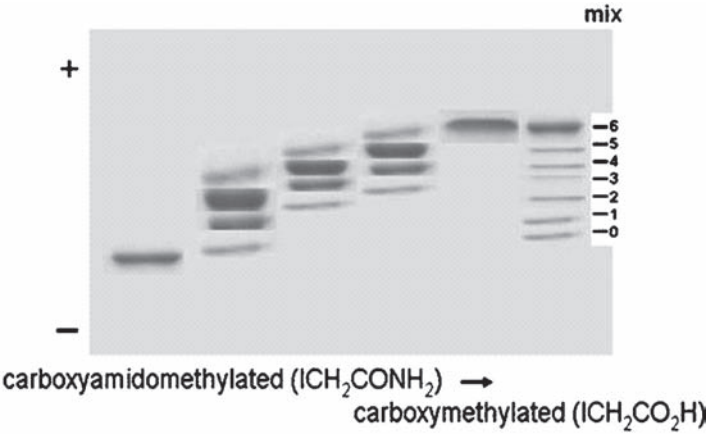

Fig. 1. Idealised electrophoretic pattern in an analysis of a protein with six cysteine residues, run with the low-pH system. Lanes 1–5 (left to right) contain (respectively) samples reacted with neutral iodoacetamide; 1:1; 1:3; 1:9 ratios of neutral to acidic reagent; acidic iodoacetate. The right hand lane contains a mixture of equal portions of the samples in lanes 1–5.

have, correspondingly, n, $n-1$, $n-2$, … 0 neutral carboxyamidomethyl groups. These species may then be separated by electrophoresis, isoelectric focusing, or by a combination of both ***(1,6,7)***. The theoretical analysis of a protein with 6 cysteines is shown in **Fig. 1**.

Creighton used a low-pH discontinuous system ***(1)***. Takahasi and Hirose recommend a high-pH system ***(6)***, whereas Stan-Lotter and Bragg used the Laemmli electrophoresis system followed by isoelectric focusing ***(7)***. It may therefore be necessary to carry out preliminary experiments to find the best separation conditions for the protein under analysis. The commonly used methods are given below.

In order to ensure that all thiol groups are chemically equivalent, the reactions must be carried out in denaturing (in the presence of urea) and reducing (in the presence of dithiothreitol, DTT) conditions. The electrophoretic separation must also be carried out with the unfolded protein (i.e., in the presence of urea) in order that the modification has the same effect irrespective of where it is in the polypeptide chain.

The original method has been modified into a two-stage process to allow for the quantification of both sulfhydryl groups and disulfide bonds (*see* **Notes 1** and **2**) ***(6,8)***. The principle of the method has also been adapted to counting the numbers of lysine residues after progressive modification of the ε-amino groups with succinic anhydride, which converts this basic group to a carboxylic acid-containing moiety.

2. Materials

2.1. Reaction Solutions

1. 1 *M* Tris-HCl, pH 8.0.
2. 0.1 *M* EDTA, pH 7.0.
3. 1 *M* DTT (good-quality, e.g., Calbiochem, Nottingham, UK).
4. 8 *M* Urea (BDH [Poole, UK], Aristar-grade, *see* **Note 2**).
5. Solution A: 0.25 *M* iodoacetamide, 0.25 *M* Tris-HCl, pH 8.0.
6. Solution B: 0.25 *M* iodoacetic acid, prepared in 0.25 *M* Tris-HCl, pH readjusted to 8.0 with 1 *M* KOH.

2.2. Solutions for Electrophoretic Analysis in the Low-pH System (pH 4.0)(9)

1. 30% Acrylamide solution containing 30 g acrylamide, 0.8 g *bis*-acrylamide **(extreme caution: work in fume hood)**, made up to 100 mL with distilled water.
2. 10% Acrylamide solution containing 10 g acrylamide **(extreme caution: work in fume hood)** and 0.25 g *bis*-acrylamide made up to 100 mL with distilled water.
3. Low-pH buffer (eight times concentrated stock) for separating gel; 12.8 mL glacial acetic acid, 1 mL *N,N,N N* -tetramethylethylenediamine (TEMED), 1 *M* KOH (approx 35 mL) to pH 4.0, made up to 100 mL with distilled water.
4. Low pH buffer (8 times concentrated) for stacking gel; 4.3 mL glacial acetic acid, 0.46 mL TEMED, 1 *M* KOH to pH 5.0, to 100 mL with distilled water.
5. 4 mg riboflavin/100 mL water.
6. Low-pH buffer for electrode buffer; dissolve 14.2 g β-alanine in 800 mL water then adjust to pH 4.0 with acetic acid. Make up to a final volume of 1 L with distilled water.
7. Tracking dye solution (five times concentrated); 20 mg methyl green, 5 mL water, and 5 g glycerol.

2.3. Gel Solution Recipes for Low-pH Electrophoresis (pH 4.0) (see Note 3)

1. 30 mL Separating gel (10% acrylamide, photopolymerized with riboflavin) is made up as follows: 10 mL 30% acrylamide stock, 4 mL pH 4.0 buffer stock, 3 mL riboflavin stock, 14.7 g urea, water (approx 2.5 mL) to 30 mL. Degas on a water vacuum pump (to removeoxygen which inhibits polymerization).
2. 8 mL Stacking gel (2.5% acrylamide, photopolymerized with riboflavin) is made up with: 2 mL 10% acrylamide stock, 1 mL pH 5.0 buffer stock, 1 mL riboflavin stock, 3.9 g urea, water (approx 1.2 mL) to 8 mL. Degas.

2.4. Electrophoresis Buffers for High-pH Separation (pH 8.9)

1. 30% Acrylamide solution containing 30 g acrylamide, 0.8 g *bis*-acrylamide **(extreme caution: work in fume hood)**, made up to 100 mL with distilled water.
2. 10% Acrylamide solution containing 10 g acrylamide **(extreme caution: work in fume hood)** and 0.25 g *bis*-acrylamide made up to 100 mL with distilled water.

3. High-pH buffer (four times concentrated stock) for separating gel; 18.2 g Tris base (in ~40 mL water), 0.23 mL TEMED, 1 *M* HCl to pH 8.9, made up to ~100 mL with distilled water.
4. High-pH buffer (four times concentrated) for stacking gel; 5.7 g Tris base (in ~40 mL water), 0.46 mL TEMED, 1 *M* H_3PO_4 to pH 6.9, made up to 100 mL with distilled water.
5. 4 mg Riboflavin in 100 mL water
6. 10% Ammonium persulfate solution (consisting of 0.1 g ammonium persulfate in 1 mL water).
7. High-pH buffer for electrode buffer; 3 g Tris base, 14.4 g glycine, distilled water to 1 L.
8. Tracking dye solution (five times concentrated): 1 mL 0.1% Bromophenol blue, 4 mL water and 5g glycerol.

2.5. Gel Solution Recipes for High-pH Electrophoresis (see Note 3)

1. 30 mL Separating gel (7.5% acrylamide, polymerized with ammonium persulfate) is made up with: 7.5 mL 30% acrylamide stock, 7.5 mL pH 8.9 buffer stock, 0.2 mL 10% ammonium persulfate (add immediately before casting), 14.7 g urea, water (approx 4.5 mL) to 30 mL. Degas.
2. 8 mL Stacking gel (2.5% acrylamide, photopolymerized with riboflavin) is made up with: 2 mL 10% acrylamide stock, 1 mL pH 6.9 buffer stock, 1 mL riboflavin stock solution, 3.9 g urea, water (approx 1.2 mL) to 8 mL. Degas.

3. Methods

3.1. Reduction and Denaturation

1. To a 0.2-mg aliquot of lyophilized protein add 10 µL of each of the solutions containing 1 *M* Tris-HCl, pH 8.0, 0.1 *M* EDTA, and 1 *M* DTT (*see* **Note 4**).
2. Add 1 mL of the 8 *M* urea solution (*see* **Note 2**).
3. Mix and incubate at 37°C for at least 30 min.

3.2. Reaction

1. Freshly prepare the following solutions using solutions A and B listed in **Subheading 2.**
   a. Mix 50 µL of solution A with 50 µL solution B (to give solution C).
   b. Mix 50 µL of solution A with 150 µL solution B (to give solution D).
   c. Mix 50 µL of solution A with 450 µL of solution B (to give solution E).
2. Label six Eppendorf tubes 1–6.
3. Add 10 µL of solutions A, B, C, D, and E to tubes 1–5. Reserve tube 6.
4. Add 40 µL of denatured, reduced protein solution prepared as in **Subheading 3.1.** to each of tubes 1–5.
5. Gently mix each tube and leave at room temperature for 15 min. Thereafter, store on ice.
6. After the 15 min incubation period, place 10 µL aliquots from each of tubes 1–5 into tube 6. Mix.

The samples are now ready for analysis (*see* **Note 5**).

3.3. Electrophoretic Analysis

1. 50 µL aliquots of each sample, Labeled 1–6, mixed with 12 µL of appropriate tracking dye solution, are loaded onto successive lanes of a polymerized high- or low-pH gel, set up in a suitable slab gel electrophoresis apparatus.
2. Low-pH buffer system: Electrophoresis is carried out toward the negative electrode, using a current of 5–20 mA for each gel, overnight at 8°C.
3. High-pH buffer system ***(10)***; Electrophoresis is carried out toward the positive electrode at 10–20 mA per gel (or 100–180 V) for 3–4 h.
4. Electrophoresis is stopped when the tracking dye reaches bottom of the gel.
5. Proteins are visualized using conventional stains e.g., Coomassie blue (Pierce, Chester, UK), silver staining (*see* Chapter 48).

4. Notes

1. The method of Takahashi and Hirose ***(6)*** can be used to categorize the half-cystines in a native protein as:

a. Disulfide bonded;
b. Reactive sulfhydryls; and
c. Nonreactive sulfhydryls. In the first step, the protein sulfhydryls are alkylated with iodoacetic acid in the presence and absence of 8 *M* urea. In the second step, the disulfide bonded sulfhydryls are fully reduced and reacted with iodoacetamide. The method described above is then used to give a ladder of half-cystines so that the number of introduced carboxymethyl groups can be quantified.

2. Urea is an unstable compound; it degrades to give cyanates which may react with protein amino and thiol groups. For this reason, the highest grade of urea should always be used, and solutions should be prepared immediately before use.
3. Electrophoresis in gels containing higher or lower percent acrylamide may have to be employed depending on the molecular weight of the particular protein being studied.
4. Where protein is already in solution, it is important to note that the pH should be adjusted to around 8.0, and the DTT and urea concentrations should be made at least 10 m*M* and 8 *M,* respectively.
5. Other ratios of iodoacetic acid to iodoacetamide may need to be used if more than about eight cysteine residues are expected, since a sufficiently intense band corresponding to every component in the complete range of charged species may not be visible. A greater ratio of iodoacetic acid should be used if the more acidic species are too faint (and vice versa).

N-Terminal Sequencing of N-Terminally Modified Proteins

Roza Maria Kamp and Hisashi Hirano

1. Introduction

A small amount of proteins separated by one-dimensional polyacrylamide gel electrophoresis (PAGE) or two-dimensional electrophoresis (2D-PAGE) and transferred from the gel onto a polyvinylidene difluoride (PVDF) membrane by electroblotting can be sequenced directly by a gas-phase protein sequencer ***(1)***. This blotting/sequencing technique has come to be widely used in protein *de novo* sequence analysis. However, even if proteins are successfully separated by PAGE and then transferred onto a PVDF membrane, N-terminal amino acid sequences of the proteins with a blocking group at the N-terminus cannot be determined by Edman degradation in the sequencer. Many proteins are N-terminally blocked ***(2,3)***. Brown and Roberts ***(4)*** found over 50% of soluble mammalian proteins to be N-terminally blocked. Thus, a simple and rapid technique for obtaining N-terminal sequence information on blocked proteins should be developed. Most techniques proposed so far for this purpose were applicable in order to obtain only the internal sequence of proteins.

Acetyl modification is the most prevalent in the blocking groups identified so far ***(5),*** and the formyl and pyroglutamyl groups are also frequently detected (*see* **Note 1**). In this chapter, techniques for deblocking and N-terminal sequencing of proteins with an acetyl, formyl, or pyroglutamyl group at the N-terminus, which are electroblotted from a polyacrylamide gel onto a PVDF membrane ***(8)***, are described (*see* **Note 2**). Techniques for PAGE and protein electroblotting of proteins are presented elsewhere in this volume (*see also* ***9,10***) (*see* **Note 3**).

On the other hand, recently, the alternative techniques using mass spectrometry have been rapidly developed, which allows the direct analysis of the N-terminally blocked peptides. The following three methods in combination with mass

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

spectrometry are available. (I) Sequencing of N-terminally blocked peptide by mass spectrometry after protease digestion of proteins (*see* **Note 3**): This technique will be described for acetylated and mirystoylated proteins in this chapter ***(5)***. (II) Enrichment of N-terminal modified peptides using DITC followed by sequencing of separated peptides using mass spectrometry: The blocked N-terminal peptides can be isolated by using diisothiothyanate (DITC)-glass, which reacts only with unmodified NH_2-groups. Blocking groups, e.g. acetylated N-terminal groups do not react with DITC and can be easily and selectively isolated from all other peptides ***(6)***. Futhermore, the modified peptides can be analyzed by using mass spectrometry. (III) Specific sorting of N-terminal blocked peptides using chromatography (COFRADIC) and sequencing by mass spectrometry: Geavaert et al. described a new method, called COFRADIC, for isolation of modified N-terminal peptides. The peptides are separated using fractional diagonal chromatography. The proteins are cleaved by using endopeptidases, e.g. trypsin, and separated by using reversed phase chromatography. In the next step the internal and unblocked N-terminal peptides are treated by using 2,4,6-trinitrobenzene sulfonic acid (TNBS) and separated again by using reversed phase chromatography. The TNBS-modified peptides show strong hydrophobic shift and can be isolated from the unaltered N-terminal blocked peptides, which do not react with TNBS. The N-terminally modified peptides, e.g. acetylated peptides can be identified using mass spectrometry ***(7)***.

2. Materials

2.1. Deblocking of N-Formylated Proteins

1. Hydrochloric acid (0.1 *M*).
2. Acetonitrile (Sequencing grade).

2.2. Deblocking of Proteins with N-Terminal Pyroglutamic Acid

1. Acetonitrile (Sequencing grade).
2. Polyvinylpyrrolidone (PVP)-40: 0.5% w/v in acetic acid (100 m*M*).
3. Phosphate buffer (0.1 *M*, pH 8.0) containing 5mM dithiothreitol (DTT) and 10 m*M* ethylenediaminetetraacetic acid (EDTA).
4. Pyroglutamyl peptidase (Takara Shuzo, Japan).

2.3. Deblocking of N-Acetylated Proteins

2.3.1. Deblocking with Trifluoroacetic Acid (TFA)

1. Trifluoroacetic acid (TFA) (Sequencing grade).
2. Nitrogen Gas.

2.3.2. Deblocking with TFA in Methanol

1. TFA (Sequencing grade).
2. Methanol (Analytical grade).

2.3.3. Deblocking with Acylamino Acid Releasing Enzyme

1. Acetonitrile (Sequencing grade).
2. PVP-40 (0.5% w/v) in acetic acid (100 m*M*).
3. Trypsin (Promega, USA, modified by reductive methylation).
4. Ammonium bicarbonate buffer (0.1 *M*, pH 8.0).
5. Pyridine (50% v/v).
6. Phenylisothiocyanate (Sequencing grade).
7. Formic acid.
8. Hydrogen peroxide (30% w/v).
9. Phosphate buffer (0.2 *M*, pH 7.2).
10. DTT (1 m*M*).
11. Acylamino acid-releasing enzyme (AARE) (Takara Shuzo).
12. Nitrogen gas.

2.4. Deblocking of Proteins with N-Acyl Groups by Pyrococcus Aminopeptidase

1. Ethylmorpholine buffer (50 m*M*, pH 8.0) containing $CoCl_2$ (0.1%, v/v).
2. *Pyrococcus furiosus* aminopeptidase (Takara Shuzo).

2.5. Sequencing of the N-terminally blocked peptides by mass spectrometry

1. Trypsin (Promega, Wisconsin, USA).
2. TFA (Sequencing grade).
3. Acetonitrile (sequencing grade)
4. Nanocapillary reversed phase column C18, 150 mm length, 0.75 μm diameter (LC Pacing, California, USA).
5. Trap column for CapLC System (Waters Corp., Massachussets, USA).
6. Electrospray ionization-quadrupole/time-of-flight mass spectrometry (ESI-Q/TOF MS)(Micromass, Manchester, UK).

3. Methods

3.1. Deblocking and Sequencing of N-Formylated Proteins

1. Separate the N-terminally blocked protein (<100 pmol) by SDS-PAGE or 2D-PAGE and electroblot it onto a PVDF membrane.
2. Cut out the portion of the PVDF membrane carrying the protein band or spot.
3. Wet the membrane with a small amount of acetonitrile and soak it in 200–500 μL 0.6 M HCl at 25°C for 24 h.
4. Wash the PVDF membrane adequately with deionized water.
5. Dry the membrane in vacuo and apply it to a gas-phase sequencer.

3.2. Deblocking and Sequencing of Proteins with N-Terminal Pyroglutamic Acid

1. Separate the N-terminally blocked protein (<100 pmol) by SDS-PAGE or 2D-PAGE and electroblot it on a PVDF membrane.

2. Cut out the portion of the PVDF membrane carrying the protein band or spot.
3. Wet the membrane with a small amount of acetonitrile and soak it in 200 µL 0.5% (w/v) PVP-40 in 100 m*M* acetic acid at 37°C for 30 min to block the unbound protein-binding sites on the membrane.
4. Wash the membrane with 5 mL of deionized water at least 10 times.
5. Soak the membrane in 100 µL 0.1 *M* phosphate buffer, pH 8.0, containing 5 m*M* DTT and 10 m*M* EDTA.
6. Add pyroglutamyl peptidase (5 µg, enzyme:substrate, 1:1–1:10 w/w).
7. Incubate the reaction solution at 30°C for 24 h.
8. Wash the membrane with deionized water.
9. Dry the membrane *in vacuo* and apply it to a gas-phase sequencer (*see* **Note 4**)

3.3. Deblocking and Sequencing of N-Acetylated Proteins

3.3.1. Deblocking with TFA and Sequencing

1. Separate the N-terminally blocked protein (<200 pmol) by SDS-PAGE or 2D-PAGE and electroblot it on a PVDF membrane.
2. Cut out the portion of the PVDF membrane carrying the protein band or spot and place the membrane in an Eppendorf tube.
3. Place the Eppendorf tube in a vial (2.6 × 6 cm) and then add 100–300 µL TFA.
4. Purge the vial with nitrogen gas for 30 s, seal with a stopper, and incubate at 60°C for 30 min (*see* **Note 5**).
5. Dry the membrane in vacuo and apply to a gas-phase sequencer (*see* **Notes 6** and **7**).

3.3.2. Deblocking with TFA in Methanol

1. Incubate the N-terminally blocked protein (<100 pmol) on glass fiber filters or PVDF membranes with TFA in methanol (1:1 v/v) at 47°C for 2–3 d ***(8)***.
2. Dry the sample and apply it to a gas-phase sequencer.

3.3.3. Deblocking with Acylamino Acid Releasing Enzyme and Sequencing

1. Separate the N-terminally blocked protein (<100 pmol) by SDS-PAGE or 2D-PAGE and electroblot it onto a PVDF membrane.
2. Cut out the portion of the PVDF membrane carrying the protein band or spot.
3. Wet the membrane with a small amount of acetonitrile and pretreat the membrane with 200 µL 0.5% (w/v) PVP-40 in 100 mM acetic acid at 37°C for 30 min.
4. After thorough washing with deionized water, digest the protein on the PVDF membrane with 5–10 µg trypsin (enzyme:substrate, 1:1–1:10, w/w) in 100 µL 0.1 M ammonium bicarbonate buffer, pH 8.0, containing 10% (v/v) acetonitrile, at 37°C for 24 h with shaking (*see* **Notes 8** and **9**).
5. Pool the digestion buffer containing tryptic peptides in an Eppendorf tube.
6. Wash the membrane by vortexing with 100 µL deionized water and the washing solution with the digestion buffer.
7. Evaporate the digestion mixture to dryness in vacuo and add 100 µL 50% (v/v) pyridine and 10 µL phenylisothiocyanate to react with the free, but not blocked N-terminal amino acids of tryptic peptides (*see* **Note 10**).

8. Flush with nitrogen gas, vortex the reaction solution and centrifuge at 3000 g for 1 min.
9. Discard the resultant supernatant containing reaction byproducts and excess reagent. Repeat this washing procedure three times and evaporate the sample to dryness in vacuo.
10. Prepare performic acid solution by mixing 9 mL formic acid and 1 mL 30% hydrogen peroxide and keep the mixture at room temperature for 1 h. Add 100 µL performic acid to the dried sample and, after mixing, place the tube on ice (1 h) to convert the N-terminal phenylthiocarbamyl groups of the peptide to phenylcarbamyl groups by oxidation.
11. Evaporate the sample solution to dryness in vacuo, resuspend in deionized water and again dry in vacuo.
12. Resuspend the sample in 100 µL 0.2 *M* phosphate buffer, pH 7.2, containing 1 m*M* DTT.
13. Dissolve 50 mU AARE in 50 µL of the same buffer and add to the mixture. Incubate at 37°C for 12 h to remove the N-acetylated amino acid.
14. Apply the sample solution to a polybrene-coated glass fiber filter mounted into the upper glass block of the reaction chamber of a gas-phase sequencer (*see* **Notes 11–13**).

3.4. Deblocking and Sequencing of Proteins with N-Acyl Groups by Pyrococcus Aminopeptidase

An aminopeptidase from the archaeon *Pyrococcus furiosus* can be applied to the deblocking, followed by internal sequence analysis of the N-terminally blocked proteins ***(6, 11–13)***. This enzyme can cleave all peptide bonds of protein sequentially from the N-terminus, except the peptide bond at the N-terminal side of proline. Therefore, the N-terminally blocked protein can be truncated from the N-terminus to one residue before proline after *Pyrococcus* aminopeptidase digestion. It is possible to sequence the generated polypeptide with a gas-phase sequencer (*see* **Note 14**).

1. Cut out the portion of the PVDF membrane carrying the protein (<100 pmol) band or spot (*see* **Note 15**).
2. Wash the membrane with 5 mL deionized water.
3. Immerse the membrane in 1 mL 70% (v/v) acetic acid and sonicate for 1/2 h.
4. Remove the acetic acid solution and evaporate the solution to dryness.
5. Resuspend the sample in 50 µL 50 m*M* ethylmorpholine buffer, pH 8.0, containing 0.1% (w/v) $CoCl_2$.
6. Add the *Pyrococcus* aminopeptidase solution. Incubate the sample solution at 50°C for 4 h for small peptides to 2 days for large proteins (*see* **Note 16**). The optimized enzyme:substrate molar ratio is from 1:100 for small peptides to 1:1 for large proteins.
7. Apply the sample solution to a gas-phase sequencer (*see* **Note 17**).

3.5. Sequencing of N-terminally Blocked Peptides by Mass Spectrometry

Proteins were separated by SDS-PAGE or 2D-PAGE and cleaved using trypsin (**Note 17**). The tryptic peptides were separated using nanocapillary HPLC and measured using mass spectrometry such as ESI-Q/TOF MS (*see* **Fig. 1**).

3.6. Enzymatic Digestion

1. Carefully excise the protein band from the 1D- or protein spot from 2D-gel using a scalpel.
2. Cut the gel in small 1 mm pieces and transfer in the Eppendorf tube. All used plastic or metal ware have to be washed using 100% acetonitrile for 5 min. and rinsed with deionized water before use.
3. Cover the gel pieces with 200 µL of 60%(v/v) acetonitrile and incubate at 37°C for 10 min. Remove and discard the solution from the tube.
4. Repeat the step 3 one or more times, depending of the colour intensity of stained gels.
5. Remove the solution and add 100% acetonitrile until the gel turned to opaque white.
6. Remove the acetonitrile.
7. Dry the gel pieces using lyophilization (Speed Vac Concentrator), about 15–30 min.
8. Prepare the enzyme solution (stock solution 1mg/ml trypsin in 50mM NH_4HCO_3 pH 8,0, for the digestion dilute direct before use to the concentration 12.5 ng/µl in 50m*M* NH_4HCO_3 pH 8,0).
9. Add 25 µL of the freshly prepared trypsin solution to the dryed gel. The protein has to be cover with the enzyme solution. When the 25 µL of enzyme solution are not enough add additionally 25µL.
10. Incubate at 37°C until the gel is rehydrated with the trypsin solution. If the solution is not absorbed completely by the gel, remove the excess from the tube.
11. Incubate overnight at 37°C in an stainless steel block or incubator oven. A shorter digestion about 5 h may be sufficient, but causes lower sequence coverage.
12. After the cleavage remove trypsin solution and transfer the gel pieces to the new clean Eppendorf tube.
13. Add 25 µL of 60% acetonitrile for the extraction of peptides. Shake the tube for 10 min. Repeat this procedure for 2–3 times to extract all peptides. The supernatants collect in the new tube.
14. Concentrate the sample in the Speed Vac Concentrator and store in the refrigerator at 4°C.

3.7. Separation of N-terminally Blocked Peptides using LC-MS/MS

1. Use nanocapillary reversed phase HPLC for separation of "in gel" digested peptides. Use reversed phase C18 column, buffer A 0,1% (v/v) TFA and buffer B 0,01% TFA in acetonitrile.
2. Equilibrate the column for 10 min with 0.1% TFA.
3. Inject the sample (25 nL) onto the column.

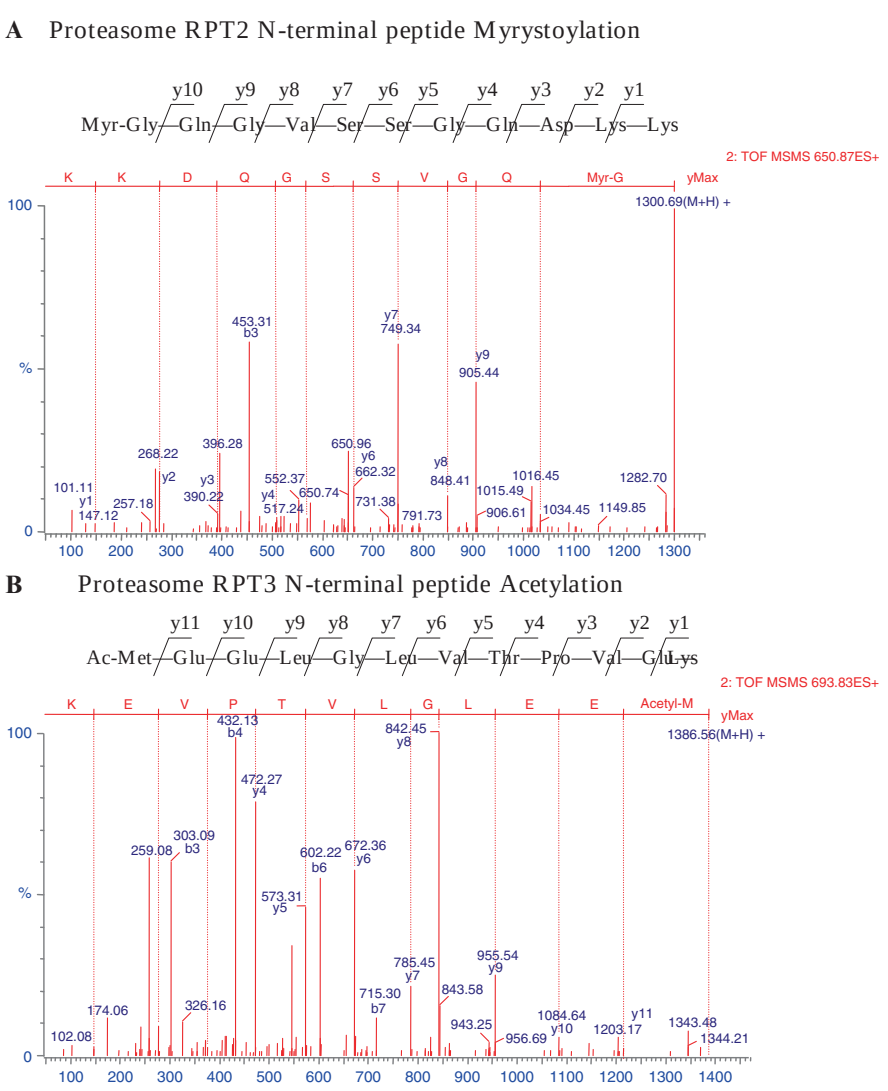

Fig. 1. ESI-MS spectrum of a) N-terminal mirystoylation of tryptic peptide from proteasome subunit RPT2 from *Saccharomyces cerevisiae*, b) N-terminal acetylation of tryptic peptide from proteasome RPT3 subunit from *Saccharomyces cerevisiae*. 4 µg of 19S proteasome was separated by SDS-PAGE, excised from the gel, digested with trypsin and 25 µl were injected in the ESI-MS.

4. Run the linear gradient 5–55% buffer B in 20 min.flow rate 500 nl/min.
5. Perform MS/MS analysis using e.g. ESI-Q/TOF MS (Micromass, Manchester, UK).

Techniques for MS analysis are presented elsewhere.

4. Notes

1. If the N-terminal peptide can be purified from a protein, the N-terminal blocking group and the sequence of the peptide may be determined by mass spectrometry.
2. Deblocking of proteins electroblotted on a PVDF membrane has several advantages:
   a. Proteins purified by PAGE can be efficiently deblocked and sequenced.
   b. Chemical and enzymatic deblocking can be easily performed without desalting, since after electroblotting on a PVDF membrane, the proteins become almost completely salt free.
   c. Proteins can be deblocked at picomole levels.
   d. Sequential deblocking as described in **Note 19** is possible.
3. Proteins are often posttranslationally modified and N-terminal blockage is a well-known posttranslational modification. Proteins are N-terminally blocked not only in vivo but also in vitro. It is possible to prevent artificial *in vitro* blocking generated during protein extraction, PAGE, and Western blotting. The use of highly pure reagents, addition of thioglycolic acid as a free-radical scavenger during the extraction, electrophoresis and electroblotting buffers, or pre-electrophoresis for removing the free-radicals from the gel may help to prevent in vitro blocking ***(14,15)***. However, if proteins are blocked in vivo, a chemical or enzymatic deblocking procedure such as that described in this chapter is required to determine the N-terminal sequence.
3. The blocked peptide can be more efficiently identified by MS, if the digests containing the N-terminally blocked peptide are roughly separated by HPLC.
4. Miyatake et al. ***(16)*** treated the protein-blotted PVDF membrane with anhydrous hydrazine vapor at 20°C for 8 h to deblock proteins with a pyroglutamic acid at the N-terminus. The N-terminal pyroglutamic acid of the protein was converted to Glu–hydrazide which then could undergo Edman degradation. But this often causes partial modification of asparagine and glutamine to their hydrazides and the conversion of arginine residue to ornithine. Milder hydrazinolysis at −5°C for 8 h may be useful to deblock the N-formylated residue ***(16)***.
5. Wellner et al. ***(17)*** indicated that an N–O acyl shift may be involved in the removal of acetyl group of N-terminal acetylserine and acetylthreonine. The advantage of this method is that deblocking is easy and rapid, although overall sequencing yields obtained by this procedure are usually low (5%).
6. When the membrane is exposed to TFA vapor for longer than 2 h, yields of the PTH-amino acids increase, but at the same time, so do those of the reaction byproducts, which prevent identification of PTH-amino acids. Reaction byproducts may be generated primarily through cleavage of polypeptide with TFA ***(18)***.
7. Proteins with either acetylserine or acetylthreonine can be deblocked by TFA treatment but not proteins with other acetylamino acids. About 36

and 4% of acetylated proteins carry acetylserine and acetylthreonine, respectively, as N-terminal amino acids. Treatment with TFA vapor should thus deblock about 40% of acetylated proteins and the remaining may be deblocked with AARE.

8. Pyroglutamated proteins with relatively high molecular mass such as hen egg riboflavin-binding protein (34 kDa) and *Geotrichum candidum* lipase (59 kDa) can be deblocked on a PVDF membrane by direct treatment with pyroglutamyl peptidase. AARE, in contrast, does not directly digest proteins of high molecular mass. As described by Tsunasawa et al. ***(19)***, AARE specifically cleaves the X-Y bond of RCO-X-Y type peptides shorter than 40 residues (R: alkyl group, X/Y: L-amino acid). Thus, prior to AARE digestion, proteins on the membrane should be digested with a protease such as trypsin. Short peptides produced are subsequently released from the membrane. In this protease digestion, 10% acetonitrile is included in the digestion buffer to reduce hydrophobic interaction between peptide and PVDF membrane ***(20)***. In this organic solvent, peptides are more efficiently eluted from the membrane. The acetylated amino acid of the N-terminal peptide extracted is selectively removed by digestion with AARE.
9. If the N-terminal peptide obtained by protease digestion has more than 10 residues, its extraction from the PVDF membrane would be difficult. In such a case, a second digestion with another protease should be performed on the same membrane.
10. Krishna et al. ***(21)*** reported an alternative method in which after fragmentation, peptides with a free amino group at the N-terminus are succinylated and the N-terminal blocked peptide is then deblocked with AARE.
11. If butyl chloride (reagent S3 in ABI protein sequencers) is delivered for 30 s prior to Edman degradation in the gas-phase sequencer to recover the N-terminal blocked amino acid released by AARE, the blocking group and N-terminal amino acid can be identified by mass spectrometry.
12. In the sequencing of cytochrome c, an N-acetylated protein, overall initial yields from successive steps including electrophoresis, electroblotting, deblocking, and sequencing ranged from 23–25%. The efficiency of deblocking and sequencing described here depends primarily on that of tryptic digestion and subsequent peptide elution from the PVDF membrane. Shaking the digestion solution containing the PVDF membrane during tryptic digestion should facilitate elution of the tryptic peptides.
13. The N-terminal myristoyl group of the blocked proteins can be removed when, instead of AARE, peptide N-fatty acylase (Wako Pure Chemicals, Japan) is used as described in **Subheading 3.3**.
14. The *Pyrococcus* aminopeptidase removes the acetylated amino acid slowly, and after cleavage of the first blocked amino acid, the speed of protein degradation rapidly increases. This makes impossible to remove only the N-terminal

blocking group with the *Pyrococcus* aminopeptidase. Therefore, the blocked N-terminal region is truncated and the internal sequence from a residue before proline can be determined by Edman degradation. Since the direct on-membrane digestion of proteins with the *Pyrococcus* aminopeptidase is not easy, it is prerequisite to elute proteins from the membranes prior to the digestion.

15. It is recommended to use the Immobilon-P membrane or teflon membrane (GoreTex). These membranes allow more efficient elution of proteins than the Immobilon-PSQ, Immobilon-CD, Hyperbond, Fluorotrans, ProBlott, Transblot, and polypropylene membranes.
16. If longer time and higher temperature (60–80°C) were used, the deacetylation is more efficient, but high background level significantly decreases the sensitivity and make identification of amino acid impossible. The treatment with the *Pyrococcus* aminopeptidase under optimized conditions results in sufficient deblocking with initial yields up to 50%. However, the initial yields in the sequencer for some large proteins are below 5%.
17. When the sequence of the truncated polypeptide is analyzed, the *Pyrococcus* aminopeptidase itself is simultaneously sequenced. The N-terminal sequence of the aminopeptidase is MVDYELLKKVVEAPGV. The digest has the N-terminal sequence of Xaa-Pro-. If the sample on a glass fiber filter is treated with o-phthalaldehyde (OPA) after the first cycle of Edman degradation, the N-terminus of the *Pyrococcus* aminopeptidase is specifically blocked. However, the digest is not blocked, since the N-terminal residue is proline. Therefore, the sequence of only the digest can be determined from the second cycle ***(9)***.
18. Purified proteins can be digested directly with protease without purification by PAGE, and subjected to MS/MS analysis.
19. The deblocking techniques may be used in combination to make possible sequential deblocking and sequencing of unknown proteins immmobilized onto PVDF membranes (see **Fig. 2**).
    a. A protein sample is transferred from the PAGE gel onto a PVDF membrane by Western blotting.
    b. The membrane carrying the protein is directly subjected to gas-phase sequencing.
    c. If sequencing (2–3 cycles) fails at step a, the membrane is removed from the sequencer, and treated with TFA vapor at 60°C for 30 min to remove the acetyl groups of acetylserine and acetylthreonine. If the protein is N-terminally blocked by acetylserine or acetylthreonine, the acetyl group is removed by this procedure and sequencing from the N-terminus becomes possible.
    d. If sequencing fails at step b, the membrane is incubated in 0.6 M HCl at 25°C for 24 h to remove formyl groups, and then subjected to sequence analysis again.

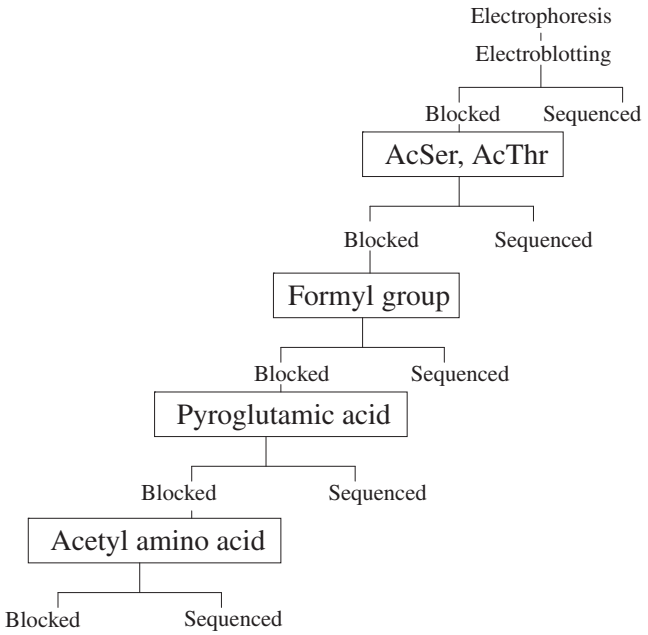

Fig. 2. Strategy of sequential deblocking for N-terminally blocked proteins electroblotted on a PVDF membrane ***(9)***.

e. If sequencing fails at step c, the sample is subjected to on-membrane pyroglutamyl peptidase digestion to remove N-terminal pyroglutamic acid and sequencing is again conducted.
f. Finally, if sequencing fails at step (d), deblocking with AARE is performed to remove acetylamino acids that are not removed in step (b) and sequencing is then attempted again. If sequencing still fails, different methods must be used.

Deblocking of Proteins Containing N-Terminal Pyroglutamic Acid

Jacek Mozdzanowski

1. Introduction

Pyroglutamic acid (pGlu) is the product of cyclization of N-terminal glutamine and is one of the common modifications found at the N-termini of proteins. This modification is typical for immunoglobulins, especially IgGs, since they often contain glutamine at the amino terminus of the heavy chain. This chemical modification, in addition to other modifications of the N-terminus, results in a "blocked" protein, which cannot be sequenced using Edman degradation. Many deblocking procedures have been reported to remove common modifications at the N-terminal end of proteins for the sequence determination by Edman chemistry ***(1)***. Deblocking of N-terminal pGlu is usually achieved by the use of either chemical methods ***(2–5)*** or by the use of pyroglutamate aminopeptidase (PGAP) ***(1,6–8)***. Removal of pGlu from peptides by PGAP with high yield has been described ***(1,6–10)*** and recommended as a standard procedure ***(1).*** However, when this protocol is applied to large proteins such as IgGs, it results in relatively low yield (<40%) of the deblocked protein. The most commonly cited procedure of Podell and Abraham ***(11, 12)*** for removal of pGlu from proteins is also recommended in the handbooks ***(1,13,14)***. However, this procedure is not consistent with the results, which demonstrated that incubation at 4°C did not yield any deblocking ***(15)***. Other existing protocols use PGAP for digestion of proteins in solution or for proteins blotted onto PVDF membranes and result in variable yields ***(2,11,13,16,17,18,19)***. The use of thermostable PGAP from Pyrococcus furiosus allows to simplify the deblocking procedure and reduce the reaction time at the expense of incomplete deblocking, and possible partial degradation/fragmentation of the deblocked protein ***(19)***. The need to confirm cDNA coded protein sequence and to determine the purity of recombinant therapeutic

proteins by reliable N-terminal sequencing requires highly efficient procedure that can remove N-terminal pGlu without protein fragmentation ***(15)***. This chapter describes such a procedure utilizing pyroglutamate aminopeptidase for deblocking of proteins in solution.

2. Materials

2.1. Reduction and Carboxymethylation of Proteins

1. Dithiothreitol (DTT)
2. 8 *M* guanidine buffer: 8 *M* guanidine, 0.35 *M* Tris-HCl, pH 8.5 (this buffer may be stored at room temperature for approx. 1 yr).
3. Iodoacetic acid, sodium salt

2.2. Desalting/Buffer Exchange

1. Sephadex G-25 column (NAP™-5, GE Healthcare, gel bed dimensions 0.9 × 2.8 cm).
2. Phosphate buffer: 0.1 *M* sodium phosphate, 2 m*M* EDTA, pH = 8.0. It is highly recommended that this buffer be prepared fresh for each experiment.

2.3. Digestion with Pyroglutamate Aminopeptidase

1. Glycerol
2. 1.0 M DTT solution in phosphate buffer (see **Subheading 2.2,** phosphate buffer). Prepare fresh for each experiment.
3. Pyroglutamate Aminopeptidase (Takara, Shuzo Co. Ltd., Code No. 7334).

3. Methods

3.1. Reduction and Carboxymethylation of Protein

1. Dissolve 0.5 mg of protein (e.g. IgG) in 1.0 mL of guanidine buffer (*see* **Note 1**).
2. Add 8.5 mg DTT and dissolve it in the reaction mixture.
3. Blanket the reaction mixture with argon.
4. Incubate at 60°C for 90 min.
5. Cool the reaction mixture down to room temperature.
6. Add 28 mg of solid sodium iodoacetate and dissolve in the reaction mixture (*see* **Note 2**).
7. Incubate at room temperature for 45 min in the dark (wrapped with aluminum foil) (*see* **Note 3**).
8. Add approx. 5 mg DTT and dissolve in the reaction mixture (*see* **Note 4**).

3.2. Desalting/Buffer Exchange

1. Equilibrate Sephadex G-25 (NAP-5) column with approx. 10 mL of 0.1 *M* phosphate buffer (0.1 *M* phosphate, 2 m*M* EDTA, pH 8.0) (*see* **Note 5**).
2. Load 0.3 mL of the reaction mixture containing reduced/carboxymethylated protein to the column (*see* **Note 6**).

3. Wait until there is no solution left above the top frit of the NAP-5 column. Discard the eluate (*see* **Note 7**).
4. Apply 0.55 mL of phosphate buffer (0.1 M phosphate, 2 mM EDTA, pH 8.0) to the column (*see* **Note 6**).
5. Wait until there is no solution left above the top frit of the NAP-5 column. Discard the eluate.
6. Place a clean vial under the column and apply 0.4 mL of phosphate buffer (0.1 *M* phosphate, 2 m*M* EDTA, pH 8.0) to the column.
7. Wait until there is no solution left above the top frit of the NAP-5 column. Collect the eluate (*see* **Note 8**).

3.3. Digestion with Pyroglutamate Aminopeptidase

1. Add 20 µL of glycerol to 0.4 mL of desalted reaction mixture (*see* desalting/buffer exchange, **Subheading 3.2**).
2. Add 5 µL of 1.0 *M* DTT solution in phosphate buffer (0.1 *M* phosphate, 2 m*M* EDTA, pH 8.0) to the reaction mixture (*see* **Note 9**).
3. Dissolve pyroglutamate aminopeptidase in 100 µL of phosphate buffer (0.1 *M* phosphate, 2 m*M* EDTA, pH 8.0) (*see* **Note 10**).
4. Add 10-20 µL of pyroglutamate aminopeptidase solution to the reaction mixture (*see* **Note 11**).
5. Blanket the reaction mixture with argon.
6. Incubate at 37°C for 24 h (*see* **Note 12**).
7. Sequence the sample (*see* **Note 13**).

4. Notes

1. Typically proteins are available as a solution. In most cases the protein solution may be mixed with the guanidine buffer to produce a final protein concentration of 0.5 mg/mL. Dilution of the guanidine buffer from 8 *M* to 4 *M* does not affect the reduction/carboxymethylation process. Proteins in dilute solutions may require concentration. The amount of protein needed for sequencing is much lower than 0.5 mg. This procedure may be modified for use with limited amounts of protein.
2. The amount of sodium iodoacetate has to be in stoichiometric excess of DTT in the reaction mixture. If the amount of DTT used in step 2 is greater than 8.5 mg, 28 mg of sodium iodoacetate may be insufficient for carboxymethylation. Sodium iodoacetate decomposes with time producing free iodine. Free iodine may result in iodination of tyrosines. Sodium iodoacetate which is pale yellow or yellow should not be used. Exposure to light increases the degradation of sodium iodoacetate.
3. Suggested incubation time for both the reduction and carboxymethylation steps is to assure a complete reaction. With many proteins a complete reaction may be achieved in a shorter time.

4. DTT is added to neutralize the unreacted iodocatetae. The exact amount of DTT added at this step is not critical.
5. Excess phosphate buffer (~10 mL) will provide very good equilibration of the NAP-5 column. The exact volume is not critical and larger volumes used for equilibration will not affect the procedure. If a desalting column of different volume is used, the volume used for equilibration should be equal to at least 3 column volumes.
6. All the volumes are given for Sephadex G-25 NAP-5 column from GE Healthcare. Other desalting columns may be used after the elution volume for a protein is established. The elution volumes may vary for different proteins. Low molecular weight proteins or peptides cannot be processed using the described desalting protocol. Certain proteins may bind to the resin and cannot be recovered from the desalting column (this is not common). The volumes given in this protocol are based on elution of IgGs.
7. The buffer flow through the column will stop as soon as there is no more liquid above the top frit. There is no danger of air getting inside the resin bed.
8. The method was not optimized for quantitative recovery of protein. This volume may require modifications for different proteins. If quantitative recovery is desired, the exact elution profile established by any suitable method (e.g., absorbance at 280 nm) will be very helpful.
9. Pyroglutamate aminopeptidase is a thiol protease and the presence of DTT is important for the activity of the enzyme.
10. Takara sells pyroglutamate aminopeptidase in lyophilized form, which is stable for several months under the proper storage conditions. After the enzyme is dissolved, it should be stored frozen (-70°C) and used within 1 month.
11. The amount of PGAP given here was optimized for IgGs. Larger amount of PGAP will improve deblocking yield. Commercially available enzyme is highly purified and the use of larger amount will have minimal effect on sequencing background.
12. Pyroglutamate aminopeptidase from *Pyrococcus furiosus* (Takara) can be used at higher temperatures. Higher incubation temperature reduces the time necessary for digestion but often increases protein degradation and results in higher background in sequencing. In some cases incubation at 37°C for 2 or 3 d may be beneficial for the deblocking yield.
13. This procedure was used for the deblocking of several IgGs. There is no reason to anticipate problems when deblocking other proteins. In general the expected deblocking yield is between 80-100%.

Detection and Characterization of Protein Mutations by Mass Spectrometry

Yoshinao Wada

1. Introduction

A significant proportion of genetic disorders are caused by point mutations in proteins. Although most structural studies of mutated proteins are carried out by genetic methods, mass spectrometry (MS) is still a more rapid way of the analysis if sufficient amounts of proteins are obtained. The process for characterization, *i.e*. finding aberrant signals in the mass spectrum and determining the site and nature of mutations, described here is applicable to recombinant proteins and to the structural studies of post-translational modifications.

The principal part of analysis includes a method called "peptide mass mapping" which aims at both detection and characterization of mutations, and employs electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI) for ionization of peptides. In addition, these soft ionization methods have allowed MS to deal with whole protein molecules for detection of mutations, and this approach is effective for the proteins of molecular mass <20,000-50,000, depending on the resolving power of mass analyzers ***(1-4)***.

For the characterization of mutations in the peptides of interest, collision-induced dissociation (CID), or tandem MS (MS/MS), is successful in most cases, because the product ion mass spectra can be read in comparison with the normal reference ones.

Summary of procedures

1. (prior to MS) Purification. alkylation, and desalting.
2. Detection of variants through mass measurement of the intact protein molecules.
3. Chemical or enzymatic cleavage.
4. Peptide mass mapping to identify mutated peptides.
5. Data interpretation.

2. Materials

2.1. Apparatus for Sample Preparation

1. Desalting tools using reversed phase media such as ZipTip (Millipore): ZipTipC4 for proteins and ZipTipC18 for peptides.
2. NAP-5 (GE Healthcare)

2.2. Chemicals

1. Dithiothreitol (Sigma).
2. Iodoacetic acid (Sigma) or iodoacetamide (Sigma).
3. Cyanogen bromide (CNBr) (Sigma) (toxic, handle with gloves in hood).
4. Acetonitrile (HPLC gradoemt grade; Merck).
5. Formic acid (reagent grade; Merck).
6. Trypsin (TPCK-treated) (Sigma type XIII).
7. Lysylendopeptidase (Wako, Osaka, Japan).
8. Endoproteinase Glu-C (Roche).
9. Endoproteinase Asp-N (Roche).
10. Solutions for reduction and alkylation: Stock solution A: 1 *M* Tris-HCI containing 4 m*M* EDTA, adjusted to pH 8.5 with HCl. Stock solution B: 8 *M* guanidium chloride. Mix stock solutions A and B at a 1:3 ratio to make a solution of 6 *M* guanidium chloride, 0.25 *M* Tris-HCl, and 1 m*M* EDTA prior to use.
11. 0.05 *N* HCl.
12. 1.5 *M* Tris.
13. 50 m*M* Ammonium hydrogen-carbonate, pH 7.8 (pH adjustment is not required).
14. 50 m*M* Ammonium carbonate, pH 8.3 (pH adjustment is not required).
15. 50 m*M* Tris-HCl, pH 7.4.
16. 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic aicd, 10 mg/mL) in acetonitrile: water:TFA (30:69.9:0.1 [v/v/v]) for MALDI matrix for proteins; 2,5-dihydroxy-benzoic acid (10mg/mL) or α–cyano-4-hydroxycinnamic acid (saturated solution) in acetonitrile:water:TFA (50:49.9:0.1 [v/v/v]) for MALDI matrices for peptides.
17. Acetonitrile:water:acetic acid (49:49:2 [v/v/v]) or methanol:water:formic acid (70:29.9:0.1 [v/v/v]) for ESI solvent.
18. Glycerol:trichloroacetic acid (95:5 [w/w]) for FAB matrix.

3. Methods

3.1. Purification and Desalting for MS

Removing salts (desalting) is preferred because the formation of adduct ions with alkali metals such as sodium and potassium reduces the abundance of the protonated molecular ion species, which are the informative ions for the mass measurement of proteins and peptides, and unnecessarily complicates mass spectra. In order to prevent this, RP-LC is recommended as the final step of purification procedures. Alternatively, a more convenient method of desalting is to use a pipette tip with a bed of chromatography media such as ZipTip according to the manufacturer's protocol shortly as follows.

1. For pre-wetting ZipTip, aspirate 50% methanol (wetting solution) into tip. Dispense to waste and repeat.
2. Equilibrate the tip for binding by washing with the equilibration solution (0.1% TFA) 3 times.
3. Bind peptides or proteins, which are dissolved in acidic solution such as 0.1%–1.0% TFA without organic solvents, to ZipTip by fully depressing the pipettor plunger to a dead stop. Aspirate and dispense sample 3 to 7 cycles for simple mixtures and up to 10 cycles for maximum binding of complex mixtures.
4. Wash tip and dispense to waste using at least five cycles of wash solution. A 5% methanol in 0.1% TFA/water wash can improve desalting efficiency.
5. Dispense 5 to 10 µL of elution solution (75% methanol / 0.1% TFA or 0.1% formic acid) into a clean vial using a standard pipette tip. Carefully, aspirate and dispense eluate through ZipTip at least three times without introducing air.
6. For ESI MS, the sample can be eluted into clean vial or into a nanospray needle for direct infusion MS, for which the elution solution in step 5 should not contain TFA. For MALDI MS, an aliquot of eluate is mixed with the same volume of sinapinic acid solution in a clean vial, and then placed on a sample target and dried.

3.2. Detection of Variants Through Mass Measurement of the Intact Protein Molecule with MS

Among the naturally occurring amino acids, Leu and lle have the same elemental composition. Lys and Gln are different in composition, but have the same nominal mass. All other amino acids differ from each other in their molecular mass by ≤129 Da. Variants having substitutions of these amino acids are different in molecular mass from the corresponding normal proteins and are thus theoretically detectable by measuring the molecular mass of the intact protein by MS.

For ESI-MS, the sample at a concentration of 1–10 µ*M* in the ESI solvent is introduced into the ion source. Any sample remaining in the delivery tube after analysis is recovered and lyophilized for further analysis, if necessary.

Fig. 1 shows the MALDI-TOF mass spectrum of the globins from a patient with a mutant hemoglobin. Two different β-globin species are clearly differentiated in the mass spectrum taken at a resolution of 3,000, and the mass separation was determined from this analysis to be 14 u (*see* **Note 1**).

3.3. Chemical or Enzymatic Cleavage

3.3.1. Reduction and Alkylation

Cysteine residues are often subject to auto-oxidation during preparation procedures, leading to a variety of products and random formation of disulfide bridges during preparation procedures. To avoid these unexpected modifications, conversion to stable derivatives by alkylation should be performed after reduction. Such a modification destroys the higher order structure of the protein by cleaving intra- or inter-molecular bridges, thus facilitating the action of proteolytic enzymes by allowing them to access cleavage sites.

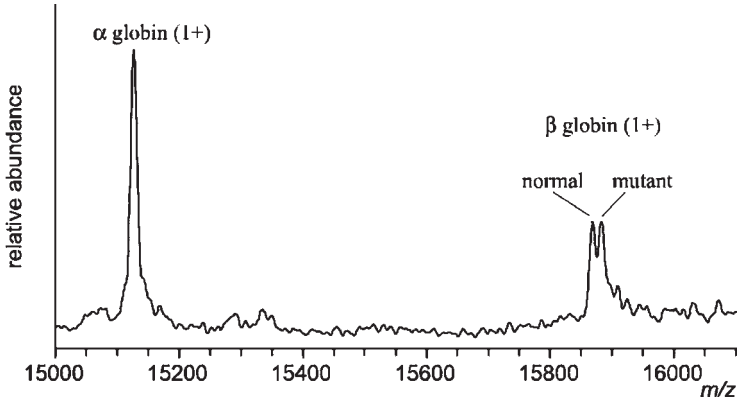

Fig. 1. Detection of a variant protein by MALDI-TOF-MS. The mass separation is determined to be 14 u.

1. Dissolve the protein at 1–20 µg/mL in a 400 µL sample buffer containing 6 *M* guanidium chloride, 0.25 *M* Tris-HCl and 1 m*M* EDTA, pH 8.5.
2. Add 5 µL of 1 *M* dithiothreitol (freshly prepared before use) dissolved in sample buffer directly and incubate under nitrogen gas at 50 °C for 30 min.
3. Chill down the tubes to room temperature.
4. Add 50 µL of 1 *M* iodoacetamide in sample buffer or iodoacetic acid in 0.1 *N* NaOH, and incubate for 30 min at room temperature in the dark.
5. Make up the volume to 500 µL with water.
6. Transfer onto a NAP-5 column equilibrated with 0.05 *N* HCl, and recover the proteins in a subsequent 1 mL solution of 0.05 *N* HCl.
7. Proteins are lyophilized or are subjected to enzymatic digestion after addition of 1/10 volume of 1.5 *M* Tris to raise the pH above 8.0.

3.3.2. Cleavage with CNBr (Optional)

CNBr cleaves only at methionine residues in proteins, generating large peptide fragments compared with enzymatic cleavage. The peptides will be <20,000 Da, which is well within the range that can be measured precisely by MS. Most of the resulting C-terminal homoserine residues of the peptides from this type of cleavage are in lactone form. Cleavage by CNBr helps to confirm a suspected site of mutation to a small part of the protein molecule and for determining the size of the molecular shift precisely.

1. Dissolve the protein at 1–20 µg/mL in 70% (v/v) TFA (*see* **Note 2**).
2. Add a >100-fold molar excess, over methionine residues, of CNBr dissolved in 70% TFA solution, and incubate in the dark under nitrogen at room temperature for 2 h.
3. Add 10 vol of water, and remove salts as described in **Subheading 3.1.**
4. ESI- or MALDI-MS, as described in **Subheading 3.1.**

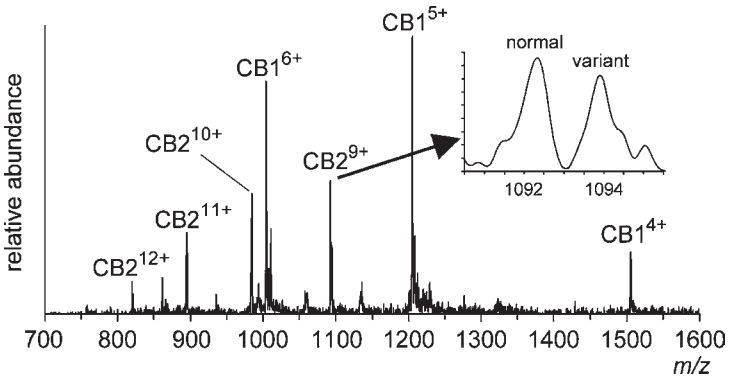

Fig. 2. ESI mass spectrum of CNBr peptides of the β-globin isolated from the same patient shown in **Fig. 1.** The region of the nine-charged ion for peptide CB2 is depicted in an inset. A Cys-containing peptide CB2 is detected at the expected mass without alkylation. The resolution is 2,000.

In the example shown in **Fig. 2**, a mutation causing a difference of 14 u is identified in peptide CB2 (M_r 9821.4 for the normal species) of β-globin. The separation of the normal and the variant species is obviously better than that of the intact proteins shown in **Fig. 1**.

3.3.3. Enzymatic Digestion and Peptide Mass Mapping

The following enzymes are amino acid-specific in their cleavage, and are employed for peptide mass mapping: trypsin, lysylendopeptidase (endoproteinase Lys-C), endoproteinase Glu-C, endoproteinase Asp-N. Using volatile buffers allows to omit the desalting process prior to peptide mass mapping. Alternatively, desalting can be performed as described in **Subheading 3.1.**

1. Dissolve proteins in the digestion buffer at about 1–20 µg/mL.
2. Optimized buffers: for trypsin and endoproteinase Glu-C, 50 m*M* ammonium hydrogen-carbonate (pH 7.8); for endoproteinase Lys-C, 50 m*M* ammonium carbonate (pH 8.3); for endoproteinase Asp-N, 50 m*M* Tris-HCl (pH 7.4) (*see* **Note 3**).
3. Add protease at >1% (w/w) ratio and digest at 37°C for 6 h.
4. Remove salts according to the procedure in **Subheading 3.1**, or lyophilize directly if volatile buffer is used.
5. ESI or MALDI MS, as described in **Subheading 3.1.**

3.4. Peptide Mass Mapping

The mass spectra of a tryptic digest of β-globin by ESI, MALDI and fast atom bombardment (FAB) are shown in **Fig. 3**. The coverage is the same between ionization methods. ESI MS of peptides can be directly forwarded to the succeeding

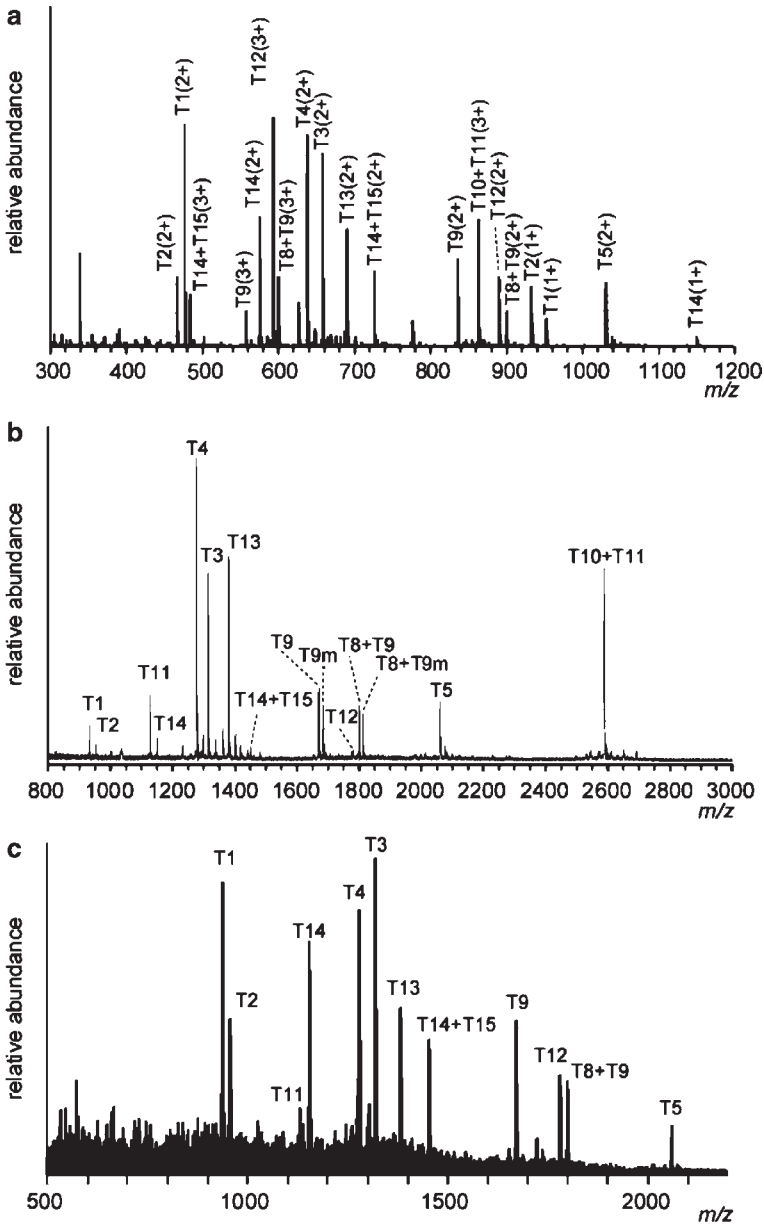

Fig. 3. Mass spectra of the tryptic digest of carboxymethylated β-globin acquired by different ionizations, **(a)** ESI, **(b)** MALDI and **(c)** FAB. The number above each peak is that of the predicted tryptic peptide starting from the N-terminus. In the MALDI-TOF mass spectrum, mutated peptides, T9m and T8+T9m, are detected beside the corresponding normal peptides **(see Fig. 8a).**

CID for sequence analysis, though the mass spectrum is complicated due to a number of multiply charged ions from the component peptides. LC/MS can be operated with ESI, facilitating detection of component peptides with good signal-to-noise ratio. MALDI-TOF produces a lucid mass spectrum comprised of singly charged ions, but the relative intensity of ions is not correlative with the abundance of the corresponding peptides (**Fig. 3b**). FAB ionization presents a simple mass spectrum as MALDI but is less sensitive than other ionizations (**Fig. 3c**).

3.5. Characterization of the Mutation

Categorized strategies are described here using examples of variant hemoglobins (*see* **Note 4**).

3.5.1. Simple Cases

1. New cleavage site: The example shown in **Fig. 4** is a hemoglobin variant with a mutation in α-globin. Tryptic peptide 6 (T6), which should be detected at *m/z* 1833.9. is missing, and a new peptide appears at *m/z* 1634.8 in the mass spectrum. The substitution of Arg for Gln at position 54 is the only possible substitution that fits the molecular mass change. The substitution can be verified by a digestion with lysylendopeptidase, which does not cleave arginyl peptide bonds; the peptide ion is shifted from the normal *m/z* 1833.9 to *m/z* 1862.0, with the increase of 28 u confirming the Gln→Arg mutation.

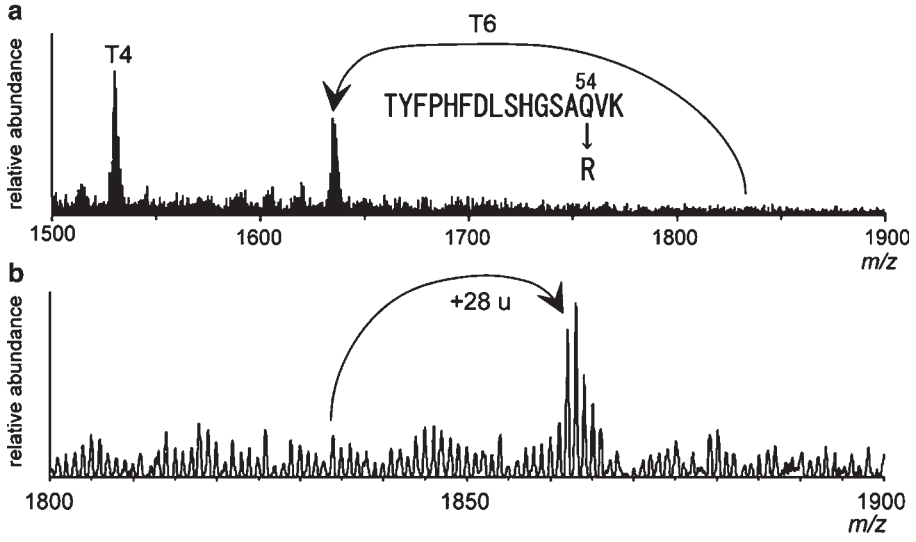

Fig. 4. FAB mass spectra of **(a)** tryptic and **(b)** lysylendopeptidase digests of an α-globin variant.

2. Missing cleavage site: In **Fig. 5**, a β-globin variant, tryptic peptides 13 (T13) and 14 (Tl4) are missing in the digest, indicating a mutation at the Lys residue at position 132. The new peptide is observed at *m/z* 2495.3, indicating the replacement of Lys by Asn.
3. Unique replacement: In **Fig. 6,** tryptic peptide 11 (T11) at *m/z* 1126.6 is missing (a trace due to insufficient separation from normal protein) and a new peptide appears at *m/z* 1152.6 in the digest of purified β-globin of the variant hemoglobin. This increase of 26 u suggests five possible mutations; His→Tyr, Ala→Pro, cmCys (carboxamidomethylcysteine)→Trp, Ser→Leu, and Ser→Ile. Since the normal peptide has His, but not Ala, Cys, or Ser residues, and has a single His residue at position 97 in the sequence, it follows that the latter has been replaced by Tyr.

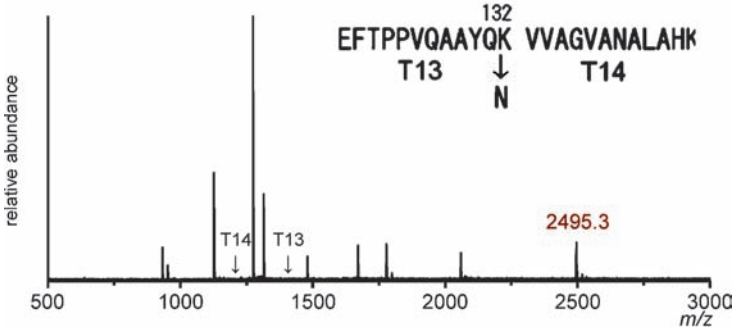

Fig. 5. MALDI mass spectrum of the tryptic digest of a β-globin variant.

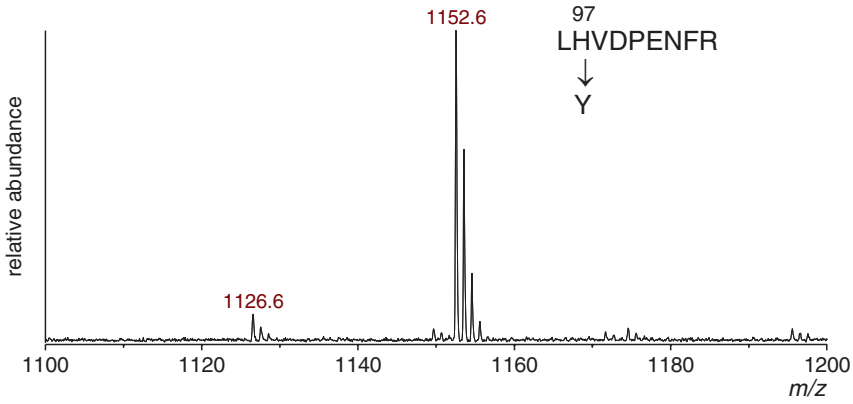

Fig. 6. MALDI mass spectrum of the tryptic digest of a β-globin variant. A trace peak at *m/z* 1126.6 is derived from contamination of normal protein.

3.5.2. Precise Measurements with High-Resolution MS

High-resolution MS that can determine the mass of peptides at least to the third decimal place is available with a Fourier transform ion cyclotron resonance (FTICR) or an orbitrap mass analyzer. The technology enhances the capacity of the peptide mass mapping strategy for structural characterization ***(5)***. For the same mutation shown in **Fig. 6**, five types of substitutions are suggested, and the corresponding mass shifts in exact mass are as follows: His→Tyr (26.0044), Ala→Pro (26.0157), cmCys→Trp (26.0487), Ser→Leu (26.0520), and Ser→Ile (26.0520). FTICR mass spectrum shown in **Fig. 7** is capable of discriminating a subtle difference in these mass shifts ocurring in a 1 kDa peptide, and the statistics from 20 repeated measurements uniquely determines the type of substitution His→Tyr for the measured mass shift of 26.00439 ± 0.00046.

3.5.3. Complex Cases

In cases where the molecular weight of the mutated peptide does not permit the assignment of a unique type and/or position of substitution, chemical data, such as the charge carried on the variant, may provide an answer. Alternatively, combination of different enzymes may give conclusion. For an example shown in **Fig. 8**, the mass spectrum of a tryptic digest of β-globin from the patient discloses new peaks near the normal peptide 9 (T9), suggesting that the mutation must be

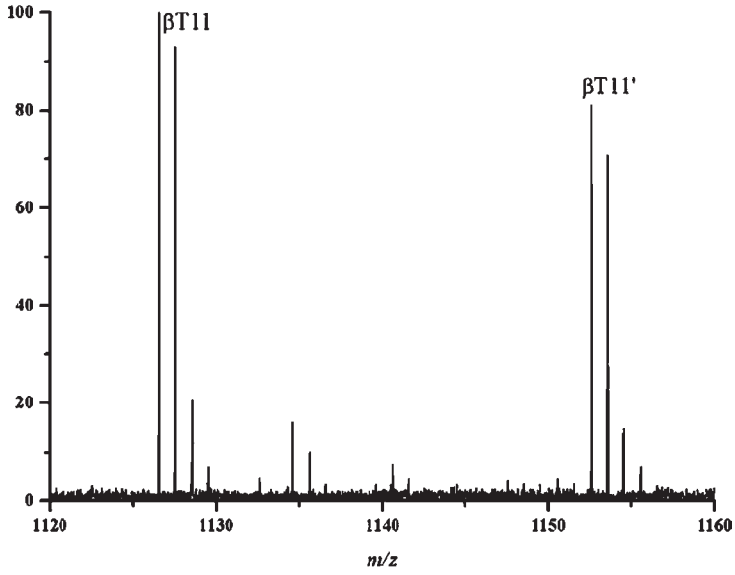

Fig. 7. FTICR mass spectrum of the tryptic digest of a β-globin variant (the same sample for Fig. 6. Reproduced from ***ref. 5*** under permission.

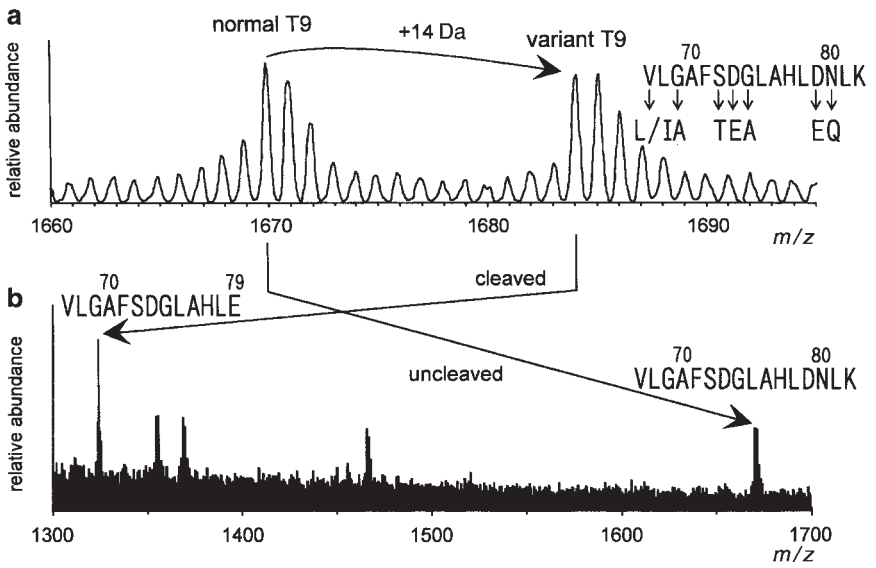

Fig. 8. FAB mass spectra of **(a)** tryptic and **(b)** endoproteinase Glu-C digests of a β-globin variant. The protonated molecular ions at *m/z* 1669.9 and at *m/z* 1683.9 are derived from the normal and variant proteins, respectively. The increase of 14 u for this peptide gives several possible types of mutations even with supporting chemical data. The substitution Asp79→Glu is determined by endoproteinase Glu-C digestion. See also **Fig. 10,** for CID analysis for verifying the structure.

in T9. The difference of 14 u suggests seven possible substitutions: Gly→Ala, Ser→Thr, Val→Leu, Val→lle, Asn→Gln, Asp→Glu, Asn→Lys, and Thr→Asp. However, even on the basis of both the normal sequence and the electrophoretic data, six different substitutions at seven possible positions are left as candidates. In this instance, the substitution of Glu for Asp at position 79 is determined, when the tryptic digest is then hydrolyzed with endoproteinase Glu-C.

3.6. CID or Tandem Mass Spectrometry

In all the cases described above, it is necessary to determine the suggested mutation by CID or tandem MS. It is usually easy to read the CID mass spectrum, because the product ions from the mutated peptide can be compared with those from the normal one. Examples of the CID mass spectrum for mutation analysis based on ESI and MALDI and low-energy collision are presented in **Figs. 9** and **10**, respectively. High-energy collision may produce key fragments, especially when discrimination of Ile and Leu is required ***(6)***. The CID analysis of intact proteins without digestion is an issue of challenge, while the information is still confined to a part of the molecule ***(7)***.

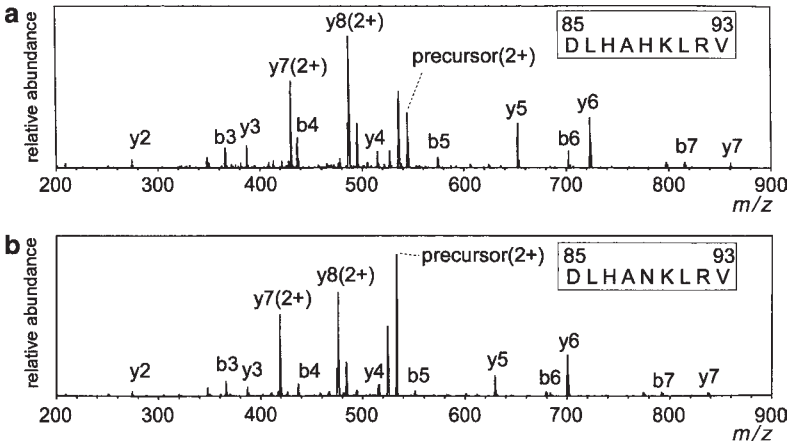

Fig. 9. CID mass spectra taken for the structural characterization of a mutated peptide by ESI ion trap MS. **(a)** As a reference, the $[M+2H]^{2+}$ ion for the normal peptide at *m/z* 544.8 was selected as the precursor. **(b)** The $[M+2H]^{2+}$ ion for the mutated peptide at *m/z* 533.3 was selected as the precursor. Note the difference in the *m/z* values for the b5 or the y5 product ion between the two spectra, indicating the mutation at position 89.

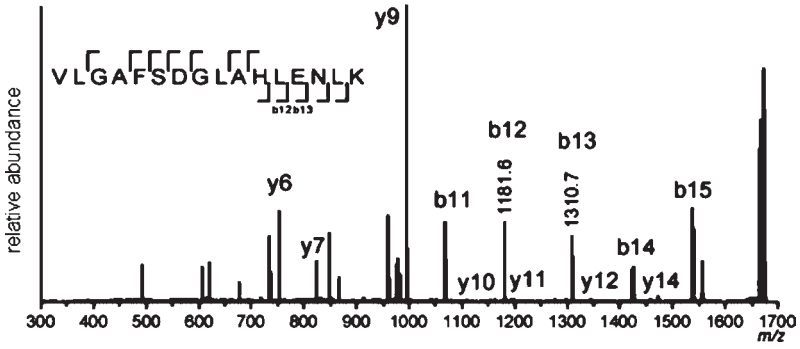

Fig. 10. CID mass spectrum of the ions for T9m (*m/z*1683.9) in **Fig. 3b.** The product ions at *m/z*1181.6 (b12) and *m/z*1310.7 (b13) indicate Glu for the 13th residue (position 79 in **Fig. 8a**) from the N-terminus of this peptide.

When mutations are suggested by MS of intact proteins or, preferably, the target sites are localized within specific peptides by peptide mass mapping, DNA sequence analysis can be efficiently applied to the corresponding gene for characterization of the responsible mutation ***(8)***.

4. Notes

1. The theoretical isotopic distributions of human β-globin (146 residues, M_r 15,867) at resolutions of 15,000 (A) and 2,000 (B) are shown in **Fig. 11**. In actual measurements of proteins of molecular mass over several kilodaltons, it is usually impossible to obtain the high ion current necessary for unit resolution as (A), nor is it possible to identify the ^{12}C species corresponding to the exact mass in the molecular ion cluster. Consequently, the average mass of the unresolved isotopic cluster or "chemical mass" is usually used. The smallest difference in molecular masses detectable by MS taken at a modest resolving power of a few thousand increases with the increasing size of the proteins. A theoretical analysis can be considered using two model proteins: β-globin (M_r 15,867) and transferrin (M_r 79,556) (**Fig. 12**). A separation of 14 u in transferrin is not clear (C in **Fig. 12b**), whereas the shapes of the clusters for 20 and 31 u differences, corresponding to D and E, respectively, in **Fig. 12b**, are similar to those for 9 and 14 u differences, corresponding to C and D, respectively, of the β-globin in **Fig. 12a**. The minimum difference in molecular mass detectable as pattern D in **Fig. 12b** for an equimolar mixture with normal proteins of M_r over 100,000 is about 20 u. This means that about half of the possible amino acid substitutions in a protein of this size will escape detection. In those cases, a strategy to detect these substitutions preferably starts with the analysis of CNBr-cleaved peptides (**Subheading 3.3.2**).

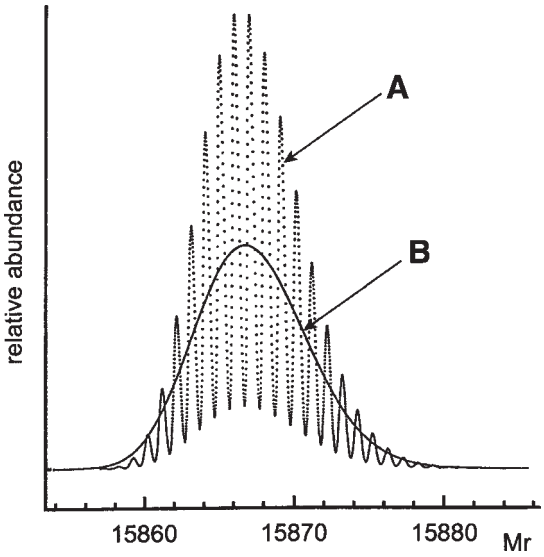

Fig. 11. Theoretical isotopic distributions of β-globin at resolutions of 15,000 **(A)** and 2,000 **(B)** (10% valley definition).

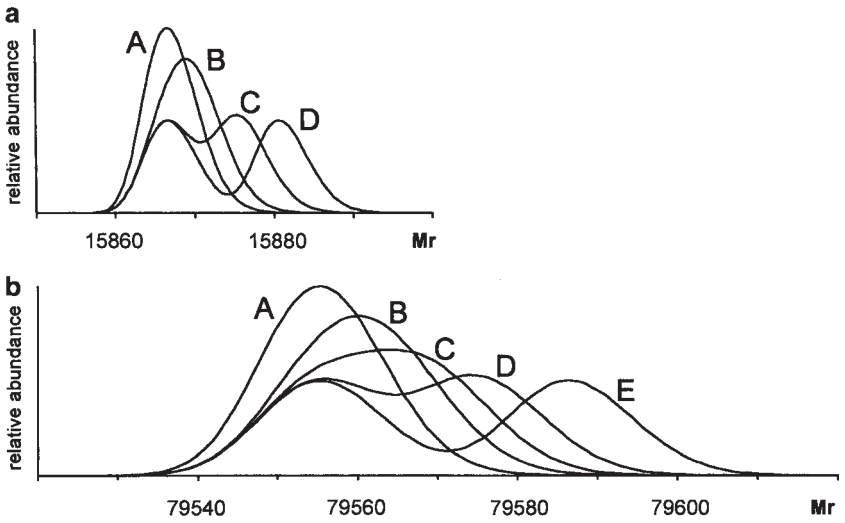

Fig. 12. Theoretical distributions of isotopic clusters corresponding to an equimolar mixture of **(a)** normal and variant β-globins. (A) Pure normal protein; (B) normal and +4 mass unit mutant; (C) normal and +9 mutant; (D) normal and +14 mutant. **(b)** Normal and variant transferrin. (A) Pure normal protein; (B) normal and +9 mass unit mutant; (C) normal and +14 mutant; (D) normal and +20 mutant; (E) normal and +31 mutant. The curves have been drawn by connecting the peak top of each isotopic ion from a display at sufficient resolution to achieve complete separation of ^{13}C isotopic peaks.

2. Cleavage in formic acid is not recommended, because it has a tendency to formylate amino and hydroxyl groups, which creates a mixture consisting of products differing in molecular mass by multiples of 28 Da.
3. Lysylendopeptidase is active in urea solution at a concentration up to 4 *M*. The digestion is often carried out in a solution of 4 *M* urea, 0.1 *M* Tris-HCl, pH 9.0, in which substrates are denatured and become susceptible to the cleavage.
4. Protein variants are heterozygous in most cases, namely both normal and mutated proteins are present in the patients as shown in **Fig. 1**. In this chapter, variant proteins, isolated from their normal counterpart, are presented, except for the cases of **Figs. 7** and **8.** *See* **refs. 7** and **8**.

Peptide Sequencing by Nanoelectrospray Tandem Mass Spectrometry

Ole Nørregaard Jensen and Matthias Wilm

1. Introduction

Electrospray ionization mass spectrometry (ESI-MS) ***(1)*** has had a profound influence on biological research over the last decade. With this technique, it is possible to generate and characterize gas-phase analyte ions from aqueous solutions of proteins, peptides, and other classes of biomolecules. ESI is performed at atmospheric pressure, which simplifies sample preparation and handling and allows on-line coupling of chromatography, such as capillary high-performance liquid chromatography (HPLC), to mass spectrometers (LC-MS). The use of ESI in combination with tandem mass spectrometry (MS/MS) provides the capability for amino acid sequencing of peptides. The optimization and miniaturization of peptide sample preparation methods for ESI as well as the development of highly sensitive tandem mass spectrometers, including ion traps and quadrupole-time-of-flight (Q-TOF) and linear ion trap-fourier transform MS hybrid instruments, makes it possible and almost routine to obtain amino acid sequences from subpicomole levels of protein in many laboratories. Peptide sequencing is typically performed by nanoelectrospray MS/MS analysis of crude, concentrated peptide mixtures or by hyphenated techniques, such as capillary HPLC coupled to micro/ nanoelectrospray-MS/MS. The sets of peptide tandem mass spectra generated in such experiments are used to query biological sequence databases with the aim to identify all protein components present in the sample. In this chapter, we describe practical aspects of nanoelectrospray mass spectrometry aimed at amino acid sequencing of peptides at subpicomole levels. We do not consider LC-MS/MS, although many of the features of the two analytical approaches are very similar.

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

1.1. The Nanoelectrospray Ion Source

The main characteristics of the nanoelectrospray ion source are low flow rate, high ionization efficiency, and extended measurement time with concomitant improvements in absolute sensitivity ***(2,3).*** These features are crucial for peptide sequencing by tandem mass spectrometry. Nanoelectrospray tandem mass spectrometry is a reliable and robust technique for identification or sequencing of gel-isolated proteins available in sub-picomole amounts ***(4,5).*** The very low flow rate of 10–25 nL/min of the nanoelectrospray source has required a change of sample preparation method from online HPLC separation to sequencing directly from desalted/concentrated peptide mixtures as outlined.

For nanoelectrospray tandem mass spectrometry and other mass spectrometric methods it is important to choose the most suitable protease for generation of peptides from a protein. Trypsin has several advantages for the generation of peptides for tandem mass spectrometric sequencing. It is an aggressive and extremely specific protease that cleaves the carboxy-(C)-terminal amide bond of lysine and arginine residues. Tryptic peptides typically have a mass between 800 Da and 2500 Da and both the amino-(N)-terminal amino group and the C-terminal residue (Lys or Arg) are basic so they generate mainly doubly charged peptide ions in electrospray. Such ions predominantly fragment at the peptide amide bond to generate singly charged N-terminal (b-type) or C-terminal (y-type) ions ***(6,7).*** Tryptic peptides rarely contain internal arginines that generate complicated fragmentation patterns. The in-gel digestion procedure ***(5,8)*** is compatible with matrix-assisted laser desorption/ionization mass spectrometry (MALDI) MS as well as nanoelectrospray mass spectrometry. In the latter case a sample desalting/concentration step is necessary (Protocol 2 or 3)

1.2. Analytical Characteristics of the Nanoelectrospray Ion Source

The flow rate of a nanoelectrospray source is about 25 nL/min. At this flow rate an analyte concentration of 1 pmol/μL results in one analyte molecule per droplet on the average ***(2).*** Furthermore, 1 μL of sample is consumed in 40 min extending the time available for optimization of experiments. The overall sensitivity is limited by the signal-to-noise level and it is therefore a function of the ionization efficiency, desolvation efficiency, ion transmission, the level of chemical background ions, and detector characteristics.

The electrospray generated with the nanoelectrospray ion source is very stable. This allows purely aqueous solutions to be sprayed even in negative ion mode without nebulizer assistance. The source can be operated with solutions containing up to 1 *M* NaCl ***(3),*** although this is not recommended. The high stability allows optimization of experimental conditions based on analyte characteristics rather than electrospray requirements, that is when choosing buffer composition.

For example, preservation of noncovalent complexes often does not allow addition of organic solvent to the sample to facilitate spraying. Because the ion source exclusively produces very small droplets, relatively soft desolvation conditions in the interface region of the mass spectrometer can be chosen.

The nanoelectrospray source consists of a metal-coated glass capillary whose tip is pulled into a needle shape with an outer diameter of about 2 µm and an orifice diameter of 1 µm (**Fig. 1**). The glass capillary is mounted in a gas-tight holder that can be pressurized by air up to about 1 bar (**Fig. 2**). The needle assembly is connected to the ion source power supply. Holder and needle are electrically connected, for example, by a small droplet of conductive carbon cement (Neubauer Chemikalien, Münster, Germany). The metal coating of the glass capillary needle ensures that the electrical potential is transferred to the liquid sample at the needle tip.

The nanoelectrospray needles are made from borosilicate glass capillaries (GC 120 F–10, Clark Electromedical Instruments, Pangbourne, UK). The desired needle shape is obtained by using a two-stage pulling cycle on a microcapillary puller (Model P-97, Sutter Instruments Co., USA; parameter set [heat, pull, velocity, time]: 1—520, 100, 10, 200; 2–490, 160, 12, 165. The first heating/pulling stage reduces the diameter of the capillary to about 0.5 mm, while the second stage pulls the glass capillary apart, producing two nanoelectrospray needles. These needles should have an opening of 1–2 µm. However, after pulling the opening diameter can be less than 100 nm and has to be widened (*see* Methods). Nanolectrospray needles and ion sources are commercially available from New Objective (Boston, MA) and Proxeon Biosystems (Odense, Denmark) as well as from several MS instrument manufacturers.

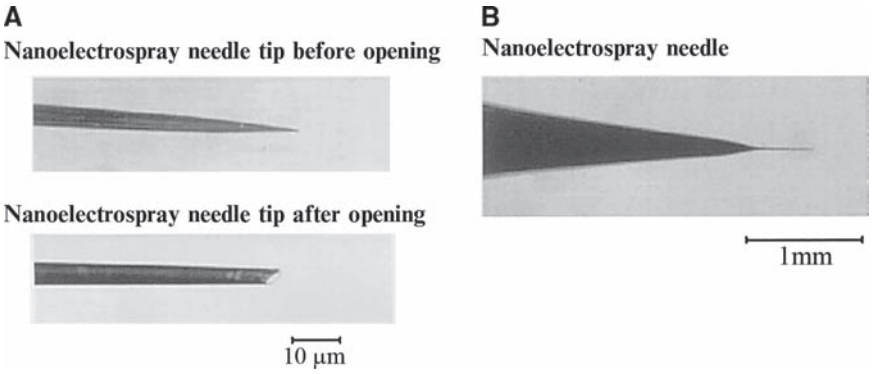

Fig. 1. Nanoelectrospray needles. Pulled glass capillary needle tip before (**A**) and after (**B**) opening. The needle tip should be 200–500 µm long with an opening of only 1–2 µm. (**C**) A two-stage heat/pull cycle on a capillary puller produces two identical glass capillary needles with a thin, tapered needle tip.

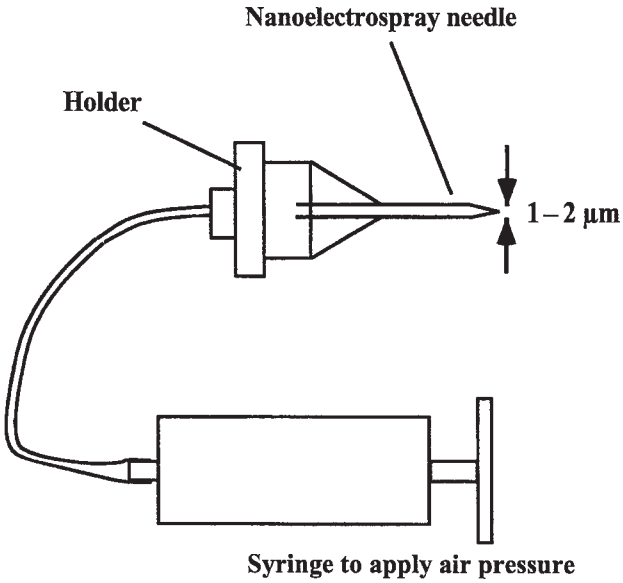

Fig. 2. Nanoelectrospray ion source. The nanoelectrospray needle is mounted in a metal holder that is connected to the ion source power supply and to a syringe that provides the air back pressure. The needle assembly is mounted onto a *x-y-z* manipulator and positioned on axis and 1.5–2 mm from the orifice of the mass spectrometer.

Liquid injected into the needle is drawn to the tip by capillary force. To reduce the flow resistance for a stable flow rate in the 10–25 nL/min range the narrow part of the tip should not be longer than 500 µm (**Fig. 1**). Needles with very short constrictions (50–100 µm) can be operated easily but with a higher risk of losing sample due to a higher flow rate. Short needles are preferred for rapid mass measurements when abundant sample is available, for example, recombinant proteins, synthetic peptides, or oligonucleotides. Longer tips (200–500 µm) are used for tandem mass spectrometry experiments when the longest possible operation time is desirable and when the sample load volume will not exceed 1 µL. A major advantage of these types of nanelectrospray needles is that they do not easily block due to the relatively short length of the needle tip.

Metal coating of the glass capillaries is achieved by metal (gold) vapor deposition in a sputter chamber (Polaron SC 7610 sputter coater, Fisons Instruments, East Sussex, UK). The needles are used only once so it is not a problem that the coating is not tightly fixed to the glass and can be rubbed off. Methods to produce a more stable metal coating include pretreatment with (3-mercaptopropyl) trimethoxysilane ***(9)*** or protecting the metal layer by a second layer of SiO_x ***(10)***. A stable gold coating is necessary when a glass needle is used for several

samples over a prolonged time. As the needle tip is fragile it should be handled carefully when loading the sample and when mounting it in the holder.

2. Materials

2.1. Sample Desalting and Concentration Employing Glass Capillary Microcolumns

1. Chromatographic resin (e.g., Poros R1, R2, or Oligo R3).
2. Pulled glass capillaries for microcolumns and nanoelectrospray needle.
3. Custom-made holder for centrifugal loading and transfer of sample from capillary column to nanoelectrospray needle (available from Proxeon Biosystems, Odense, Denmark).

2.2. Sample Desalting and Concentration Employing Microcolumns Packed in GELoader Tips

1-mL plastic syringe; GELoader tips (Eppendorf brand). The syringe is adapted to the GELoader tips by using the top part of a "yellow" plastic tip.

3. Methods

3.1. Operation of the Nanoelectrospray Ion Source

Nanoelectrospray ion sources are now optional on a number of electrospray mass spectrometers or they can be custom made for individual instruments. Note that electrospray ion sources are operated at high voltages and care should be taken to avoid electrical shock.

1. *The geometrical location of the ion source*. The nanoelectrospray source is mounted directly in front of the orifice of the mass spectrometer, usually at a distance of 1.5–2 mm from the orifice. Electrospray at a low flow rate generates very small droplets with a diameter of 200 nm or less. Desolvation is therefore achieved in a very short time and distance.
2. *The voltage applied to the source*. To initiate the electrospray a minimal electrical field strength at the surface of the liquid has to be reached ***(11)***. Conventional electrospray ion sources are operated with a 3–5 kV potential difference between the needle and counterelectrode (i.e., the orifice plate of the mass spectrometer). The very small tip diameter of the nanoelectrospray needle allows a spray cone to be established at a much lower electrical potential, typically 500–900 V.
3. *The desolvation conditions in the interface region*. Because the charged droplets generated by the nanoelectrospray ion source are very small, softer desolvation conditions in the interface (skimmer) region of the mass spectrometer are used. The electrical gradient and the countercurrent gas flow can be reduced. This appears to lead to the generation of colder molecular ions as compared to conventional electrospray sources, facilitating, for example, studies of noncovalent molecular interactions. The main objective when operating the nanoelectrospray source is

to achieve a low and stable flow rate despite sample-to-sample variations. This is achieved by applying air pressure to the needle which helps to adjust the flow rate and thereby compensates for differences in needle orifice size and sample viscosity.

A step-by-step guide for installing the nanoelectrospray source is given in the following list. The order of events may not be compatible with all nanoelectrospray ion sources:

1. Mount the pulled and metal coated nanoelectrospray needle in the holder. Connect the holder to the ion source power supply.
2. Make electrical contact between the needle and the holder, for example, by applying a droplet of graphite paste. (Alternatively, the power supply can be connected directly to the needle with a clamp.)
3. Mount the ion source on an x-y-z manipulator in front of the mass spectrometer.
4. Inject the sample. Dissolve proteins and peptides in 5% formic acid in 20–50% methanol and inject 0.5–2 µL into the nanoelectrospray needle using a micropipet with a gel loader tip.
5. Connect the needle holder to a 20-mL syringe or pressurized gas which provides the backing air pressure for the nanoelectrospray ion source.
6. Position the nanoelectrospray needle 1.5–2 mm from the orifice of the mass spectrometer. Monitor the position of the needle tip with a microscope or a video camera.
7. Gently pressurize the needle by air using the 20 mL syringe or an adjustable gas valve.
8. If no liquid appears at the needle tip then briefly and gently touch it against the interface plate of the mass spectrometer under microscopic control. The needle is not visibly shortened but a small sample droplet appears after the contact, indicating the opening of the needle tip (*see* **Fig. 1**). Note: Needle and plate should be at the same electric potential. A tiny droplet will appear on the metal plate—it spreads out as a faint shadow in a few seconds.
9. Reposition the needle in front of the orifice of the mass spectrometer.
10. Apply the voltage to needle/holder and mass spectrometer interface and start scanning the mass spectrometer. If there are ions in the spectrum reduce the air pressure in the needle to the lowest value that still keeps the flow stable.

3.2. Sample Preparation for Nanoelectrospray Mass Spectrometry

The nanoelectrospray ion source unfolds its full potential when the available sample is concentrated to 1 µL or less. Microcolumns packed in glass capillaries or in gelloader pipette tips can be used to desalt and concentrate protein and peptide samples to microliter volumes ***(3,13,14)***. A pulled glass capillary or a partially constricted gelloader tip is packed with a few hundred nanoliters of Poros resin (Applied Biosystems, Boston, MA). Working in the perfusion mode, Poros material generates only a small flow resistance when packed into a capillary. Peptide solutions are normally desalted/concentrated on Poros R2 resin, protein solutions on Poros R1 resin, and hydrophilic samples (such as small peptides and phosphopeptides) on R3 material (anion-exchange resin).

Purification of phosphopeptides or highly negatively charged peptides can be accomplished by immobilized metal affinity chromatography (IMAC) using Fe(III) or Ga(III) ions ***(15,16)***.

3.3. Sample Desalting and Concentration Employing Glass Capillary Microcolumns

For peptide analysis we routinely use the Poros R2 material (Applied Biosystems) as chromatographic resin. Remove the smallest particles by sedimenting the resin 3–5•in methanol. In a 1.5-mL microcentrifuge tube make a slurry of 10–20 µL resin in 1.2 mL of methanol.

1. Mount a pulled glass capillary into a custom-made capillary holder (Fig. 3A) or into a pierced lid of a 1.5-mL microcentrifuge tube. Use a micropipet with a gel loader tip to transfer 5 µL of resin slurry into the capillary.
2. Load the chromatographic resin into the tip of the glass capillary by centrifugal force using a manually operated tabletop minicentrifuge (e.g. PicoFuge, Stratagene, Palo Alto, CA) at low speed (500–2000 rpm). The pulled glass capillaries used for the columns are the same as used for nanoelectrospray emitters but they are not sputter-coated with metal. The chromatographic material is visible against a dark background but nearly invisible in front of white paper.
3. When sufficient chromatographic resin has been loaded into the capillary (1–2 mm resin height) the glass tip is widened/broken by gently touching it against the tabletop. The opening should allow liquid but not column resin to exit the capillary during centrifugation. Do not centrifuge the resin too fast; otherwise it becomes compressed and may block the flow of liquid. The centrifugal capillary column is only used once to avoid sample-to-sample contamination.
4. Rinse the capillary column by injecting 5 µL of 50% MeOH followed by gentle centrifugation.
5. Equilibrate the column resin by injecting 5 µL of 5% formic acid into the capillary followed by centrifugation until all liquid has passed through the column.
6. Dissolve the sample in 10–20 µL of 5% formic acid and inject it onto the capillary column in aliquots of 5 µL followed by centrifugation. For best recovery, dissolve the dried protein or peptide sample in 80% formic acid and then immediately dilute it to 5% by addition of water.
7. Wash the column resin twice by centrifugation with 5 µl of 5% formic acid solution. This desalting step is very efficient as the column is washed with 50–100• its resin volume. Before beginning the elution step the washing solution must be completely removed by gentle centrifugation.
8. Elution of sample into a nanoelectrospray needle. Mount the capillary column in-line with a premade nanoelectrospray needle in a custom-made capillary holder that fits into a microcentrifuge (Fig. 3A). Elute the peptide mixture into the nanoelectrospray capillary by centrifugating twice with 0.5 µL of 60% methanol–5% formic acid. Elute proteins with 60–70 % acetonitrile–5 % formic acid. This procedure allows handling of elution volumes between 10 µL and 0.2 µL. Elution, however, should be performed twice because the first elution does not completely

deplete the column. Keep in mind that signal intensity in an electrospray spectrum is concentration dependent, so keep the elution volume as small as possible.
9. Mount the loaded nanoelectrospray needle onto the ion source and begin the experiment.

3.4. Sample Desalting and Concentration Employing Microcolumns Packed in GELoader Tips (see Notes 1 *and* 2)

This sample desalting/concentration method is very simple and can be used prior to MALDI-MS and nanoelctrospray MS. The resin is held in place by making a constriction at the end of a GELoader pipettor tip. Sample loading, washing and elution is performed by loading liquid on top of the resin and applying air pressure to generate a low flow through the column. No frits are necessary.

1. Prepare a slurry of 100–200 µL of chromatographic resin, for example, Poros R1, R2, or OligoR3, in 1 mL of methanol.
2. Make a partially constricted GELoader pipet tip by gently squeezing or twisting the end of the tip (**Fig. 3B**). This allows liquid to flow through the tip while retaining the chromatographic resin.
3. Use another GELoader tip to load 5 µL of slurry of resin into the GELoader tip from the top and pack it by applying air pressure with the 1-µL syringe adapted to fit the GELoader tip microcolumn. The column height should be 2–4 mm.
4. Equilibrate resin by flushing 10–20 mL of 5% formic acid through the GELoader tip by air pressure (syringe). 5 Redissolve the peptide or protein sample in 20–40 mL of 5 % formic acid. 6 Load 5–20 µL of sample onto the microcolumn and gently press it through the column by air pressure using the syringe 7 Wash resin by flushing 10–20 µL of 5% formic acid through the packed GELoader tip by air pressure (syringe).
5. Elute the sample using a small volume of 5% formic acid–50% methanol. The eluate can be collected in a microcentrifuge tube, deposited directly onto the MALDI probe tip, or eluted directly into a nanoelectrospray needle. In the latter two cases the elution volume should be 1–2 µL only.

3.5. Nanoelectrospray Tandem Mass Spectrometry of Unseparated Peptide Mixtures

Peptide sequencing with tandem mass spectrometry *(17,18)* consists of three steps: (1) measuring the *m/z* values of peptides in a sample and determination of the charge state z; (2) acquiring the tandem mass spectra after collision-induced dissociation (i.e., fragmentation) of selected peptides; and (3) interpreting the tandem mass spectrometry data. With the nanoelectrospray source the first two steps are performed in one experiment with the unseparated peptide mixture.

The *m/z* values of analyte peptides are detected by comparing a "single MS" mass spectrum to a representative spectrum of the autolytic peptides of the enzyme used (i.e., trypsin) or a representative control from a particular experiment. For

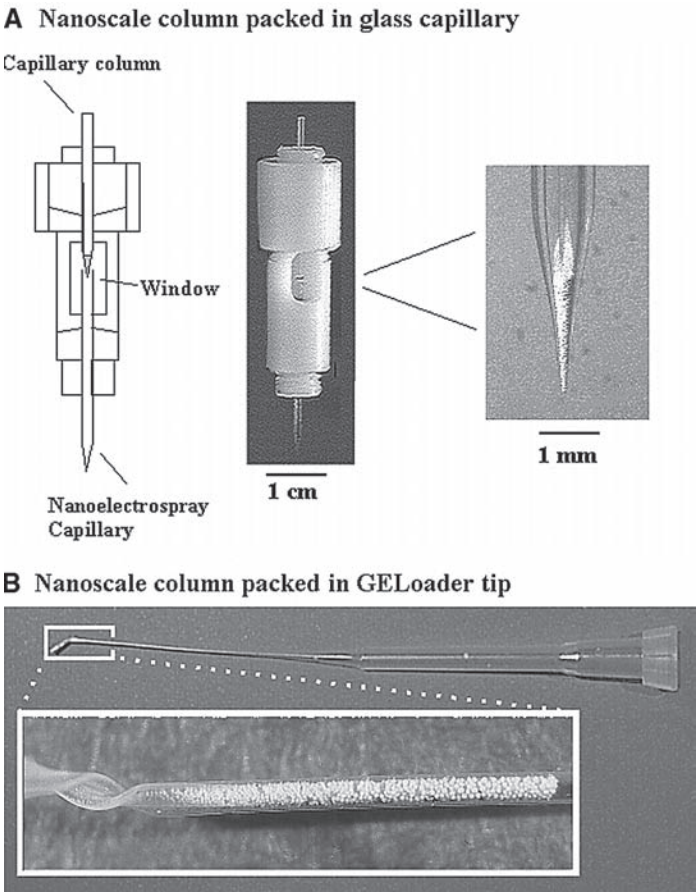

Fig. 3. Microcolumns for peptide and protein desalting/concentration prior to nanoelectrospray mass spectrometry. (**A**) Capillary column made from a pulled glass capillary and filled with a small volume of Poros resin. The sample is rinsed and then eluted from the column capillary directly into the nanoelectrospray needle by centrifugal force using a tabletop centrifuge. (**B**) Microcolumn made from a GELoader tip. The sample is loaded and eluted by air pressure from a syringe adapted to the GELoader tip.

electrophoretically isolated proteins it is often advantageous to process an empty gel piece excised near the protein band of interest as control. The charge states of peptide ions are determined by considering the isotopically resolved ion signal: An isotope spacing of 0.5 Da corresponds to a doubly charged species whereas an isotope spacing of 0.33 Da reflects a triply charged ion.

At subpicomole protein amounts on the gel it is possible to employ the precursor ion scan capability of the triple-quadrupole tandem mass spectrometer to

detect peptide ion signals that were below the chemical noise in the normal Q_1 spectrum (**Fig. 4**) ***(19)***. Precursor ion scans of the abundant *m/z* 86 immonium ion of isoleucine/leucine detect peptides that contain these common amino acids. For the parent ion scan the mass spectrometer parameters are adjusted to obtain optimum detection efficiency at reduced mass resolution. The parent ion scan technique can also be used to selectively detect phosphopeptides by monitoring *m/z* 79 in the negative ion mode ***(19–21)***, to selectively detect glycopeptides by monitoring *m/z* 162 or 204 in the positive ion mode ***(19,22)***, and to detect intact proteins or oligonucleotides in contaminated samples ***(23)***. A similar method has recently been implemented on Q-TOF type instruments ***(24)***.

Once a set of peptide *m/z* values has been determined by either "single MS" scans or by precursor ion scans, high-resolution scans can be performed for selected peptide ion signals in the "multiple ion monitoring" mode to determine the exact peptide mass and the peptide charge state based on the isotope spacing. The reduction of sensitivity when measuring at high resolution is compensated by adding many scans, for example, 50 or more, to one spectrum. The latter feature further demonstrates the utility of long measurement times

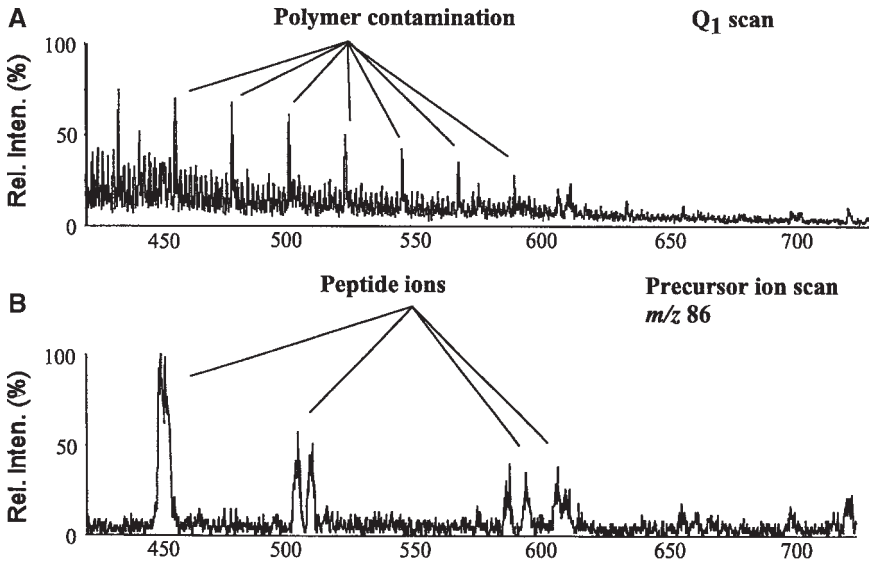

Fig. 4. Parent ion scan for the leucine/isoleucine immonium ion (*m/z* 86) detects peptide ions below the chemical noise level. (**A**) The nanoelectrospray quadrupole mass spectrum (Q1 scan) of a tryptic peptide mixture displays only polymer ion signals and chemical background which suppress peptide ions. (**B**) The nanoelectrospray triple-quadrupole MS/MS precursor ion (*m/z* 86) analysis of the same sample reveals several peptide ion signals that subsequently can be selected for sequencing by product ion analysis by tandem mass spectrometry.

that the nanoelectrospray source provides. It is advantageous to select doubly charged tryptic peptide ions for tandem mass spectrometry experiments because they generate relatively simple fragment ion spectra. Triply charged tryptic peptides can also be fragmented and often allow determination of long stretches of amino acids sequence, that is, 15–25 consecutive residues, via doubly charged fragment ion series.

3.6. Fragmenting Peptides by Collision-Induced Dissociation

Once a set of peptide *m/z* values has been accurately determined each peptide is fragmented in turn. For peptide sequencing by tandem mass spectrometry using a triple quadrupole or a Q-TOF instrument two main instrumental parameters are adjusted to obtain high quality amino acid sequence information. First, the resolution setting of the first quadrupole (Q_1) is adjusted according to the abundance of the peptide ion signal, that is, the lower the ion intensity the higher the resolution setting in order to reduce the chemical background noise in the lower half of the tandem mass spectrum for a better signal-to-noise ratio. Second, the collision energy can be adjusted according to the peptide mass and varied depending on the mass range scanned (**Fig. 5**). The collision gas pressure is kept constant throughout the MS/MS experiment.

It may be advantageous to acquire a tandem mass spectrum in two or three segments. The high *m/z* segment is acquired with a wide parent ion selection window (low resolution) and a low collision energy to generate and detect

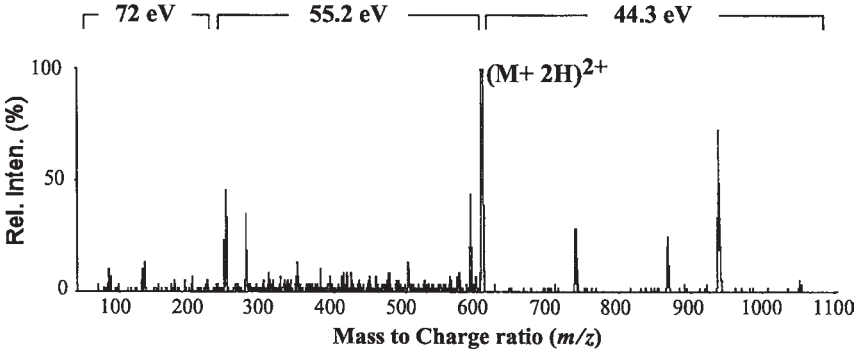

Fig. 5. Peptide tandem mass spectrum acquired in separate segments in a triple-quadrupole instrument. The *m/z* range above the precursor ion, $[M+2H]_{2+}$, is acquired at low collision energy and at relatively low mass resolution to efficiently generate and detect large peptide fragment ions. The *m/z* range below the precursor ion is acquired at higher resolution and with stepped collision energies, that is, intermediate collision energy to generate low *m/z* sequence ions and high collision energy to generate immonium ions and the a_2 and b_2 fragments.

relatively large peptide ion fragments. The low *m/z* region is acquired at higher resolution and at higher collision energies to generate and detect low *m/z* fragments and immonium ions. The nanoelectrospray allow this and other types of optimization due to the stability and long duration of the spray.

When investigating a peptide mixture by tandem mass spectrometry as many peptides as possible should be fragmented. This motivated the development of semiautomatic software routines to assist in data acquisition. The list of peptide *m/z* values is stored by customized software that calculates the optimum hardware settings for subsequent sequencing of each individual peptide. However, for *de novo* sequencing of long stretches of amino acid sequence it is not yet advisable to use automated software routines for data acquisition. Careful adjustments of collision energy and mass resolution is required to obtain high-quality data for unambiguous sequence assignments.

3.7. Generation of Peptide Sequence Tags from Tandem Mass Spectra of Peptides

Complete interpretation of tandem mass spectra of peptides can be complicated and requires some experience. However, it is often relatively straightforward to generate short consecutive sequences of two to five amino acid residues from a tandem mass spectrum. This information is valuable for sequence database searches as follows. A "peptide sequence tag" is assembled from the peptide mass, a short internal sequence of consecutive amino acid residues, and the distance in mass to the N- and C-terminus of the peptide ***(25)*** (**Fig. 6**). The search specificity of this construct is very high because the amino acid sequence is "locked" in place by the masses of the "unknown" parts of the peptide. The modular composition of a peptide sequence tag makes it tolerant to errors in any one of the modules. As only a fraction of the information content of the tandem mass spectrum is used to generate a peptide sequence tag used to querythe sequence database, the remaining information confirm a retrieved peptide sequence: Every significant fragment ion signal should correlate to the peptide sequence. A peptide sequence tag consisting of three residues typically retrieve only one protein from a database containing more than 500,000 sequences when using high mass accuracy data obtained on a Q-TOF tandem mass spectrometer ***(26)***. If longer stretches of sequence can be read out of a tandem mass spectrum, that is, six or more residues, it is advantageous to search by amino acid sequence instead of by peptide sequence tags. Searching by amino acid sequence is more flexible and allows sequence homology searches.

As mentioned previously, tryptic peptides have the desirable feature that they contain an N-terminal amino group and a C-terminal Lys or Arg residue, localizing protons at both the N-terminus and the C-terminus of the peptide. Tandem mass spectra of tryptic peptides very often contain a continuous y-ion series that can

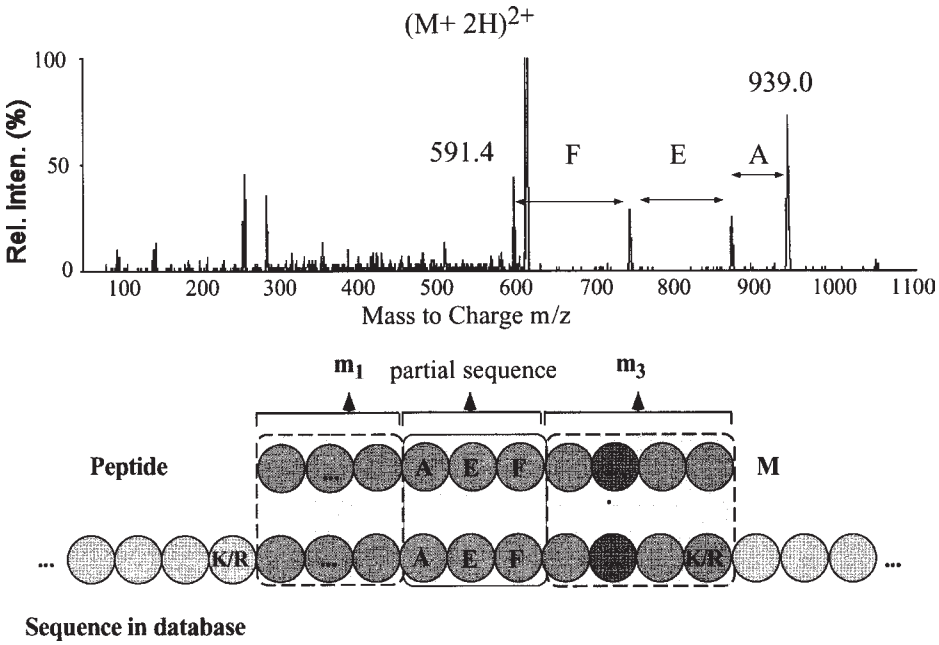

Fig. 6. eptide sequence tag generated from a tandem mass spectrum. A short search string, (591.4)FEA(939.0), is readily identified in the tandem mass spectrum of this tryptic peptide with mass M. It is subsequently converted to a peptide sequence tag, e.g. by using the Mascot software (www.matrixscience.com) and used to query a database. The modular composition of a peptide sequence tag permits error tolerant searches where one or two of the modules are allowed to contain an error.

be readily assigned in the *m/z* range above the doubly charged parent ion signal. The spectrum interpretation strategy builds on this characteristic. It is guided by the demand to identify a protein in sequence databases or to reliably sequence peptides for cloning of the cognate protein.

Several algorithms can identify proteins based on sequence database searches with uninterpreted peptide tandem mass spectra ***(27,28)*.** Such software tools are very useful for a first screening of peptide tandem mass spectra because they immediately identify peptides originating from known proteins. The Mascot search engine and a number of other useful Internet-based services can be found via the URL http:// www.protein.sdu.dk.

3.8. Guidelines for Interpreting Tandem Mass Spectra of Tryptic Peptides

The following list summarizes a few basic empirical rules that we use in interpreting tandem mass spectra of tryptic peptides. Because peptides differ in

their fragmentation behavior in a sequence-dependent manner it is possible to find exceptions to these rules.

1. The goal of the interpretation is to find a series of peaks that belong to one ion series—for tryptic peptides mostly y-ions (C-terminal fragments).
2. Initial peak selection: The high *m/z* region of a tandem mass spectrum is often straightforward to interpret. Choose a large ion signal in this region as the "starting peak."
3. Assembly of a partial amino acid sequence: Try to find ion signals that are precisely one amino acid residue mass away from the starting peak (up or down in mass). We use software which marks all the possibilities in the spectrum. This provides a good overview whether there is more than one possibility for sequence assignments. If there is a repeating pattern of fragment ion peaks with satellite peaks representing an H_2O loss (−18 Da) or an NH_3 loss (−17 Da) a fragment ion series has been identified (for tryptic peptides a y–ion series is more likely).
4. By repeating step 3 a peptide sequence tag consisting of two to four amino acids is assembled that is subsequently used to identify a protein in the sequence database. As default for tryptic peptides, the database is searched under the assumption that a y–ion series was determined. However, even for tryptic peptides the tandem mass spectrum can be dominated by b-ions if a peptide contained an internal basic residue or when the C-terminal peptide of the protein had been sequenced.

3.9. Confirming Protein Identifications Madevia Peptide Tandem Mass Spectra

If a protein sequence is retrieved by a database search with a peptide sequence tag or by similar methods then the amino acid sequence of the retrieved peptide should fit the tandem mass spectrum in order to be called as a positive match. Two or more peptides from a sample should independently identify the same protein in a database. To verify a match, the peptide fragment masses must be correct within the expected error of the mass measurement. For tryptic peptides the y-ion series should be nearly complete, except when a peptide contains an internal proline residue (*see below*). The N-terminal b_2 and a_2 fragment ions, generated at relatively high collision energy, should be present in the low *m/z* region. Odd fragmentation patterns should reflect the amino acid sequence as discussed in the following paragraphs.

Peptides that contain internal basic residues (lysine or arginine) do not fragment in the vicinity of these residues because a charge is localized at the sidechain of the basic residue and therefore not available for amide backbone cleavage. If the triply charged precursor ion was fragmented then doubly charged y ions are present in the spectrum.

Internal proline residues deserve special attention. Cleavage of the C-terminal bond of a proline is observed to a low degree. The N-terminal bond of a proline is labile giving rise to an intense y–ion fragment. Internal fragmentation of peptides

containing a proline often confirm a sequence: The y–ion generated by fragmentation at the N-terminal side of Pro will dissociate a second time to produce a y–ion series which is superimposed on the original y–ion series. However, the b–ions generated from this Pro containing fragment serve to confirm the C-terminal part of a peptide sequence up to and including the internal proline residue.

Isoleucine and leucine cannot be differentiated by amide bond cleavage alone because they have the same elemental composition and therefore identical molecular weight. Pairs of amino acid with identical nominal mass, Lys/Gln (128 Da) and oxidized Met/Phe (147 Da), can often be distinguished. Lys and Gln differ in their basicity and trypsin cleaves C-terminal to Lys and not at Gln so internal Lys is rarely found in tryptic peptides. However, if the latter is the case then the tryptic peptide usually acquire an additional proton for a total of three charges and the tandem mass spectrum will often contain a doubly charged y-ion series. If an internal Lys residue is suspected then the peptide mixture can be inspected for the presence of the limit peptide produced by tryptic cleavage at this Lys residue. Oxidized methionine (147.02 Da) and phenylalanine (147.07 Da) residues are differentiated relatively easily as follows. Tandem mass spectra of peptides which contain an oxidized methionine residue (i.e., methionine sulfoxide) display satellite peaks that appear 64 Da below each methionine sulfoxide-containing y-ion fragment due to loss of CH_3SOH from methionine sulfoxide ***(29,30)***. The oxidation reaction is often not complete so inspection of the peptide mass spectrum (Q_1 spectrum) may reveal a peptide 16 Da below the one containing oxidized methionine. The high resolution and mass accuracy of Q-TOF, LTQ-FT-ICR and LTQ-FT-Orbitrap type MS instruments enable differentiation of Gln/Lys and OxMet/Phe by accurate mass determination.

If no proteins are retrieved with a simple database search then redo the search under the assumption that some of the amino acids in the peptide are modified, containing for example, an oxidized methionine or a *S*-acrylamidocysteine. An error tolerant search can be launched in which only partial correspondence between the peptide sequence tag and a database entry is required ***(25)***. Additional information about the protein can be used to select possible candidates if more than one protein sequence is retrieved (such as protein size, organism, or function).

If a protein cannot be identified by any of its peptide sequence tags we conclude that it is unknown. For proteins from human, mouse, or other model organisms, the peptide sequence tags are then screened against a database of expressed sequence tags (ESTs) ***(31)***. ESTs are short stretches of cDNA, that is, single-stranded DNA generated from expressed mRNA by reverse transcriptase, and thus represent the set of expressed genes in a given cell line. If a database search retrieves a cDNA sequence then library screening and cloning is straightforward. If the EST database search produces no hit then *de novo* peptide sequencing has to be pursued to obtain longer stretches of amino acid

sequences for homology searches. It has been demonstrated that peptide MS/MS data is useful to identify genes in raw genomic sequences ***(32)***.

3.10. De Novo Peptide Sequencing by Nanoelectrospray Tandem Mass Spectrometry

To sequence unambiguously an unknown protein for homology searching and cloning, it is necessary to be able to confidently call extended series of b-type and y-type fragment ion signals.

A useful method to recognize y-ion series employes ^{18}O-labeled water (*see*, e.g., **refs. *26, 33, 34***). By performing the trypsin digestion in a 1:1 mixture of normal water and ^{18}O labeled water all the tryptic peptides will incorporate ^{18}O at the C-terminus with a yield of approx 50%. Each peptide ion appears in a mass spectrum as a doublet separated by 2 Da. Selecting both isotope species together for fragmentation (low resolution setting in Q_1 precursor ion selection) produce tandem mass spectra that display y–ions as a series of split peaks, that is, separated by 2 Da, whereas b–ions are single peaks. This isotope-splitting is easily resolved in modern tandem mass spectrometers, particularly Q-TOF instruments ***(26)*** and aids in the interpretation of a peptide tandem mass spectrum because y-ion series are confidently assigned (**Fig. 7**). Note that the ^{18}O-labeled

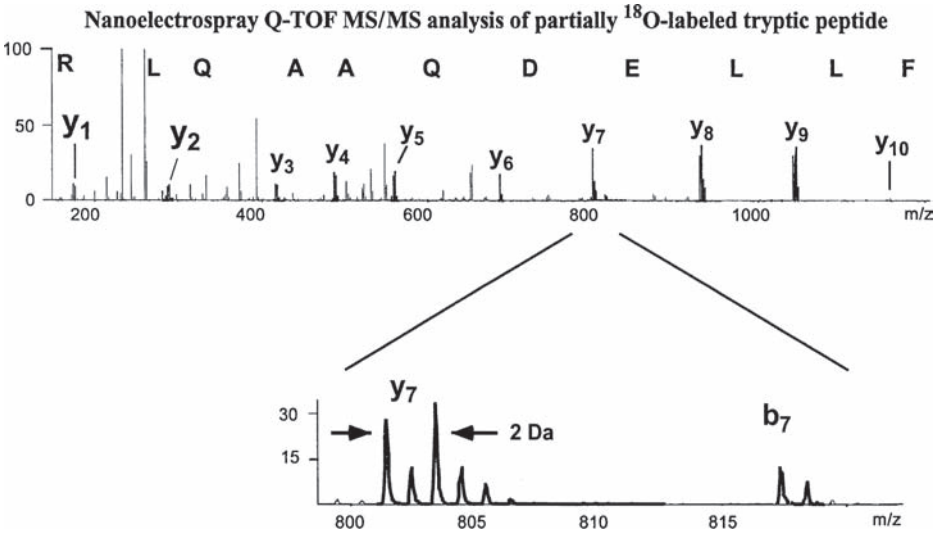

Fig. 7. Incorporation of the O stable isotope in peptides facilitates sequence interpretation in MS/MS. Digestion of protein by trypsin a solution of $H_2{}^{16}O$/ $H_2{}^{18}O$ water (1:1) results in partial labeling of the C-terminal carboxyl group in each peptide, except the C-terminal peptide of the protein. Identification of y-ion series is now straightforward due to appearance of y-ion signal peak splitting in a 1:1 ratio and a mass spacing of 2 Da.

water has to be very pure to avoid chemical background noise. Redistillation of commercially available ^{18}O-labeled water is recommended.

Another method uses derivatization of free carboxyl groups, including the C-terminal carboxyl group of peptides. The tryptic peptide mixture is split in two portions. The first portion of the mixture is analyzed by nanoelectrospray tandem mass spectrometry and long peptide sequences are generated through complete interpretation of tandem mass spectra using the guidelines described in the preceding. The other portion of the peptide mixture is *O*-methyl-esterified ***(17,35,36)*** and then analyzed. Every free carboxyl-group including the C-terminus of peptides is esterified and therefore increase in mass by 14 Da. The number of methyl-esters in a peptide can be determined by the mass shift of peptides which is predictable from the previously interpreted tandem mass spectra of the native peptides. Because all y–ion fragments produced from an esterified peptide contain the C-terminus they are all shifted up in mass. Comparison of a set of tandem mass spectra obtained from a peptide and the corresponding esterified peptide serve to confirm the amino acid sequence because the y–ion series can unambiguosly be assigned. In addition, internal acidic residues, Asp and Glu, are methylated as well and can easily be differentiated from their corresponding amide residues, Asn and Gln, which otherwise differ in mass by only 1 Da.

3.11. Perspectives

Novel peptide sample preparation methods, mass analyzer configurations, and peptide dissociation techniques are continuously developed to increase sensitivity, mass accuracy, mass resolution, or sample throughput for peptide mass analysis and sequencing by mass spectrometry. The combination of the MALDI source with a Q-TOF hybrid instrument ***(37)*** and the development of electron capture dissociation (ECD) and electron transfer dissociation (ETD) for MS/MS sequencing of large peptides and small intact proteins ***(38)*** are just two recent examples. Posttranslational modification of proteins leads to a change in the molecular mass of the affected residues and mass spectrometry is, therefore, a versatile analytical tool for structural characterization of modified peptides and proteins ***(39,40)***. MS-based approaches to peptide and protein quantitation using stable isotope labeling are also being pursued ***(41)*** and the use of multidimensional chromatography methods combined with ESI-MS/MS is an alternative or complement to two-dimensional gel electrophoresis for analysis of very complex protein mixtures ***(42–44)***. There is no doubt that applications of mass spectrometry in biological research will expand substantially in the future as the structure and function of all the gene products encoded in genomes of model organisms, including humans, have to be characterized in molecular details.

4. Notes

1. Peptide separation may be improved by eluting the sample from the microcolumn by a step gradient using a series of mobile phases containing 5% formic acid in 15% methanol, 30% methanol, and 50% methanol, respectively.
2. For MALDI-MS analysis, elute the sample directly onto the MALDI probe using matrix solution, for example, HCCA, SA, or 2,5-dihydroxybutyrate (2,5-DHB) dissolved in 30–50% methanol or acetonitrile. Deposit the eluate in a series of tiny droplets rather than one large drop ***(13)***. Trifluoroacetic acid or acetic acid can be used instead of formic acid in the mobile phases, whereas acetonitrile can substitute for methanol. Formic acid and methanol are recommended for nanoelectrospray mass spectrometry.
3. Troubleshooting: The nanoelectrospray ion source is a very robust device. However, problems may occur if the sample contains high concentrations of buffers, polymers or salts or if the shape of the needle tip is not within the dimensions described in the preceding. In this subheading we provide a few troubleshooting tips.

    a. If there are no ions or no noise in the spectrum then the needle is not spraying. Repeat step 8 in Protocol 1 to open the needle tip.
    b. If the spray becomes instable then jitter and spikes will appear in the spectrum or the spectrum will contain an unusually high level of chemical background. Increasing the air pressure of the needle helps stabilize the flow. If this simple measure is insufficient then the spraying voltage may be too low (increase it by 100–150 V) or the opening of the needle tip is still too small (repeat step 8 in **Subheading 3.1**).
    c. Be aware that the nanoelectrospray needle has a very small diameter. Small changes in the applied potential (increases of 100 V) change the field density at the tip considerably. Electrical discharge can be initiated and ionize atmospheric gas which generates a mass spectrum. These ions are usually small (<400 Da), and therefore chemical background ions in the higher mass region are missing. Atmospheric gas ionization can be visible as a blue corona around the needle tip (when light sources are switched off) and may lead to oxidations of methionine containing peptides ***(12)*****.**
    d. If opening of a needle is not successful by the means described in the preceding then apply voltage to the needle, pressurize it, and briefly touch it against the mass spectrometer interface plate (the potential difference between needle and interface plate should be about 500 V). The combined mechanical and electrical stress opens almost every needle. It is not advisable to routinely open needles by this approach because

it tends to damage the metal coating at the tip. High electrical current drawn from very thin tips can heat the glass to a degree that the glass melts. The damaged piece of the tip can often be broken off and analysis can proceed with a larger opening.

e. Two effects can prevent or stop spraying from an opened needle: The high surface tension of the liquid or precipitation of salts, polymers, or other nonvolatile sample constituents when their concentration is high. In the former case the needle can easily be reopened by slightly touching it to the interface plate, thereby destroying the surface tension by physical contact. In the latter case, the harsher procedure employing mechanical and electrical stress for needle opening (described earlier) can be attempted.

Protein Identification by Peptide Mass Fingerprinting using MALDI-TOF Mass Spectrometry

Judith Webster and David Oxley

1. Introduction

Developments in mass spectrometry technology, together with the availability of extensive DNA and protein sequence databases and software tools for data mining, has made possible rapid and sensitive mass spectrometry-based procedures for protein identification. Two basic types of mass spectrometers are commonly used for this purpose; MALDI-TOF-MS and ESI-MS. MALDI-TOF instruments are now quite common in biochemistry laboratories and are very simple to use, requiring no special training. ESI instruments, usually coupled to capillary/nanoLC systems, are more complex and require expert operators. We will therefore focus on the use of MALDI-TOF-MS, although the sample preparation is identical for both methods. The principle behind the use of MALDI-TOF-MS for protein identification is that the digestion of a protein with a specific protease will generate a mixture of peptides unique to that protein. Measuring the molecular masses of these peptides then gives a characteristic dataset called a peptide mass fingerprint (PMF) ***(1)***. The PMF data can then be compared with theoretical peptide molecular masses that would be generated by using the same protease to digest each protein in the sequence database, to find the best match. Provided the protein being analyzed is present in the database being searched and the data is of sufficient quality, the best match should be the correct protein. In order to judge the validity of a protein identification by this method, some means of scoring the quality of the match must be used.

The procedure described here involves cutting protein bands or spots from 1-D or 2-D PAGE gels, destaining the gel pieces, reducing and alkylating the

protein, digesting with trypsin, using MALDI-TOF mass spectrometry to determine the mass of the tryptic peptides and database searching with the PMF data to identify the protein.

The sample processing steps can be performed in microfuge tubes or in 96 well plates. One person can easily process a 96 well plate in a day, but if higher throughput is required, each step can be automated, allowing the possibility of several hundred protein identifications per day. Spot cutting, sample processing and sample plate loading robots are commercially available and routinely used in many high-throughput laboratories.

2. Materials

1. 0.5 mL microfuge tubes (or 96 well V-bottom polypropylene microtitre plates) (*see* **Note 1**).
2. One Touch Spot Picker (1.5 mm) (The Gel Company) - optional.
3. Silver destaining solution (for silver stained gels only) - dissolve potassium ferricyanide (2 mg/mL) in sodium thiosulphate solution (0.2 mg/mL). Make fresh immediately before use.
4. Sonicator bath (or vortex mixer with attachments for unattended use with 0.5 mL microfuge tubes or 96 well microtitre plates).
5. Aqueous buffer: 50 m*M* NH_4HCO_3 – make fresh weekly.
6. Organic buffer: 50 m*M* NH_4HCO_3/acetonitrile 1:1 – make fresh weekly.
7. DTT solution: (DL-Dithiothreitol ultra pure) 10mM DTT in aqueous buffer - make fresh immediately before use.
8. Iodoacetamide solution: (ultrapure) 50 m*M* iodoacetamide in aqueous buffer - make fresh immediately before use. Note iodoacetamide is toxic!
9. Trypsin solution (Modified Sequencing Grade, Promega) (*see* **Note 2**).
10. Centrifugal vacuum concentrator.
11. Matrix solution (*see* **Note 3**).
12. Peptide calibration mixture (*see* **Note 3**).
13. MALDI sample plate.
14. MALDI-TOF mass spectrometer.

3. Methods

Protein identification by PMF is usually performed on protein bands or spots cut from 1-D or 2-D PAGE gels and so this is the method described here, however it can also be applied to proteins in solution with minor modifications. One of the biggest problems that may be encountered, particularly when low amounts of protein are analyzed, is contamination. **Note 1** describes some precautions to minimize the effects of contamination.

All washing steps during the processing of the gel pieces can be done either on a vortex mixer or in a sonicator bath.

3.1. Removing Gel Spot or Band from the Gel and Destaining

Ideally, the gel should have been stained with a Coomassie stain (preferably a colloidal Coomassie if detection sensitivity is an issue, (e.g. ***(2, 3)*** or one of the commercially available stains). This method is also compatible with Sypro stains (though a uv transilluminator will be required to visualize the protein bands or spots during excision). Standard silver stains are not compatible, but certain modified silver stains (e.g. ***(4),*** or one of the commercially available "mass spectrometry compatible" silver stains) can be used, however, even these usually give inferior mass spectrometry data compared to Coomassie or Sypro stained gels.

3.1.1. Removal of Gel Piece

1. Place the stained gel in a disposable petri dish on a light box and cut out the spot/band with a manual spot picker or a clean scalpel/razor blade, without taking any excess gel.
2. If necessary, cut the gel spot/band into 1mm pieces and transfer into a 0.5mL microfuge tube or one well of a 96 well microtitre plate.

3.1.2. Destaining Coomassie or Sypro-Stained Gel Pieces

1. Wash with aqueous buffer (100 µL) 1 × 5 min.
2. Wash with organic buffer (100 µL) 2 × 5 min.

3.1.3. Destaining Silver-Stained Gel Pieces (5).

1. Wash with silver destaining solution (100 µL) until destained (approx 5 – 30min) - the gel will retain a pale yellow colour.
2. Wash with high purity water (100 µL) 2 × 5 min.
3. Wash with aqueous buffer (100 µL) 1 × 5 min.
4. Wash with organic buffer (100 µL) 1 × 5 min.

3.2. In-Gel Reduction and Alkylation of the Protein

Reduction of disulphide bonds followed by alkylation of the free cysteines to prevent reoxidation, while not essential for the digestion of most proteins, generally gives better results. This is due to increased susceptibility of the reduced/alkylated protein to tryptic digestion and the absence of any disulphide-linked peptides (which are not matched in the database search) from the PMF data ***(6).***

1. Incubate destained gel pieces in DTT solution (100 µL) for 1h at 50°C in an oven. If using a 96 well plate, use sealing film or a sealing lid, to exclude oxygen and prevent drying out.
2. Cool to room temperature, remove and discard DTT solution. Add iodoacetamide solution (100 µL) and incubate with occasional mixing (vortex) for 1 h in the dark at room temperature.

3. Discard supernatant and wash gel pieces with aqueous buffer (100 µL) for 5 min, then with organic buffer (100 µL) for 2 × 5min.
4. Dry the gel pieces completely in a centrifugal vacuum concentrator. Caution should be exercised in handling the dried gel pieces, as they are easily lost from tubes or plates.

3.3. In-Gel Digestion of the Protein with Trypsin

1. Take an aliquot of trypsin (10 µL of 10× stock solution) from the freezer, add aqueous buffer (90 µL) and mix.
2. Rehydrate gel pieces for 10 min in trypsin solution (approx. 1 µL per mm^3 gel). There should be little or no excess liquid after rehydration.
3. Add an equal volume of aqueous buffer and incubate at 37°C overnight (or for at least 3 h). Use an incubator, not a heating block. If using a 96 well plate, use sealing film or a sealing lid, to prevent drying out.
4. Add 1/10 th volume of 10% TFA and sonicate/vortex for 5 min.
5. The resulting supernatant is used directly for MALDI-TOF-MS.
6. Residual peptides can be washed from the gel piece if required with a small amount of 0.1% TFA.

3.4. Mass Determination of Peptides by MALDI-TOF-MS

The quality of the MALDI-TOF spectrum that will be obtained from the sample depends crucially on the sample/matrix preparation. The basic requirements are for a uniform microcrystalline layer of matrix/sample and the removal of salts and other contaminants. There are numerous published methods, but the one described here is robust and quite simple, requiring no preclean-up steps. For the best results, a high quality matrix, as supplied by MALDI-MS manufacturers or in a commercial PMF kit, should be used. Alternatively, analytical grade matrix can be recrystallized *(7)*.

MALDI-TOF spectra must be calibrated in order to achieve sufficient accuracy for database searching. This is done by acquiring spectra on peptide standards to generate a calibration curve, which is applied to the experimental data. The calibration peptides can be analyzed separately from the experimental sample (external calibration) or they can be mixed with the experimental sample (internal calibration). Internal calibration is more accurate (typically 10–20 ppm for a strong spectrum) than external (typically 100 ppm or more), but is more difficult as the amount of standard peptides used needs to be matched to the level of the experimental sample peptides. The addition of too much peptide standards can suppress the signal of the sample peptides and *vice versa*. A commonly used variation of the internal calibration method utilizes the autodigestion fragments of trypsin (842.5094 and 2211.1040 for porcine trypsin) for calibration, instead of adding additional peptides *(7)*.

3.4.1. Applying the Sample and the Calibration Mixture to the MALDI Plate

1. Apply matrix solution (0.5 µL) to a clean MALDI plate and allow to dry (sample spot).
2. Apply protein digest (0.2–2 µL) to the sample spot and allow to dry. If a large amount of gel was used for the digestion, the supernatant volume could be much larger than 2 µL (up to 20 µL). It is not usually necessary to use all of the supernatant unless the protein band was quite weak. In this case the entire supernatant can be concentrated to 1–2 µL and used (*see* **Note 4**).
3. Apply 0.1% TFA (5–10 µL) to each sample spot, leave for 30 s, remove and discard, then repeat; this step desalts the sample.
4. If using external calibration, apply 0.2 µL of peptide calibration mixture as close as possible (but not touching) to each sample spot and allow to dry (calibrant spot).

3.4.2. Measuring the Peptides Masses in the MALDI-TOF-MS Instrument

The precise operation of the MS is instrument-dependent, but the basics are very similar. Increasing the laser power increases the signal, but also decreases the resolution and "burns" off the sample faster. Therefore, the laser power should be set to the lowest level that gives a good signal. Set the mass range (e.g. m/z 600–3500), the number of shots to be acquired (100–200 is reasonable) and set the laser power low. Gradually increase the power until an even distribution of noise appears across the whole mass range. Within a few shots, peaks should begin to appear above the noise. Continue to adjust the laser power until the signal level is satisfactory.

The heterogeneous nature of the matrix surface means that some areas of the sample spot will give better peptide signals than others. The difference can be dramatic, so it is a good idea to periodically move the laser position, while assessing the signal intensity, to find the hotspots.

If external calibration of the spectrum is to be used, a spectrum of the calibration standards should be acquired immediately, using the same power setting. **Fig. 1** shows a typical MALDI spectrum obtained from the trypsin digestion of a weak colloidal Coomassie-stained 1D gel band.

3.5. Generating PMF Data and Searching Protein Databases

The PMF data must now be extracted from the MALDI spectrum using the appropriate software associated with the MS instrument used. The baseline threshold should first be adjusted to ensure that all of the peptide signals are detected, without including any noise. If the spectrum has been obtained on a high resolution (reflectron) instrument, the peptide signals will appear as multiple peaks separated by 1Da, due to the presence of ^{13}C isotopes in the peptides

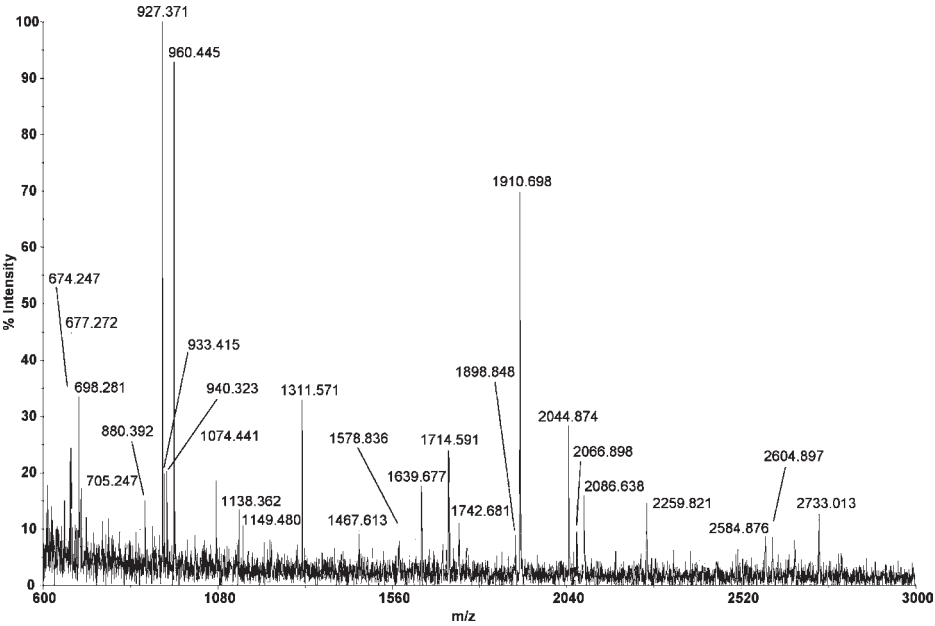

Fig. 1. MALDI-TOF spectrum of a trypsin digested 1-D gel band. Peaks are labelled with their monoisotopic masses. Note that these are not the masses of the peptides, but of the peptide (pseudo)molecular ions. In MALDI spectra, peptide molecular ions arise predominantly through the addition of a proton to the peptide, giving a mass increase of 1.007 Da. The molecular ions are usually denoted as MH+ or [M+H]+.

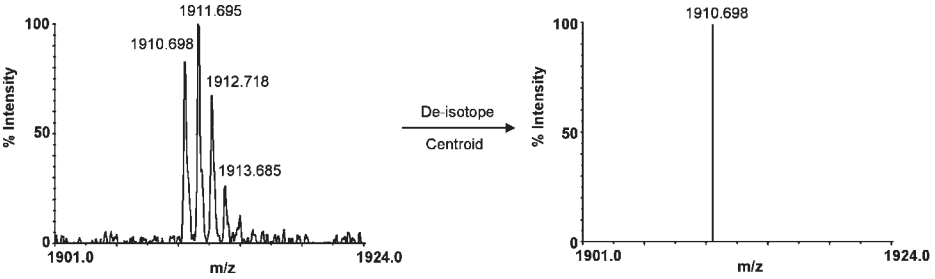

Fig. 2. Expanded view of the peptide signal at around m/z 1910 from the MALDI-TOF spectrum in **Fig 1**. De-isotoping removes the ^{13}C isotope peaks and centroiding reduces the remaining peak to a single data point.

(*see* **Fig. 2**). "De-isotoping" and "centroiding" of the MS data is necessary, so that only the monoisotopic peptide masses are included in the PMF data. The MS data analysis software will have an option for the data to be shown as a list of

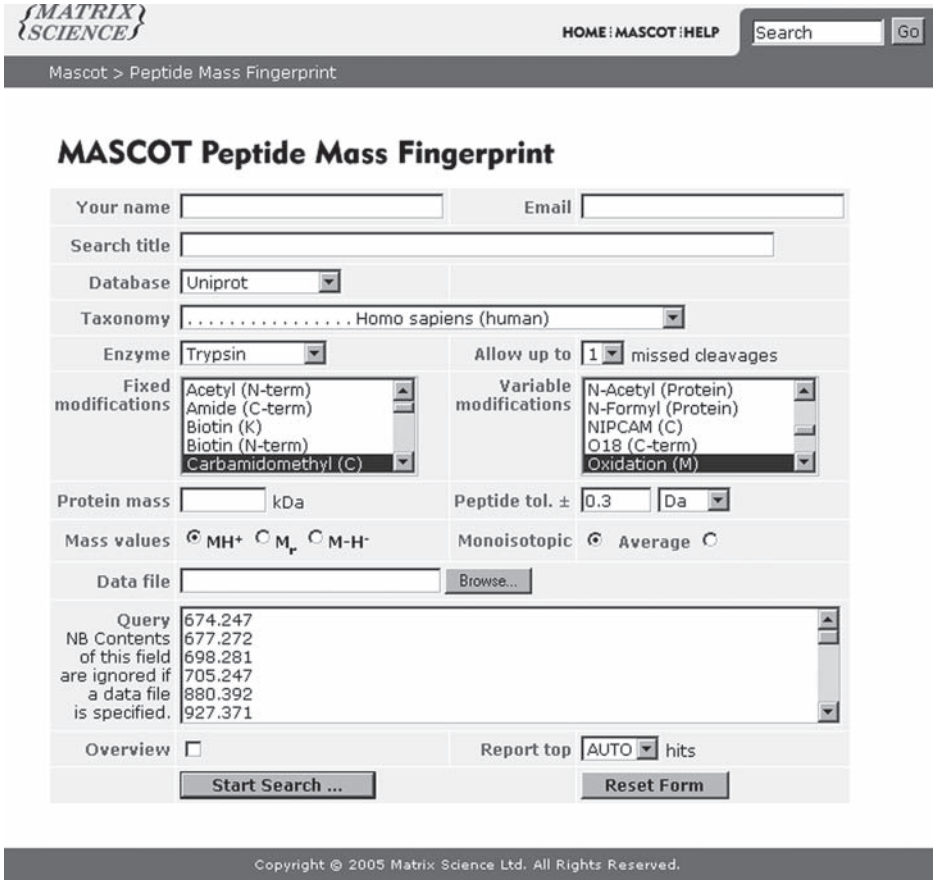

Fig. 3. Mascot PMF search page.

masses (peak list), which can be saved as a text file or simply copied directly into the data entry field of the database search engine. There are a number of search engines that can be used for PMF searches, some of which are freely available on the internet (*see* **Note 5**). We will use Mascot to demonstrate a search, but all have essentially the same functions.

The Mascot PMF search page is shown in **Fig. 3**. Detailed explanations of the various terms and parameters are available from the web site; brief descriptions are given in **Note 6**.

1. Select the database to be searched from the drop-down list e.g. Uniprot.
2. If taxonomic information is known for the sample origin, select from the list, otherwise select "All entries".
3. Select "trypsin" as the enzyme.
4. "Allow up to" 1 missed cleavage.

5. Select "Carbamidomethyl (C)" as a fixed modification.
6. Select "Oxidation (M)" as a variable modification.
7. If the MALDI spectrum was internally calibrated, the peptide tolerance can be set to 0.1 Da, otherwise 0.3 to 0.5 Da is a reasonable starting point.
8. Select "MH+" for Mass values.
9. Select "Monoisotopic" if the MALDI data were acquired in reflectron mode, or "Average" for data acquired in linear mode.
10. If the peak list was saved as a text file, browse to the file location, otherwise paste the list directly into the "Query" field.
11. Select "Auto" from "Report top" hits.
12. Start search.

Within a few seconds the search result will appear which should look similar to **Fig. 4**. This shows a graphical representation of the results and a list of significant matches. A single significant match is indicated by the graph with a maximum score of 226, well above the significance threshold of 61. The score is related to the probability that the match is real rather than purely random, and is also expressed as an expect value equivalent to the BLAST E-value, 1.8e-18 in this case, indicating that this is almost certainly a genuine match.

In the "Concise Protein Summary Report" shown, all of the proteins matching the same set or subset of masses are listed under a single entry. Typically, these will represent multiple database entries for the same protein as well as sequence variants, fragments, and so on.

Clicking on a protein accession number from the list brings up further information (*see* **Fig. 5**), including the matched peptides, listed and mapped onto the protein sequence, as well as the % sequence coverage and any unmatched masses. There will almost inevitably be some unmatched masses; they can be due to the presence of contaminating proteins in the digest, non-tryptic cleavages, incomplete digestion, modified peptides, errors in the database sequence etc ***(8).***

The graph at the bottom of **Fig. 5** plots the error for each of the matched peptide masses and is useful for assessing whether the tolerance setting used for the search was appropriate. If desired, a more appropriate setting could be chosen and the data researched.

3.6. Failure to Obtain a Significant Hit

Some of the most common reasons why a database search may not give a significant match. are:

1. Too few masses in the PMF data – depending on the size of the database and the parameters settings, a minimum of 4–6 matched peptides are required for a significant hit. This situation could arise simply because the spectrum is very weak and so only a few of the strongest peptide signals are visible, or because the particular protein does not yield many peptides within the useful mass range (e.g. small

Fig. 5. Detailed information for the protein identified in the Mascot search results in **Fig. 4**.

data, this can result in all of the scores dropping below the significance threshold. The presence of contaminants e.g. trypsin or keratins has the same effect, however, known peptide masses derived from keratins and trypsin can be removed from the PMF data prior to searching ***(9).***

4. Peptide tolerance set too low or too high.
5. Incorrectly calibrated spectrum.
6. Searching EST databases – ESTs are generally short and therefore do not usually provide sufficient numbers of matched peptides for a significant score.
7. The protein is not present in the database being searched.

4. Notes

1. Contamination is a serious concern when attempting to identify low amounts of protein by MALDI-MS. Use only the highest quality reagents, HPLC grade solvents and high quality plasticware to minimize non-protein contamination. Ideally a set of glass/plasticware and reagents/buffers should be dedicated for MALDI-MS analysis. Laboratory dust is a major source of protein contaminants (keratins) and so every effort to exclude dust from samples, buffers and reagents must be taken. Communal buffers, stains, destains, and so on, are often contaminated with dust and should be avoided. Rinse all glassware with high quality water before making up buffers etc. Wear nitrile gloves (latex contains protein contaminants) and lab a coat. Keep a cover over the gel during staining, and so on. Never stain a gel in a container that has been used for processing Western blots, as they will be contaminated with blocking proteins. Only handle the gel if absolutely necessary and then avoid touching parts of the gel that are to be cut. Gel pieces can be cut and processed in laminar flow cabinets, although this is usually not necessary if sensible precautions are taken.
2. Modified trypsin is preferred for protein digestion as it is less susceptible to autodigestion ***(7).*** The trypsin 10x stock solution is prepared by dissolving the trypsin (20µg) in the solvent supplied with the enzyme (50 m*M* acetic acid; 200 µL). This is stored at −70°C in aliquots (10 µL) and is stable for at least one year.
3. MALDI analysis kits (e.g. Sequazyme peptide mass standards kit from Applied Biosystems) are a convenient way to obtain matrix, peptide standards and solvents, however these items can easily be purchased independently. Any peptides which span a reasonable proportion of the useful mass range can be used for calibration, provided their accurate molecular weights are known.

   α-cyano-4-hydroxycinnamic acid is the most common matrix used for peptide analysis. Matrix solution is prepared by dissolving 5mg of matrix in 1 mL of 4:1 acetonitrile/water containing 0.1% TFA.

   A mixture of peptide calibration standards e.g. des-Arg^1-bradykinin (monoisotopic mass 904.4681), Angiotensin 1 (monoisotopic mass

1,296.6853), ACTH (1–17 clip) (monoisotopic mass 2,093.0867), ACTH (18–39 clip) (monoisotopic mass 2,465.1989) is made to a concentration of 2 pmol/μL each in 0.1% TFA in water. This solution is then mixed 1:1 with matrix solution to give the final peptide calibration mixture.

4. Larger volumes of digests can be concentrated by vacuum centrifugation, but this can lead to significant peptide losses, particularly if the sample is concentrated to dryness. Alternatively, peptides can be concentrated and desalted by using a micro scale pipette-tip format solid-phase extraction device (e.g. micro C18 Zip Tips from Millipore, Omix C18MB tips from Varian or STAGE tips from Proxeon). The details of their use in desalting peptide solutions for MALDI analysis are given with the product, but for the final elution step, use the matrix solution described above, to elute the peptides directly onto the MALDI plate.
5. Freely available PMF search engines include: Mascot from Matrix Science (http://www.matrixscience.com/cgi/search_form.pl?FORMVER=2&SEARCH=PMF), MS-Fitfrom Protein Prospector (http://prospector.ucsf.edu/cgi-bin/msform.cgi?form=msfitstandard) and Aldente from ExPaSy (http://www.expasy.org/tools/aldente).
6. SwissProt is a relatively small, but highly annotated database with minimal redundancy. Uniprot, NCBInr and MSDB are much larger, but have multiple entries for many proteins. Other search engines may have additional database choices and in-house copies allow custom databases to be used.

   Specifying the taxonomy as closely as possible reduces the number of database entries which need to be considered in the search. This reduces search times, but more importantly, reduces the threshold score for significant matches, increasing the confidence of any protein identification.

   The cleavage specificity of trypsin is C-terminal to Lys and Arg residues (except where followed by Pro). However, not every such peptide bond will be cleaved. The number of missed cleavages to consider can be specified, but increasing the number decreases the significance of any match and should normally be set to 1.

   Fixed modifications are modifications to specific amino acids which are considered to be complete i.e. every occurrence of the amino acid in the sequence is assumed to carry the modification and the unmodified amino acid is not considered. Variable modifications, on the other hand, are incomplete and therefore both the modified and unmodified amino acid is considered in the search. In the example discussed above, the reduction/alkylation should result in complete carbamidomethylation of all cysteine residues, thus “Carbamidomethyl (C)” was chosen as a fixed modification, whereas methionine oxidation, a common artifactual modification which is usually incomplete, was selected as a variable modification. The use of

multiple variable modifications will greatly reduce the significance of any match and should therefore be used with caution.

Most PMF search engines allow a molecular weight for the protein to be entered; the search will then consider only database entries within a window around this value. This can be dangerous, as proteins are subject to processing/degradation which can significantly increase or decrease their molecular weight. Mascot uses a more complex method of applying this parameter, but in most cases this can be left blank.

The peptide tolerance is a window around each mass value in the peak list within which a theoretical database peptide mass must fall, in order to be matched.

Protein Ladder Sequencing

Rong Wang and Brian T. Chait

1. Introduction

The ladder peptides are generated by stepwise chemical degradation in a controlled manner. In our first experiment, we obtained ladders by a manual method using stepwise Edman degradation in the presence of a small amount of terminating agent ***(1)***. Subsequently, three additional chemical approaches have been developed for generating N-terminal peptide ladders. The first of these employed short coupling reaction times (incomplete reaction) in an automatic gas-phase amino acid sequencer ***(2)***, while the second used volatile coupling reagents in a set of manual reactions ***(3)***, and the third utilized rapid acid hydrolysis reaction with microwave irradiation ***(4)***. In meanwhile, new terminating agents of Edman degradation were developed and tested for producing N-terminal peptide ladders, such as allyl isothiocyanate (AITC) ***(5)***. More recently, a new terminating agent, N-(9-fluorenylmethoxycarbonyloxy)succinimide (Fmoc-OSU), was reported ***(6)***. Following the Edman degredation, the Fmoc group can be removed from the N-terminus and any reacted side chains by piperidine treatment and yield N-terminal peptide ladders without chemical modifications ***(6)***. Although we are discussing peptide ladder generation by chemical means, the peptide ladders can also be produced by enzymatic digestions using exopeptidase, such aminopeptidase and carboxypeptidase. The application of carboxypeptidases is the major experimental method to generate C-terminal peptide ladders for protein ladder sequencing ***(7–11)***.

Here, we will describe our early manual approach, using phenylisocyanate (PIC) as the terminating agent to produce the latter peptides ***(1,12)***. A small quantity of 5% phenylisocyanate (PIC) is used as the terminating agent in the coupling step. The resulting phenylcarbamyl (PC) peptide derivatives are stable to

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

the trifluoroacetic acid (TFA) used in the subsequent cleavage step. A small fraction of N-terminally blocked peptide is generated at each cycle. A predetermined number of cycles are performed without intermediate separation or analysis of the release amino acid derivatives. The resulting mixture of peptides (the ladder) is measured by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry ***(13)***. The mass spectrum contains peaks corresponding to each terminated peptide species present. The amino acid residues are identified from the mass differences between consecutive peaks. The order of these mass differences in the data set gives the amino acid sequence of the original peptide (**Fig. 1**).

Protein ladder sequencing has several potential advantages compared with conventional amino acid sequencing.

1. The amino acid sequence is read out from one spectrum. Thus, optimally, all members of the sequence-defining fragments of the peptide, each differing by one

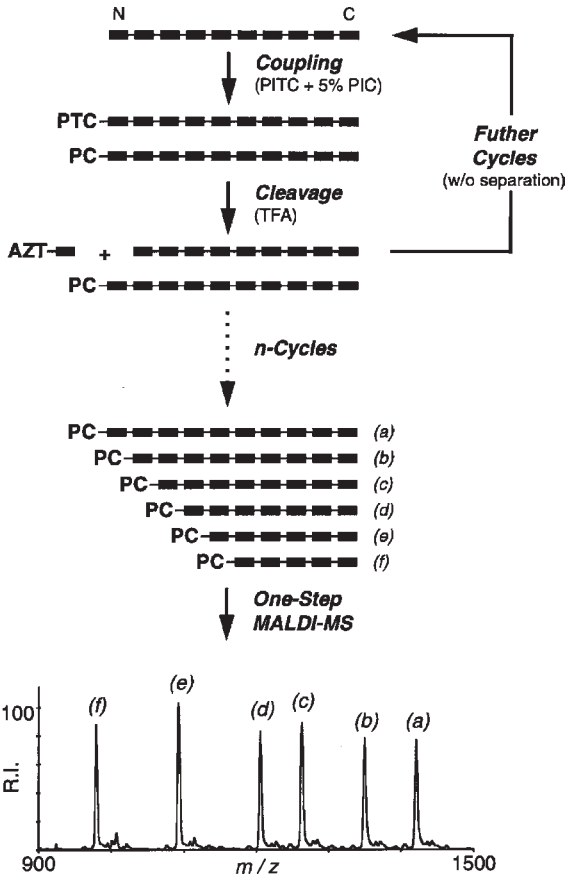

Fig. 1. The principle of N-terminal protein ladder sequencing. A stepwise Edman degradation is carried out in the presence of small of amount of terminating reagent (phenylisocyanate, PIC) in the coupling step. The resulting phenylcarbomyl (PC) peptides are stable to trifluoroacetic acid (TFA) used to cleave the terminal ammo acid from the phenylthiocarbomyl (PTC) peptides in the cleavage step. A ladder peptide mixture is formed as the result of PC-peptide accumulation in successive Edman cycles. Each black block represents an amino acid residue.

amino acid residue, are simultaneously examined. The sequence of the peptide is deduced from the set of fragmentation products. Such a data set contains mutually interdependent information that determines the identity and the order of each amino acid residues in the parent peptide. Carry over resulting from incomplete sequencing reactions cause no ambiguities in the present method.
2. The method can be used to obtain sequence information from peptide mixtures.
3. Direct detection of posttranslational modifications can be made with ladder sequencing ***(14,15)***.
4. The ladder generating chemistry does not require complicated apparatus and can be done in any chemistry laboratory. However, the current procedure requires at least 100 pmol of peptide, since sample loss generally occurs in the liquid-phase extraction.

Protein ladder sequencing has the potential to be used in the following biological applications.

1. In conjunction with peptide fragment mass mapping, the method can provide additional sequence information and facilitate protein sequence database searching for protein identification ***(8)***.
2. The method can be used to study the nature and to determine the sites of chemical modifications and posttranslational modifications (e.g., phosphorylation, and glycosylation) ***(14,15)***.
3. In protein processing and metabolism pathway studies, the method can be used to identify and confirm the terminal of protein processing products ***(16).***

2. Materials

2.1. Chemicals and Reagents (see Note 1)

1. Phenylisothiocyanate (PITC) [Thermo Scientific (Pierce), Rockford, IL or Sigma-Aldrich Co., St. Louis, MO].
2. Phenylisocyanate (PIC), >98% (Sigma-Aldrich Co.).
3. Pyridine [Thermo Scientific (Pierce)].
4. Hexafluoroisopropanol (HFIP, 99.8+% (Sigma-Aldrich Co.).
5. Heptane [Applied Biosystems Inc., Foster City, CA or Thermo Scientific (Pierce)]
6. Ethyl acetate [Applied Biosystems Inc., Thermo Scientific (Pierce), or Sigma-Aldrich Co.].
7. Trifluoroacetic acid (TFA), anhydrous [Thermo Scientific (Pierce)].
8. 12.5% Trimethylamine (TMA) (Applied Biosystems Inc.).
9. α-Cyano-4-hydroxycinnamic acid, 97% (Sigma-Aldrich Co.).
10. Acetonitrile (Applied Biosystems Inc.).
11. Nitrogen, 99.99% (Matheson, Montgomeryville, PA).
12. Distilled and deionized water (prepared by using Milli-Q UV Plus water purification system).

2.2. Laboratory Equipment

1. Eppendorf Micro-Centrifuge (Brinkmann Instruments, Westbury, NY).

2. Savant SC110 Speed-Vac (Savant Instruments, Farmingdale, NY).
3. Multi-Block Heater (Lab-Line Instruments, Melrose Park, IL).
4. Fisher Vortex (Fisher Scientifics, Pittsburg, PA).
5. In-house laboratory vacuum.
6. Polypropylene microcentrifuge tube (PGC Scientifics, Gaithersburg, MD).

2.3. Mass Spectrometry

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometer (*see* **Note 2**).

2.4. Preparing Reagents (see Note 3)

1. Coupling buffer: Pyridine/water (1:1, v/v, pH 10.1). 250 µL water and 250 µL pyridine.
2. Coupling reagent: PITC/PIC/pyridine/HFIP (24:1:72:3, v/v). (Prepared under a blanket of dry nitrogen). 120 µL PITC, 5 µL PIC, 360 µL pyridine, 15 µL HFIP.
3. Cleavage reagent: 500 µL TFA.
4. Conversion buffer: 12.5% TMA/pyridine (1:1, v/v). 100 µL 12.5% TMA, 100 µL pyridine.
5. Conversion reagent: PIC/pyridine/HFIP (1:80:2.5, v/v). 2 µL of PIC, 160 µL pyridine, 5 µL HFIP.
6. Washing solvent A: Heptane/ethyl acetate (10:1, v/v). 10 mL heptane, 1 mL ethyl acetate.
7. Washing solvent B: Heptane/ethyl acetate (2:1, v/v). 8 mL heptane, 4 mL ethyl acetate.
8. Mass spectrometric matrix solution. 2 mg α-cyano-4-hydroxycinnamic acid, 200 µL of 0.1% TFA in water, 100 µL of acetonitrile. Vortex vial thoroughly to suspend the solid into liquid phase to form turbid mixture and then centrifuge the turbid mixture at 16,000g for 2 min. The saturated matrix solution will be used in the sample preparation for mass spectrometric analysis.

3. Methods

3.1. Ladder Generating Reaction by PITC/PIC – Wet Chemistry

This is manual method to produce ladder peptides based on a manual Edman chemistry ***(17)*** (*see* **Note 4**). All of the reactions are carried out in a 0.6-mL polypropylene microcentrifuge tube. Since PITC is very sensitive to oxidation, some of the operations are perform under a blanket of day nitrogen. Operations requiring a nitrogen blanket will be indicated.

3.1.1. Coupling Reaction

1. Dissolve peptide sample in 20 µL of coupling buffer.
2. Add 20 µL of coupling reagent (under a blanket of dry nitrogen).
3. Incubate the reaction vial at 50°C for 3 min with a block heater.

3.1.2. Removal of the Coupling/Terminating Reagents and Byproducts by Two-Phase Liquid Extraction (see **Note 5***)*

1. Remove the reaction vial from the block heater.
2. Wipe the outside of the reaction vial with a pre-wet paper towel to condense the reaction liquid.
3. Centrifuge the reaction vial briefly at 16,000 g.
4. Add 200 µL of washing solvent A to the reaction vial, vortex gently, and centrifuge at 14,000 rpm for 1 min to clear the phase.
5. Aspirate the upper phase by vacuum suction. Extreme care should be taken to avoid loss of the lower phase liquid.
6. Repeat steps 4 and 5 one more times with washing solvent A and twice with washing solvent B. It is advisable to use a fine bore pipette tip for this task.
7. After these four extractions, dry the remaining solution in a Speed-vac centrifuge for about 5–8 min.

3.1.3. Cleavage Reaction

After the reaction mixture is dried, add 20 µL of anhydrous TFA to the reaction vial (under a blanket of dry nitrogen). Incubate the reaction vial at 50°C for 2 min with a block heater.

3.1.4. Removal of Cleavage Reagent

Remove the cleavage reagent, TFA, by drying the reaction vial in a Speed-vac centrifuge for about 5 min.

3.1.5. Conversion of Free N-Termini to Phenylcarbamyl Derivatives

After the last cycle of coupling-washing-cleavage steps, subject the total peptide mixture to an additional treatment with PIC to convert any remaining unblocked peptides to their phenylcarbamyl derivatives.

1. Add 20 µL of conversion buffer and 20 µL of conversion reagent to the reaction vial.
2. Carry out the reaction at 50°C for 5 min.
3. Extract the reagents as described in Section 3.1.2.
4. Repeat steps 1–3 one more time (*see* **Note 6**).

3.1.6. Acidify the Peptide Mixture (see **Note 7***)*

Add 5 µL of TFA to each reaction vial and vortex briefly.
Remove TFA by a Speed-vac centrifuge for about 5 min.

3.2. Mass Spectrometric Analysis

Add 3 µL of matrix solution to the reaction vial and vortex briefly. Apply 1 µL of this peptide/matrix solution on the sample probe and dry at ambient temperature. Acquire mass spectra in the positive ion mode using a laser desorption/ionization time-of-flight mass spectrometer.

3.3. Sequencing Data Interpretation

A successful measurement will result in a mass spectrum (*see* **Note 8**) that contains a group of peaks as illustrated in **Fig. 2**. The mass spectrum is plotted using relative intensity (*y*-axis) vs mass-to-charge ratio (*x*-axis). The measured value is the ratio of mass/charge (m/z) for each ion detected by the mass spectrometer. Since the peaks observed in the spectra usually represent single protonated peptide ions (unity charge, $[M+1]^+$) in matrix-assisted laser desorption/ionization mass spectrometry, the amino acid sequence is determined by calculating the m/z or mass differences between two peaks sequentially from high mass to low mass in the mass spectrum. In the example shown in **Fig. 2**, peak (a) has an m/z value of 1419.6 Dalton and peak (b) has an m/z value of 1348.5 Dalton. The mass difference is calculated as 1419.6 – 1348.5 = 71.1 Dalton. The identity of this amino acid residue (Ala) is determined by comparing the calculated mass difference with the amino acid residue masses. The identities of other amino acid residues are determined in the same fashion as Ser (86.8), Gly (57.2), Ile/Leu (113.0), and Ile/Leu (113.2) (*see* **Note 9**). The amino acid sequence (amino-terminal to carboxy-terminal) is determined from the order of the residues identified from high to low mass of the sequencing ladder (i.e., Ala-Ser-Gly-Ile/Leu-Ile/Leu).

Chemically modified amino acid residues can be identified by the same procedure using the mass differences obtained from the spectrum ***(15)*** (*see* **Note 10**). These residue masses can be used to determine the identity of the modifications.

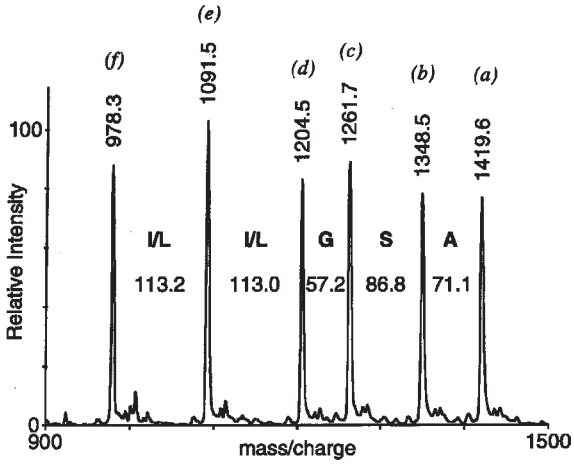

Fig. 2. Amino acid sequence read-out from a mass spectrum of ladder peptides. The vertical labels are measured m/z values for the peaks in the spectrum. The horizontal numbers are calculated mass differences between adjacent peaks. The identified ammo acid residues are indicated. The ammo-terminal sequence is read from right to left.

4. Notes

1. All chemical and solvents used in the ladder-generating chemistry should be protein sequencing grade or the highest grade available.
2. The laser desorption/ionization time-of-flight mass spectrometer was constructed at The Rockefeller University and described in detail elsewhere ***(18)***. This mstrument is equipped with a 2-m-long flight tube and uses a Nd-YAG laser source (HY 400, Lumonics, Kanata, Ontario, Canada) that generates pulsed laser light (wavelength 355 nm) with a duration of 10 ns. Commercial matrix-assisted laser desorption/ionization time-of-flight mass spectrometers should also be suitable for reading out the masses of the ladder peptides.
3. Amount of sequencing reagents prepared here are enough for sequencing four peptide samples and five cycles per sample. Fresh PITC and TFA (both in ampule) are used for each experiment.
4. A detailed discussion on manual Edman chemistry is given in ***ref. 17***.
5. Special care should be taken to remove the coupling reagents and byproducts of the coupling reaction. Otherwise, nonvolatile salt will form and affect subsequent reactions and mass spectrometric analysis.
6. It is necessary to perform the conversion twice, since the concentration of PIC is limited by its solubility and may be too low to yield 100% conversion.
7. The matrix-assisted laser desorption/ionization mass spectrometric analysis of protein and peptide requires acidic conditions. Unless the pH is lowered, the base used in the coupling reaction will significantly reduce the sensitivity of the mass spectrometric measurement.
8. It is important to note that the mass spectrometric response of a peptide is dependent on its amino acid composition. The sensitivity, in general, is enhanced when the peptide contains basic amino acid residues. On the other hand, the sensitivity is reduced when no basic amino acid residues are present. The modification on ε-amino group of lysine residues by phenylisocyanate may decrease the mass spectrometric response, especially for peptides that do not contain arginine residues.
9. Leucine and isoleucine have identical residue masses (113 Dalton). These isobaric amino acid residues cannot be distinguished by the present ladder sequencing method. Lysine and glutamine have the same nominal residue masses (128 Dalton). However, they can be distinguished from each other; since the ε-amino group of lysyl residue is modified by PIC and results in a mass shift of 119 (residue mass of PC-lysine is 247.3 Dalton).
10. To detect a posttranslational modification using ladder sequencing, the modification should not be labile to the ladder sequencing chemistry. In certain cases, ambiguous results may result from posttranslationally modified amino acid residues that have similar masses to nature amino acid residues.

Sequence Analysis with WinGene/WinPep

Lars Hennig

1. Introduction

Retrieving information from sequence data is becoming increasingly important. Currently, a multitude of public services is available via the internet. However, many scientists are annoyed by slow network connections and busy serves. Moreover, identifying appropriate Internet pages while struggling with outdated links is often extremely time consuming. For these reasons, PC-based stand-alone applications constitute a useful alternative to Internet services. As available commercial software is usually quite expensive, WinGene and WinPep were developed that may be used free of charge by researchers in academic institutions ***(1)***.

WinGene and WinPep merge diverse analysis possibilities with maximal comfort for the user. Thus, the programs combine data analysis and data presentation. Simple, general principles of Windows® programs allow immediate usage without lengthy training. Specialized analysis tasks for which Internet connections are extremely advantageous, such as structure predictions and database searches, were not included in the software. The first version of WinPep was released in 1998 ***(1)*** and became very popular. The latest versions, WinPep 3.01 and WinGene 2.31, contain several improvements and new functions. **Tables 1** and **2** summarize the abilities of WinGene 2.31 and WinPep 3.01, respectively. The following sections describe some features in more detail.

2. Materials

2.1. Hardware

The programs run on any PC currently marketed, but also on most older models. The computer should be at least a PC/486 equipped with 8MB RAM. WinGene/WinPep require one of the following operating systems: Windows®95,

Windows®98, Windows®NT, Windows®2000, Windows®XP or Windows®Vista. At least 5MB hard disk space must be available. Connection to the internet is only needed for downloading and updating the software.

2.2. Software

WinGene/WinPep can be downloaded free of charge from http://www.pb.ethz.ch/downloads. WinGene performs restriction analysis of nucleotide sequences (cf. section 3.2.2.) requiring an enzyme database. Recent versions be obtained from REBASE (ftp.neb.com, http://rebase.neb.com) ***(2)***.

3. Methods

3.1. General features

The programs come with extensive help files that explain most procedures and contain major references. Most parameters of WinGene/WinPep are saved in INI files and can be modified from within the program. Alternatively, direct editing of the INI files with any text processor is possible.

Sequence data can be entered by different means: Direct typing, *Copy&Paste*, via the clipboard, import from text files or files in FASTA format are possible (cf. **Note 1**). Moreover, WinGene allows to in silico translate nucleotide sequences into amino acid sequences and to export them directly into WinPep. All results can be easily printed or copied to the clipboard. After pasting in other applications further editing of text and graphics is possible. Moreover, graphical representations can be saved to a disk in Enhanced Windows Metafile (EMF) format. Sequences can be exported in FASTA format.

3.2. WinGene

3.2.1. Miscellaneous

With WinGene, nucleotide sequences can be easily reverse-complemented by clicking on the “Complement the sequence” button. After selecting the part of the sequence, the “Primer check” function calculates base composition and

melting temperature of the selected oligonucleotides ***(3,4)***. If there was no selection, the dialog box will open for *de novo* entry of the oligonucleotide sequence. The resulting report can be printed or pasted into any text processor software, for instance for keeping records of available oligonucleotides.

3.2.2. Restriction Analysis

WinGene can be used to perform restriction analyses of given nucleotide sequences. The source file for restriction enzymes is gcg.009 from the REBASE database ***(2)*** (cf. **Note 2**). In the "Restriction Analysis" Dialog, the options for the current task can be set. The user can choose one of the following enzyme subgroups: (1) all enzymes, (2) only enzymes with recognition sites equal to or longer than a defined value, (3) a pre-selected, saved subset of enzymes ("YFE," your favorite enzymes), or (4) an arbitrary selection from the list of all enzymes. To generate an YFE list, first select the desired enzymes. Then click on "Make YFE." The file YFE01.txt will be created in the program directory. This file contains the ID numbers of the selected enzymes for fast and convenient access during subsequent analyses (cf. Note 3). In addition, the selected subset can be restricted further by activating "Only commercially available enzymes". The provided sequence will be considered as linear unless the "Circular DNA" item is checked.

Output may contain the sequence with indicated restriction sites ("Map") and/or a table of all occurrences of the recognition sequences in the input sequence ("Table"). If desired, recognition sites can be marked automatically by bold letters.

3.2.3. Translation and Identification of Open Reading Frames

Translation of the nucleotide sequence is initiated by clicking on the "Translate the Sequence" button. The translate window displays the sequence with its translation in three frames below. Basic text formatting (bold, underline, italics) is available. WinGene will indicate which sequence (original or complementary) is used and corresponds to the sense (upper) strand. The individual strands and frames can be de-selected from current display. This feature is useful, if for instance only display of the sense strand with one translated frame is desired. A list of all ORFs (Open Reading Frames) longer than a specified minimum (cf. Note 4) is available with the position of the first occurring methionine given. If only one frame is displayed, the longest ORF in this frame can be exported directly into WinPep ("Export into WinPep" command in the "File" menu).

3.3. WinPep

3.3.1. Physicochemical Properties

A basic set of calculations determines some physicochemical properties of the given peptide, including amino acid composition, molecular weight, molar absorption coefficients for native ***(3)*** and denatured states ***(8)*,** and isoelectric point (cf. **Note 5**). Furthermore, the sequence can be searched for the occurrence of sequence motifs.

In the age of genomics, there is an increasing need for processing large groups of sequences instead of just individual ones. WinPep serves such demands by being able to process a file containing a basically unlimited number of polypeptide sequences in FASTA format and calculating the predicted physicochemical properties for all encoded polypeptides. Results are saved in a tab-delimited text file that can easily be read by any spreadsheet software such as MS Excel. Furthermore, some statistical parameters can be included in the output. The "Batch options" dialog allows specifying the features to be analyzed. The only field that is always present in the output file is the sequence name. By default, the settings of the user's last analysis are activated when the dialog box next time. It is possible to tabulate length, molecular weight, molar absorption coefficients, relative and absolute amino acid composition, isoelectric point, grand average of hydropathy (GRAVY, ***(5)***), and number of predicted transmembrane helices. The following statistical parameters can be calculated for each molecular property: Mean, median, maximum, minimum, standard deviation and standard error.

If desired, a log file of the analysis is generated. This file includes date, name of the input file, name of the output file, number of successfully recognized sequences, used hydropathy scale for GRAVY, and used threshold value for identifying potential transmembrane helices. By default, analysis of a file "name.txt" generates the output file "name_results.txt" and "name_results_log.txt".

3.3.2. Sequence-specific Cleavage and the Identification of Posttranslational Modifications

For the simulation of sequence-specific cleavage, proteases and cleaving agents can be selected out of a provide list or can be defined individually. Use the "Select" or "Unselect" buttons to obtain a subgroup of agents to be used (cf. **Note 6**). The "Specificity" filed displays the specificity of the selected agents; user entry is not possible. Subsequently, either all possible fragments or only those from a complete digest are displayed (cf. **Note 7**).

The identification of potential posttranslational modifications is a function of WinPep2.11 and later. If mass spectroscopy yields peptides with an unexpected molecular weight, an algorithm tests whether this value might result from a posttranslational modification. First a simulation of a sequence-specific cleavage most be performed. The generated list of fragments is the basis for the subsequent analysis. WinPep displays a list of potential modifications. Furthermore, the presence of residues that could carry these modifications is indicated.

3.3.3. Helical Wheel

Part of the sequence can be displayed in a circular way with an offset of 100 degree, representing the typical α-helix. The view menu can be used to change the size of the image and to switch between color and monochrome display. In color mode, positively charged amino acids are red, negatively charged blue, hydrophilic uncharged green and hydrophobic uncharged gray (cf. **Note 8**).

Clicking with the right mouse-button invokes a floating menu where the displayed part of the sequence can be modified by opening the helical wheel dialog box. In addition, the amphipathy moment can be calculated. This quantitative value was defined to facilitate the identification of potential amphipathic helices: Considering the hydropathy of all amino acids within the given sequence window but not their distribution along the axis, the gradient across the axis is calculated. Accordingly, an amphypathy moment close to zero results from a relatively even distribution of hydrophilic and hydrophobic side chains while large values indicate clustering of hydrophilic and hydrophobic side chains on opposite sides of the helix. The amphypathy moment can be plotted along the entire sequence to further facilitate the identification of amphyphilic stretches. Thus, the amphypathy moment provides indications for further experimental validation.

3.3.4. Hydropathy Plots

Selected subsequences can be displayed as a hydropathy plot (cf. **Note 9**). For most scales, sequence stretches that average below zero are mainly hydrophilic and therefore likely to be surface-exposed, while stretches that average above zero are mainly hydrophobic and therefore likely to be buried or membrane-spanning.

Mean hydropathy (GRAVY score) and scale in use are indicated. Kyte and Doolittle ***(5)*** showed for their scale that none of 84 analyzed soluble proteins had a GRAVY score >0.5. Nevertheless, although a GRAVY-score >0.5 is a good indication that a protein is membrane bound, several membrane-embedded proteins have GRAVY scores below zero. Therefore, the amino acid sequence alone does not suffice to distinguish soluble from membrane-bound proteins ***(5)***. If the scale by Kyte and Doolittle is used, putative transmembrane stretches are marked by a red line; the used threshold value is displayed next to the size of the sliding window. Kyte and Doolittle showed in a statistical analysis of several proteins that the mean hydropathy for the most hydrophobic 19-aminacid-stretch averages at 1.08 ± 0.22 for soluble and 1.86 ± 0.38 for membrane-bound proteins ***(5)***. Therefore, they concluded that if a given 19-residue stretch has a mean hydropathy of at least 1.6 there is a high probability for membrane spanning. By default, WinPep uses a threshold of 1.6 to predict putative transmembrane segments. Nevertheless, it was also shown that the occurrence of multiple membrane-spanning segments often correlates with a lower hydrophobicity of the individual segments ***(5)***. Therefore, the user might to modify the default hydropathy threshold.

Furthermore, individual residues can be marked by an arrow. Line color and font may be changed for each mark by double-clicking on it with the "Select" tool. Using the "Insert text" tool, user defined text items can be inserted. The position, font and content may be edited by clicking on them with the "Select" tool. Some text items are inserted by default (e.g. the currently used scale and mean hydropathy). They can be modified, repositioned or deleted by the user. However, once edited the automatic update of these items ceases.

Clicking the right mouse button invokes a floating menu where the displayed part of the sequence may be modified by opening the "Hydropathy plot properties" dialog. If the user has previously zoomed in, the display can be reset to the default view. In addition, results of selecting with the left mouse button may be toggled between zoom-in and opening a helical wheel display.

3.3.5. Domain drawing

A sketch of the domain composition of the sequence is easily generated using WinPep. Every display contains at least one domain – the entire sequence. Further domains can be added freely by the user. Domain color, name, font and text-color need to be specified. If domains overlap, domain defined last (i.e. last in the list) will appear on top of the others. Therefore, the shortest domain should be defined last. By changing the default scale, drawings of proteins of different lengths may be generated at a common scale. These individual drawings can be aligned in any graphic processing software. Individual residues can be marked. Line color and font are adjustable by double clicking on the mark. Furthermore, text items can be inserted and modified easily.

4. Notes

1. When sequences are pasted into WinGene or WinPep, any numbers, spaces or special characters will be deleted. Therefore, it is not require to remove sequence numbering manually beforehand.
2. Make sure to use the file in "gcg" format.
3. Installation of an updated "gcg.*" file may corrupt the existing YFE file by changing the numbering.
4. The minimal ORF length can be changed in the options menu.
5. The defaults pK_a values on which the calculations are based were taken from ***(6)***. However, these values can easily be changed in the options menu.
6. Available proteases can be edited and new ones added in the options menu.
7. Using the view menu, the list of fragments can be sorted by weight, start position or length.
8. The default settings for color coding amino acid residues can be changed for each helical wheel with the "Change colors" option in the options menu.
9. The program comes with two predefined scales ***(5,7)***. However, additional scales can be defined in the options menu.

Acknowledgments

The author thanks everybody who tested the programs, reported bugs or contributed suggestions for additional features, especially my wife Dr. C. Köhler, Dr. S. Frye and Dr. J. Swire.

HPLC and Mass Spectrometry of Integral Membrane Proteins

Julian P. Whitelegge

1. Introduction

HPLC separations of membrane proteins can be conveniently divided into two categories. Firstly, there are many methods available for isolation of functional membrane proteins. Typically the proteins are maintained in configurations as close to their native state as possible through the use of mild detergents that provide solubility without denaturation, allowing convenient ion-exchange or size-exclusion chromatography, for example. Proteins or complexes isolated in this way are subsequently used for functional analysis or crystallization, and so on. These isolation techniques have been well reviewed and readers are referred to literature specific to the protein or membrane of interest. The second category of separations are those used to separate membrane proteins from detergents and salts for the purpose of protein chemistry; while tempting to call these methods "denaturing" there is substantial evidence that this is not always the case. The focus of this chapter is to review the latter category of HPLC techniques with specific reference to those methods that provide conditions compatible with mass spectrometric analysis, especially on-line electrospray ionization.

1.1. Biological Mass Spectrometry

The discovery of mild ionization techniques for mass spectrometry (MS) of biological macromolecules has revolutionized HPLC, since it is now convenient to monitor elution profiles not only by UV absorbance but by MS as well. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF ***(1)*** uses samples co-crystallized with a small UV absorbing matrix molecule to transfer molecules from a dried solid phase to the gas phase, and is thus not directly compatible with HPLC though spotting small aliquots (> 0.5 µL) of sequential fractions for

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

MALDI-TOF remains a useful option. However, it was the application of electrospray-ionization (ESI) ***(2)*** that introduced the option of coupling HPLC directly to MS and the first liquid chromatography mass spectrometry (LC-MS) experiments provided an exciting breakthrough in technology ***(3).*** The HPLC eluent is directed straight to the ESI source for continuous ionization while the mass spectrometer measures mass to charge ratio (m/z) of ions detected during the course of a scan through the m/z range; a process that typically takes from 1 to 10 s. The read-out of mass spectra with time is thus complementary to the UV profile providing the opportunity to rapidly distinguish between different proteins and other UV absorbing molecules. As a consequence of the very low tolerance of MS to salts, LC-MS has been most widely applied using reverse-phase HPLC with volatile solvents (eg: acetonitrile) and ion-pairing agents (eg: TFA) though success is also achievable with size-exclusion HPLC provided salts are excluded. Variants of these methods have been successfully applied to a wide range of integral membrane proteins with structures containing up to fifteen transmembrane helices ***(4–7)***.

1.2. Mass Spectrometry of Membrane Proteins

Both ESI and MALDI-TOF have been applied to membrane proteins and peptides derived from them ***(4–13)***. The focus of this discussion will be ESI in the context of on-line LC-MS since it provides superior mass accuracy and resolution compared to MALDI-TOF, especially for intact proteins. The ability to use ESI-MS for analysis of integral membrane proteins was first demonstrated in 1993 ***(9, 10)*** using flow-injection methods. LC-MS was applied in 1997 ***(14)*** though the gradient elution with undiluted formic acid can be regarded as somewhat extreme and mass accuracies in the 0.01–0.05% range were lower than obtained for water-soluble proteins. The adoption of a reverse-phase system involving elevated concentrations of aqueous formic acid (60%) and gradient elution with isopropanol allowed routine achievement of 0.01% accuracy ***(4)***. A size-exclusion LC-MS method for intrinsic membrane proteins was reported in 1999 ***(5)*** and has proved broadly applicable ***(6, 7)*** again with routine achievement of 0.01% accuracy (+/– 9 Da at 90 kDa). Figure 1 shows the results of a size-exclusion LC-MS experiment performed upon bacteriorhodopsin. The mass spectrum **(Fig. 1A)** collected during elution of the protein shows a characteristic

Fig.1. (continued) (protons) associated with a particular protein molecule, in this case from 15 to 29 with the most abundant at M + 24 H^+. The singly charged CHAPS molecules presumably remained associated with the protein during chromatography but were separated during ionization. Minor signals at the center of the mass spectrum result from minor isoforms of the protein that are more clearly visualized in the molecular weight spectrum (B). Note resolution of lesser sub-populations of all species that measure 16–18 Da larger and probably correspond to singly oxidized species (+ O, 16 Da) or possibly carry a single bound water (+ 18 Da). Running the column at the usual operating temperature of 40 °C results in predominance of the apoprotein.

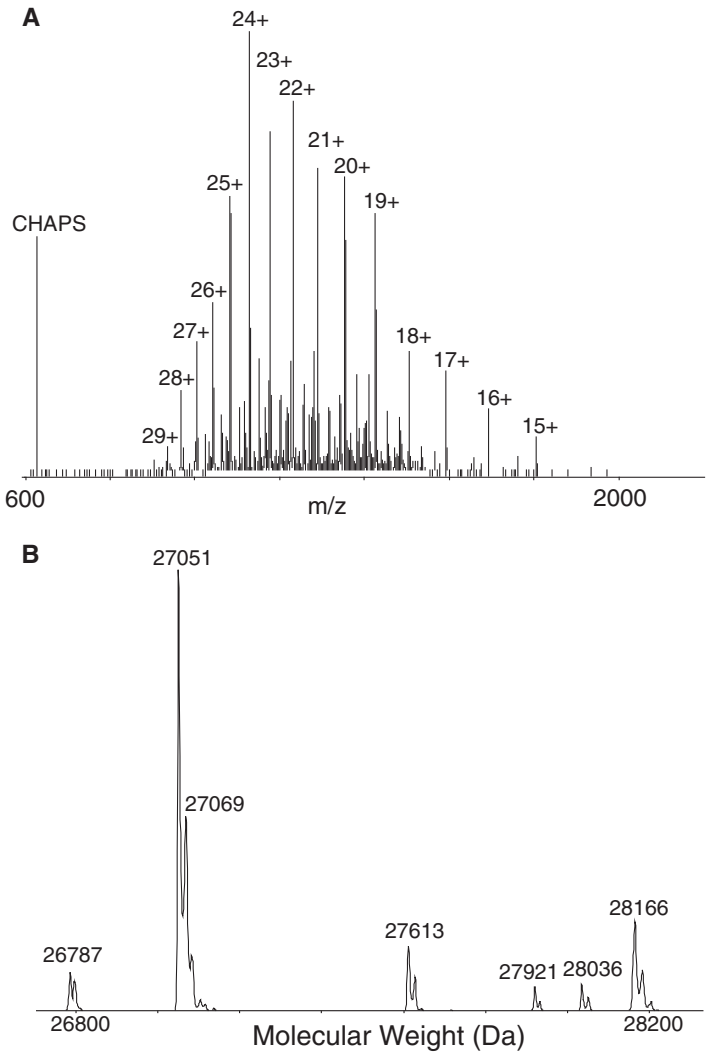

Fig. 1. Electrospray-ionization mass spectrometry of bacteriorhodopsin via online size-exclusion HPLC. Bacteriorhodopsin (Sigma, 50 µg) suspended in 1 mM CHAPS was acidified by addition of two volumes of formic acid/isopropanol (1/1, v/v) and loaded immediately onto an HPLC system with a size-exclusion column (Super SW 2000, 4.6 × 300 mm; Tosohaas) equilibrated in chloroform/methanol/1% aqueous formic acid (4/4/1, v/v; 250 µL/min.; 24°C). Eluent was passed through a UV detector and directly to an electrospray-ionization source (Ionspray™) of a triple quadrupole mass spectrometer (API III, PE Sciex). The instrument was operated with an orifice potential of 65 V and scanned from m/z 600–2300 with a step size of 0.3 and a dwell of 1 ms to give a scan time of 6 s. Scans collected during the elution of the first major protein peak were averaged **(A)** and processed by computer to generate a zero-charge spectrum **(B)**. Multiple charging during the electrospray process generates a cluster of ions that differ in m/z as a consequence of the number of charges

cluster of multiply-charged ions corresponding to the protein itself (15–29 H^+) and the singly-charged ion derived from the detergent CHAPS. A computerized reconstruction of the zero-charge molecular weight spectrum (**Fig. 1B**) shows predominance of the holoprotein (27051 Da; calculated 27050.06 Da), a small amount of apoprotein (26787 Da; calculated 26783.64 Da) and other minor species that probably correspond to incompletely processed forms of bacteriorhodopsin that have nevertheless bound the retinal cofactor.

1.3. Proteomics

While many proteomics studies are using 2-D gel electrophoresis as the primary separation technology there are recognized disadvantages of applying these methods to some classes of integral membrane proteins ***(15)***. Therefore, alternative technologies are sought with HPLC separations playing a potentially important role. **Fig. 2** shows a modification of LC-MS for use in proteomics. By inserting a liquid-flow splitter between HPLC and mass spectrometer it is

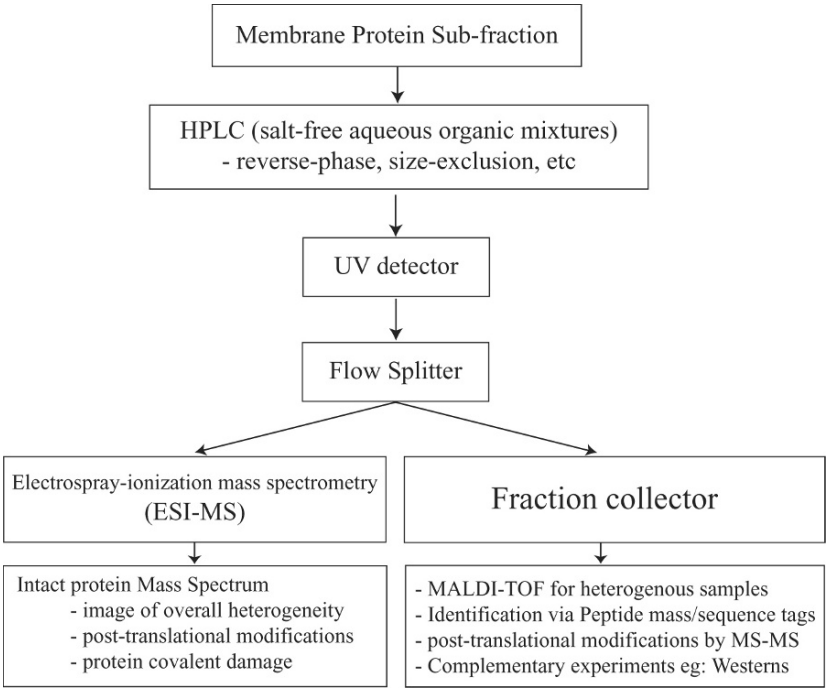

Fig. 2. Liquid chromatography with mass spectrometry and fraction collection (LC-MS+). Use of a flow splitter after the HPLC detector allows concomitant mass spectrometry and fraction collection. Fractions can be analyzed after analysis of intact protein mass spectra to allow increased confidence of identification and characterization of post-translational modifications.

possible to collect fractions concomitant with MS (LC-MS+) which can be used in downstream experiments for protein identification and characterization of post-translational modifications. This approach was applied successfully to the cytochrome b_6f complex from higher plants, identifying a ninth subunit as ferredoxin/$NADP^+$ oxidoreductase (FNR) ***(16)***. Since typical membrane preparations are too complex to fully resolve by a single chromatographic separation, it is suggested that sub-fractions should be employed ***(17)***.

1.4. Solubility and Aggregation of Membrane Proteins

Following extraction from bilayers, membrane proteins have an extreme tendency to aggregate and precipitate unless stabilized in detergent micelles. For HPLC separations in the absence of detergent it is then necessary to find solvent conditions compatible with both solubility and dis-aggregation of the analyte. During attempts to isolate hydrophobic peptides derived from proteolytic cleavage of the photoaffinity-labeled D1 herbicide receptor ***(18)*** it was observed that the labeled peptide of interest would only be *retained* in size-exclusion HPLC using 50% formic acid, 50% methanol as mobile phase. The observation that the peptide eluted in the void when 50% aqueous formic acid or 50% aqueous acetic acid or 50% acetic acid, 50% methanol were used as mobile phase emphasized that both solubility *and* dis-aggregation were necessary for chromatographic separation. While formic acid is a very useful reagent for solubilization/dis-aggregation it should be recognized that at high concentrations it will modify proteins with formyl groups that appear as multiple + 28 Da adducts in the mass spectrum. Consequently, more recent protocols, while using high concentrations of formic acid for initial solubilization, emphasize immediate transfer to more inert solvents.

2. Materials

2.1. Hardware

1. HPLC pumps/plumbing:

The techniques described here use standard HPLC systems, with syringe pump instruments for flow rates less than 200 µL/min. High concentrations of formic acid (60–90%) are rinsed promptly from pumps/syringes but are probably no more corrosive than 1 M NaCl, for example. High-pressure lines use stainless steel tubing and ferrules but lower pressure lines use Peak™ tubing and Fingertight™ fittings (< 2000 psi). Fused-silica capillaries (PolyMicro) are used to interface LC to the ESI source using minimal length connections due to the possibility of chromatography on the inner glass surface. All systems are modified to minimize liquid paths and dead volumes of connections. Absorbance is measured at 214 nm or 280 nm if solvent background is prohibitive at 214 nm (high [formic acid]; chloroform, and so on). Note that some flow cells are sensitive to excessive back-pressure and that it is sometimes necessary to use splitters or wider bore

tubing to avoid expensive accidents. HPLC systems typically need servicing after 2–3 years of moderately heavy use but need no specialized treatment for the methods described. An oven is often used in order to run columns at elevated temperatures.

2. Syringe pumps

HPLC systems with syringe pumps are typically used for LC-MS at lower flow rates. Well-serviced machines provide good performance provided care is taken to ensure buffers/solvents are thoroughly degassed. Pistons and seals are replaced when necessary. Syringes are typically purged empty at the end of the day. Sometimes specific problems can be overcome by appropriate modification. For example, an ABI 120A being used for LC-MS work had a static mixer (a small C18 column) placed before the purge valve that resulted in an over-pressure condition when purging high viscosity solvents such as 60% formic acid/isopropanol. The static mixer column was consequently situated after the purge valve such that it was eliminated from the purge cycle.

3. Columns

For reverse-phase chromatography, polystyrene-divinylbenzene copolymer is preferred over silica-based columns. This media can be regenerated more thoroughly and run at higher temperatures. PLRP/S (Varian Inc.) provides excellent chromatographic performance while PRP (Hamilton) provides an acceptable less-expensive alternative. For size-exclusion chromatography, the SW series of silica supports (Tosoh Biosciences) provides the only suitable media. Several other companies have advertised equivalent performance but tests have shown that only the Tosoh product performs adequately in chloroform/methanol/1% aqueous formic acid (4/4/1). While this solvent exceeds the manufacturers recommended organic percentage limit we experience excellent longevity and the column can be stored in this solvent. Elevated concentrations of formic acid shorten PLRP/S column life significantly. Virgin columns provide ultimate chromatographic resolution and researchers should not expect the extended lifetime achievable when these columns are used for peptides. A cost of around $50 per membrane protein experiment is projected. Guard columns are not used but the column is protected with a post-injector 0.2 μm filter.

4. Grounding and safety

Use of electrospray ionization involves high potential differences between source and mass spectrometer that can be conducted down solvent lines. Thus the HPLC stack must be grounded to the mass spectrometer. Furthermore, source voltage must be removed prior to manipulation of solvent lines to protect the operator. Protective clothing and eyewear must be used when working with pressurized solvents and acids. An extractor at the ESI source is also useful to avoid accumulation of solvent/acid vapors.

2.2. Chemicals

The use of MS with HPLC makes the operator very aware of the quality of solvents and chemicals being used. Remarkable differences in chemical background can be observed with different suppliers. Thus different batches or alternative supplies are tested carefully in the chromatographic systems of interest to ensure low background.

1. Trifluoroacetic acid (TFA) is from Pierce (1 mL sealed ampules of Ionate™ grade).
2. Formic acid is from Fisher (90%, ACS grade) and is not stored for long periods (*see* **Note 1**).
3. Water is double distilled in Quartz or from a Millipore reverse osmosis system (> 18 MegaOhm).
4. Organic solvents are from Fisher; methanol is HPLC grade, acetonitrile is Optima grade and chloroform/isopropanol are ACS grade. Solvents are mixed in glass (try LC-MS with a chloroform containing solvent that was mixed in plastic for your amusement) and degassed briefly by sonication under vacuum. Solvent mixtures containing chloroform or isopropanol are made up daily whereas standard TFA buffers may be kept for at least one week. Aqueous TFA supports microbial life and is usually discarded after two weeks. Note that halogenated solvent waste is generated by nearly all the methods described and should be disposed of properly.

3. Methods

3.1. Sample Purification

There are numerous methods for isolation of membrane fractions, membrane protein complexes and monomeric membrane proteins but these are not the focus of this chapter and are covered by many other authors.

3.2. Sample Preparation

Once a membrane protein fraction has been isolated in a functional state, it is typically accompanied either by native lipids or detergents. Sometimes it may be possible to load a sample in this state and use the chromatography to separate the protein from these contaminants. Often however, small amphiphiles remain associated with and/or coelute with the protein and interfere with chromatography/mass spectrometry. Thus it is usual to precipitate the protein with organic solvents in order to remove contaminating lipids/detergents, or at least deplete them, prior to chromatography. In the case of the chlorophyll-binding proteins of the thylakoid membrane the pigment must be extracted for successful separations, easily achievable by acetone precipitation.

3.2.1. Precipitation with acetone.

Acetone precipitation is achieved at 80% concentration by volume at −20°C. Either add acetone to 80% or add 80% acetone to a small sample volume. Stocks should be at −20°C. Precipitation usually occurs rapidly within 10 min at −20°C

but can take longer. Concentrated samples may work better if aliquoted out whereas dilute samples may be lost. Some lipids will remain associated with precipitated protein. Detergents interfere with acetone precipitation dramatically and should be avoided. If detergents are present, protein should be precipitated at the interface of a chloroform/methanol/water phase separation. Precipitates are recovered by brief centrifugation (10,000 × g; 1 min.).

3.2.2. Precipitation with chloroform/methanol/water phase separation

The protocol, modified from Wessel and Flugge ***(19),*** for this precipitation is shown in **Fig. 3** and represents an important breakthrough in membrane protein chemistry. Precipitation at the interface is usually efficient even in the presence of 2% SDS/ 1% Triton X100™ in the sample. Of course overall yields vary with sample type and amount of detergent. More lipid is removed than with acetone precipitation though some may remain. The most hydrophobic of proteins can partition into the lower phase; these are the proteolipids and can be recovered by size-exclusion chromatography **(Subheading 3.3)** or by precipitation with ether at low temperature.

3.2.3. No Precipitation

Precipitation can be disadvantageous and even lead to covalent modification of the sample. A good example is bacteriorhodopsin, a seven-transmembrane protein that carries a Schiff base linked retinal cofactor that is central to its function as a light-driven proton pump ***(20)*****.** Initial success in analysis of the protein by LC-MS was achieved after precipitation of purple membrane with acetone, solubilization in formic acid/water/isopropanol and LC-MS in the 60% formic acid/isopropanol system **(Subheading 3.2)** though the majority of the protein was recovered as the apoprotein. When the sample, instead of acetone precipitation, was dispersed in detergent (1 mM CHAPS) and acidified with formic acid/isopropanol (three volumes of 1:1) prior to LC-MS, nearly complete recovery of the holoprotein resulted. It is believed that stabilization of the Schiff-base results due to retention of some secondary/tertiary structure ***(4)*****,** despite what seem rather harsh conditions. Addition of four volumes of 90% formic acid is routinely used in today's protocol for "purple membrane." Some bacteriorhodopsin may be captured on the filter used to protect the columns and can be removed with follow up formic acid injections.

3.2.4. Dissolution

Following precipitation with organic solvents, samples are typically dried for about two minutes at room temperature and atmospheric pressure. This is to allow evaporation of excess organic solvents but not water. Thorough drying at this

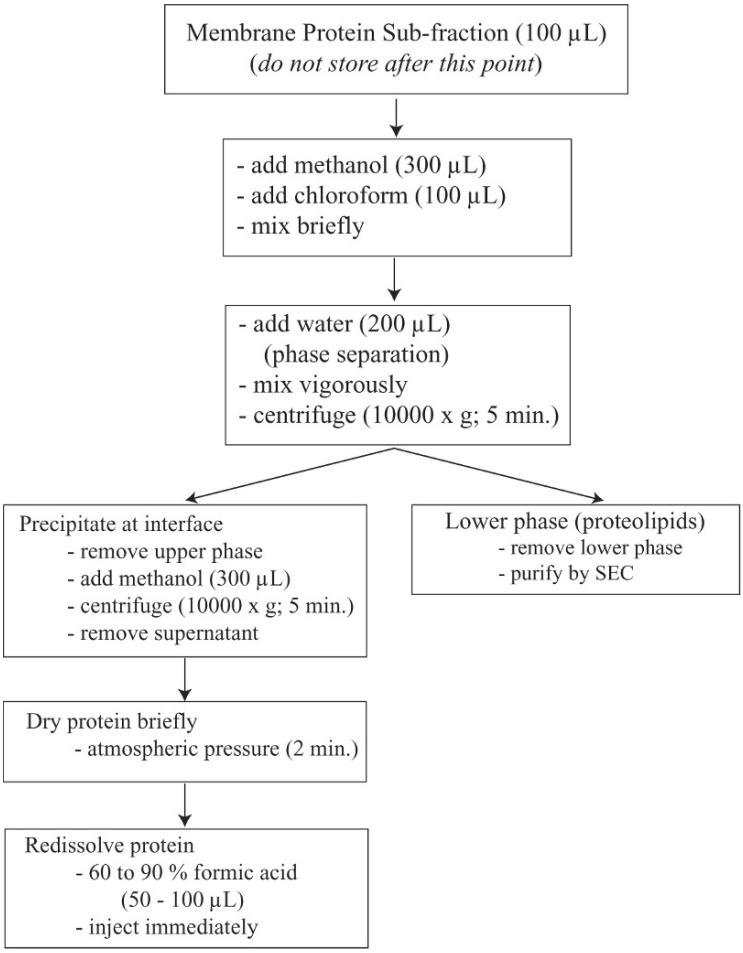

Fig. 3. Chloroform/methanol/water phase separation for precipitation of protein and removal of lipids and detergents. Protein can be precipitated from remarkably high concentrations of detergents. Procedure modified from Wessel and Flugge ***(19)***.

stage results in pellets that are more resistant to redissolution. A small aliquot of solvent (50–100 µL) is added to the "wet" pellet for immediate redissolution and injection to HPLC. The solvent used most frequently is 60% formic acid but 90% formic acid was necessary to dissolve the *E. coli* lactose permease. Acetic acid can often be substituted for formic acid. TFA (50–100%) is also effective for solubilization though there is increased tendency for backbone hydrolysis in this strong acid. Solubility is sometimes influenced by additions of organic solvents, such as isopropanol, trifluoroethanol or hexafluoroisopropanol at this stage though it should be noted that such additions may lead to *decreased* as

well as increased solubility. Conditions for specific samples are best determined empirically. Furthermore solubility is influenced by the precipitation protocol used, which influences degrees of denaturation and delipidation, as well as specifics such as the actual concentration of protein during precipitation. It is suggested that extreme attention to detail is applied to all aspects of the sample preparation protocol with any storage steps minimized especially after removal of lipids/detergents (*see also* **Note 3**).

In cases where samples were not precipitated it is usual to acidify the sample prior to injection, with four volumes of formic acid, for example. If the sample is not acidified it will, in specific cases, remain bound to the column until an aliquot of the appropriate acid is passed down the column. This behavior can be used to advantage for on-column delipidation or detergent removal, for example.

3.3. Reverse-Phase HPLC (RP-HPLC).

The compatibility of the solvent systems used in reverse-phase with LC-MS combined with the often superior chromatographic resolution makes this a frequently used option for HPLC of integral membrane proteins, especially when a mixture is present. Many have described standard reverse-phase chromatographic systems and the first system to be described here is the author's version that includes a polymeric stationary phase and has given satisfactory results for many integral membrane proteins.

3.3.1. TFA/Acetonitrile System

While many intrinsic membrane proteins elute efficiently from a reverse-phase stationary phase with the TFA/acetonitrile system, there are some proteins that have very low elution efficiencies such that little or no protein is observed to elute at all. These are typically the most hydrophobic, such as bacteriorhodopsin. However, it should be appreciated that this behavior provides the opportunity to wash proteins of lipids and detergents on-column and to specifically enrich these molecules on-column, for subsequent elution with secondary gradients of more powerful eluents.

1. Buffer A is 0.1% TFA in water, buffer B is 0.1% TFA in acetonitrile. Buffers are degassed prior to use, typically by sonication and vacuum aspiration (with trap).
2. Column (PLRP/S, Varian Inc.; 300 Å, 5 µm; 2 × 150 mm; 40°C) is equilibrated in 5% B for 10 minutes (100 µL/min).
3. Sample injection (100 µL loop) initiates gradient program. 5% B for 5 minutes followed by a linear gradient from 5–100% B over 60 minutes. System runs at 100% B for 5 minutes and returns to 50% B (syringe pumps) or 5% B (regular pumps) over 5 minutes. Gradient may be adjusted for optimal separations of specific samples.
4. A preliminary run with no injection should show a flat baseline. A second preliminary run with injection of formic acid (100 µL) will then reveal potential ghosts

from previously retained proteins as well as UV absorbing material contaminating the formic acid. Mass spectrometry (ESI-MS) can be used to distinguish ghosts from UV absorbing material of nonprotein origin. If ghosts are detected the column must be regenerated/replaced.

5. Dual wavelength detection at 214 and 280 nm.
6. Column regeneration (*see* **Note 2**).

3.3.2. TFA/Acetonitrile/Isopropanol System

The addition of isopropanol to acetonitrile has been known to improve elution efficiency of many integral membrane proteins in reverse-phase chromatography for many years ***(21)*****,** enabling the purification of rhodopsin, for example. Bacteriorhodopsin elutes quite efficiently allowing fully resolved spectra of many different isoforms of widely varied abundance.

1. As above but buffer B is 0.05% TFA in acetonitrile/isopropanol (1:1 by volume). Buffer B is prepared freshly daily in glass by mixing equal volumes of 0.1% TFA in acetonitrile and isopropanol. Use glass stoppers on HPLC bottles rather than plastic lids that will leach plasticizers.
2. Gradients may be adjusted to focus upon the 50–100% B part of the chromatogram where the most hydrophobic of the integral membrane proteins elute (*see* ***Ref. (23)***).
3. Column regeneration (*see* **Note 2**).

3.3.3. Formic Acid/Isopropanol System

While addition of isopropanol to acetonitrile often improves elution efficiency, there will most usually be some residual intrinsic membrane protein remaining column bound. A solvent system with elevated formic acid concentration in the polar phase and isopropanol as the eluting solvent was originally described for separation of poliovirus proteins with quantitative recovery of material ***(22)*****.** Most intrinsic membrane proteins elute with close to 100% efficiency in the 60% formic acid/isopropanol system described here though exceptions are possible. The major subunit of *Torpedo* Vo ATPase (four transmembrane helices) has reduced elution efficiency and the lactose permease (twelve transmembrane helices) from *E.coli* was not recovered at all under these conditions. In both examples elevation of formic acid concentration to 90% allowed full recovery of the proteins. The major disadvantage of the technique is the potential for protein formylation that results in multiple +28 Da adducts, very apparent in protein ESI mass spectra. Protein exposure to formic acid should be minimized or avoided. Acetic acid may provide a suitable alternative in some cases.

1. Buffer A is 60% formic acid, buffer B is isopropanol. Buffers are degassed prior to use, typically by sonication and vacuum aspiration (with trap).
2. Column (PLRP/S, Polymer Lab.s; 300 Å, 5 µm; 2 × 150 mm; 40°C) is equilibrated in 5% B for 10 minutes (100 µL/min).

3. Sample injection (100 µL loop) initiates gradient program. 5% B for 5 minutes followed by a linear gradient from 5–100% B over 40 minutes. System runs at 100% B for 5 minutes and returns to 50% B (syringe pumps) or 5% B (regular pumps) over 5 minutes. Extended runs should be avoided due to the potential for sample formylation.
4. Detection is at 280 nm.
5. Column regeneration (*see* **Note 2**).

Size-Exclusion Cromatography (HPLC-SEC)

While the 47 kDa *E.coli* lactose permease could be eluted in reverse-phase by increasing the formic acid concentration to 90%, the resulting mass spectrum showed multiple formylation adducts resulting in over estimate of mass by 100–150 Da. Thus an alternative chromatographic separation was sought that would permit separation of the purified permease from residual detergent/lipid and the multitude of small molecules contaminating 90% formic acid. John E. Walker had previously reported success with ESI of mitochondrial inner membrane proteins using a solvent system containing chloroform/methanol/1% aqueous formic acid (4/4/1, v/v) ***(13)*** though separations were performed off-line prior to ESI-MS. Based upon previous success in size-exclusion HPLC with Tosoh silica SW media using formic acid/methanol (1/1, v/v) ***(18)***, the Walker solvent system was substituted. The precipitated permease was dissolved in 90% formic acid and immediately injected onto a SEC LC-MS system using an SW2000 column equilibrated in the 4/4/1 solvent mixture. Rather than precipitating as expected, the protein was quickly transferred to the running solvent. Small molecule contaminants were retained and the permease eluted before them, close to the void, allowing spectra to be recorded with excellent signal/noise ratio ***(5)***. The SEC-MS system described has proved robust allowing general success with a variety of membrane and other proteins ***(6, 7)***. The main limitation of the technique is the lack of chromatographic resolution afforded by SEC such that samples must be quite highly purified. The thylakoid cytochrome b_6f complex provided a good example of the complexity of the mixture that could be resolved. Five larger subunits coeluted but could be recognized in the rather complex mass spectrum since small subunits and small molecule contaminants were more highly retained and thus eliminated from the spectrum ***(16, 23)***. A typical elution profile is shown in **Fig. 4**. Protein elutes first followed by smaller UV absorbing molecules (**Fig. 4A**). The total ion chromatogram is a read-out of total mass spectrometer signal with time and shows the separation of the protein (concomitant with A_{280}) from other small molecules that give strong signals during mass spectrometry and would spoil the protein mass spectrum unless removed.

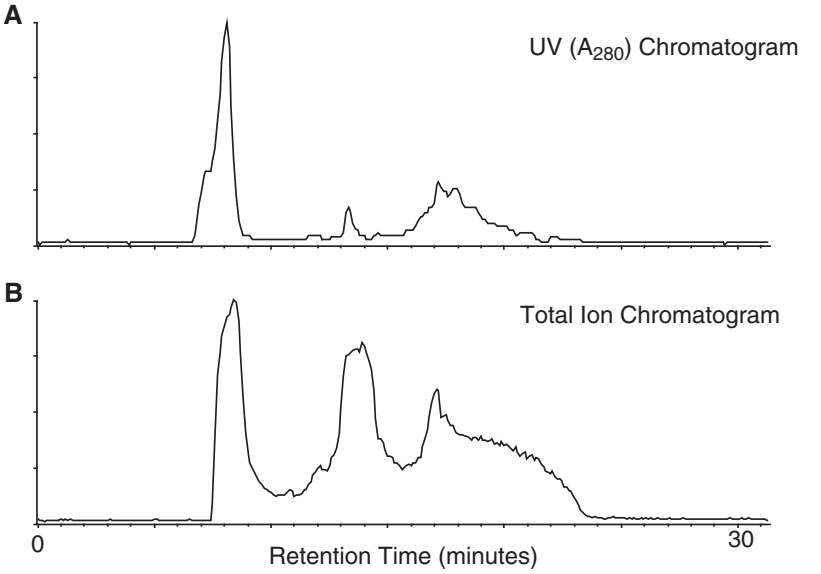

Fig. 4. Elution profile during size-exclusion liquid chromatography mass spectrometry (LC-MS). A protein sample (100 µg KcsA in 25 µL; a kind gift of Chris Miller, Brandeis University) was acidified (75 µL 90% formic acid) and subjected to size-exclusion chromatography mass spectrometry on Super SW2000 (Tosohaas; 4.6 × 300 mm) equilibrated in chloroform/methanol/1% aqueous formic acid (4/4/1; v/v) at a flow rate of 250 µL/min and 40°C. The absorbance profile at 280 nm **(A)** is compared to the total ion chromatogram **(B)**. The total ion chromatogram is generated by summing the total signal in one scan of the mass spectrometer (6 s) and plotting against time. Note the appearance of strong mass spectrometric response concomitant with the first UV peak as the protein elutes. The forward shoulder on the UV profile is probably a result of some protein running in an aggregated or oligomeric state and thus eluting in the void. The protein is clearly separated from other molecules that absorb UV light and exhibit strong response in mass spectrometry, with retention times greater than 10 min.

1. Buffer is chloroform/methanol/1% formic acid in water (4:4:1; by volume) and degassed as above. The solvent is prepared freshly each day and mixed/stored in glass containers.
2. Column (Tosoh Biosciences, Super SW2000, 4.6 × 300 mm; 40°C) is equilibrated for several column volumes (250 µL/min) until ESI-MS reveals drop in chemical background to very low levels. Note that the columns ship in sulfate/phosphate containing buffers which must be thoroughly washed away with water prior to transfer of the column first to 80% methanol and then the final solvent.
3. Sample is introduced with a 100 µL loop initiating the run which is complete within 35 min unless large amounts of small molecules such as detergents have been

introduced. Complete removal of excessive SDS or salt contamination can take days of washing.
4. Columns may be connected in series for improved chromatographic resolution.
5. Detection is at 280 nm.
6. Column regeneration (*see* **Note 2**).

3.4. UV Detection with Mass Spectrometry

The availability of mass spectrometers able to tolerate a continuous flow of liquid to the source enabled the advent of liquid chromatography mass spectrometry (LC-MS) ***(3)***. Not only has this development revolutionized biological mass spectrometry but also HPLC. The eluent from the HPLC UV detector is directed to the electrospray ionization source of the mass spectrometer that thus becomes an on-line detector **(Fig. 1)**. The combination of UV and mass spectral data provides vastly improved detection because proteins are not only visualized by their general UV profile but also their unique mass spectral profile including covalent heterogeneity. Many protein modifications can change retention properties and thus mass spectral information becomes essential for interpreting data. An excellent illustration of this point is provided by a study that used changes in retention time to conclude that formic acid treatment leads to reduction of disulfide bonds within insulin and other proteins. When insulin was treated with formic acid there were changes in retention time to values similar to the individual α and β subunits. However, repetition of these experiments using LC-MS revealed formylation of the intact insulin molecule with corresponding changes of retention time (Tjon, Stevens, Faull and Whitelegge, unpublished data). Reliance upon retention time alone had led to complete misinterpretation of the data. Though listed as a strong reducing agent by the Merck index, we have found no evidence of disulfide reduction by formic acid in several different proteins.

Many are tempted to collect fractions and perform mass spectrometry later. While such an approach may be tolerated where necessary, many benefits of LC-MS are lost. Perhaps the most significant of these is the very low chemical noise that a well set up LC-MS system provides though loss of material due to adsorption, loss of solubility and covalent modification can all contribute to dilution of benefits.

3.5. Sample Recovery and Tertiary Structure

If it is necessary to collect fractions for further experiments, the benefits of LC-MS can be retained through the use of a splitter as described (LC-MS+; **Subheading 1.3**). If yield must be maximized then the whole sample can be collected at the expense of mass spectrometric detection. For structural measurements samples can be dried onto Germanium chips for attenuated total reflectance

Fourier transform infrared (ATR-FTIR) spectroscopy; both bacteriorhodopsin dried down from the 60% formic acid/isopropanol system (Whitelegge and Waring, unpublished) as well as the lactose permease dried down from the chloroform/methanol/1% aqueous formic acid system (Whitelegge, le Coutre and Kaback, unpublished) showed FTIR spectra indicative of substantial α-helix, supporting the possibility of retention of structure in these solvents.

3.6. The Future

While the techniques/protocols above provide a sound starting point for quite highly purified preparations there is a great need for techniques that provide superior resolution in separations of all intrinsic membrane proteins and especially crude mixtures. There are a wealth of different surface chemistries and solvent mixtures available for HPLC and LC-MS providing a huge practical area for further exploration. A recent paper from J.E. Walker's group highlights the considerable progress that has been made in the analysis of intact mitochondrial membrane proteins and includes a novel hydrophilic interaction chromatography (HILIC) protocol that will be interesting to explore in other membrane systems ***(24)***. There will be a dramatic expansion in top-down mass spectrometry (intact proteins are fragmented in the mass spectrometer) in the next few years and the techniques discussed herein are all compatible with this process – early results suggest great promise for the study of integral membrane proteins **(23–25)**.

4. Notes

1. Formic Acid.Considerable attention should be paid to formic acid stocks used for protein chemistry. The reagent should be clear and colorless as supplied. Aging in the laboratory leads to a yellowish/brown appearance than can become intense after prolonged storage. Unfortunately, formic acid is typically shipped in plastic bottles that leach plasticizers readily. UV 280 absorbing contaminants as well as molecules that ionize readily during ESI accumulate steadily with storage, contributing to chemical background. While chromatographic separations can be relied upon for separation of such contaminants from molecules of interest, it is preferable to replace stocks regularly and to test each new stock in case it sat in a warehouse for some months before delivery. Different sources of formic acid show varying potentials for protein formylation and the relationship between this activity and contaminants is not clear. Despite these drawbacks, formic acid is never-the-less most useful for membrane protein chemistry.
2. Column Regeneration. Reverse-phase columns were originally regenerated by running gradients of formic acid/isopropanol (A: 90% formic acid, as supplied by Fisher, undiluted; B: isopropanol) from 5% B to 100% B

with prolonged washing for 1 h at 100% B. While effective for regenerating the columns, this protocol shortens the life of polymeric columns substantially. Now reverse-phase columns are equilibrated first in 80% methanol and then chloroform/methanol/1% aqueous formic acid (4/4/1). Aliquots of undiluted formic acid are injected in a repetitive fashion until LC-MS shows that such injections give no further release of protein. For regeneration of the silica Tosohaas SEC columns, the same latter protocol is used. If protein contamination is particularly tenacious with substantial elution of protein even after say five formic acid injections, the column can be regenerated with 90% formic acid/[chloroform/methanol/water; 4/4/1] (8:1, v/v) for one column volume, though this wash is avoided accept where absolutely necessary.

3. Pressure-Assisted Solubilization. During analysis of samples of bovine rod outer-segment membranes, highly enriched in the G-protein coupled receptor rhodopsin, it was common to observe a dramatic increase in system pressure upon injection of sample. Typically 2000–2500 psi could be reached before a sudden return of the system to standard operating pressure occurred. While we have not investigated this phenomenon further, a reasonable explanation is that elevated pressure played a role in transferring the rhodopsin protein to the soluble/retained phase prior to successful elution in the gradient.

Acknowledgements

The techniques described here are evolved from huge amounts of groundwork by many others, especially Gobind Khorana and John Findlay. My career in HPLC and mass spectrometry would not have been possible without the generous mentorship of Kym Faull and my colleagues at UCLA. I have learnt hugely from my peers and I acknowledge invaluable contributions from Sir John E. Walker, Ian Fearnley, H. Ron Kaback, and Bill Cramer amongst many others to whom I apologize for not mentioning. I specifically thank John R. Bowyer and Patrick Camilleri who understood and shared my interest in techniques compatible with mass spectrometry and Chris Gerrish for his skillful help with HPLCs.

Enrichment of Serum Peptides and Analysis by MALDI-TOF Mass Spectrometry

Yanming An, Habtom W. Ressom, and Radoslav Goldman

1. Introduction

Serum and plasma are readily available patient samples frequently utilized in measurement of disease markers ***(1)***. The presence of peptides in serum and plasma reflecting various disease processes was demonstrated in several recent studies ***(2–9)***. The combination of improved mass spectrometric and sample preparation methods allows gradual improvement in peptidomic marker discovery. The various solutions to marker discovery search for an ideal compromise in throughput required to compare a sufficient number of patient samples and in resolution allowing quantification of low abundant analytes. A comprehensive quantitative comparison of low abundant peptides expected to exist in connection with disease processes continues to present a significant challenge ***(10–11)***. In this chapter, we describe a method for concentration and desalting of serum peptides on magnetic beads that reduces signal suppression in subsequent MALDI-TOF mass spectrometric quantification of the low mass analytes. Further removal of high abundant serum proteins by denaturing ultrafiltration narrows the dynamic range of the complex mixture ***(12)***. The magnetic beads are coated with functional groups such as reverse phase C8, commonly used in liquid chromatographic columns. Recovery of peptides from magnetic beads can be automated to allow a reproducible processing of a relatively large number of patient samples. The resulting micro volumes of purified peptides are conveniently analyzed by MALDI-TOF/TOF or other proteomic strategies.

2. Materials

2.1. Blood Sample Collection and Serum Preparation

1. Vacutainer serum tubes (BD 366430) (Becton Dickenson, Franklin Lakes, NJ)
2. Vacutainer Safety-Lok blood collection set (BD 367281)
3. Vacutainer holder (BD 364815)
4. NUNC cryotubes (Nalge Nunc International, Rochester, NY, Cat. No. 377267)

2.2. Capture of Peptides on Magnetic Beads

1. Purification Kit 1000 MB HIC 8 (Bruker Daltonics, Part No. 223324)

The kit includes Binding Solution, Washing Solution, magnetic beads C8, and water.

2. Trifluoroacetic acid (TFA) (Sigma-Aldrich) (Highly corrosive)
3. Acetonitrile CHROMASOLV Plus, for HPLC ≥99.9% (Sigma-Aldrich) (Highly flammable and harmful)
4. 0.2 mL low profile thin-walled 8-tube & flat cap strips (ABgene Cat. No. AB-0773)
5. Radio-Immuno-Assay tube (Sarstedt Aktiengesellschaft & Co. Germany, D-51588)
6. The Magtration SX-8G sample processing robot (Precision System Sciences USA, Inc., Livermore, CA) (*see* **Note 1**)
7. DN 70 pipette tip with filter (Precision System Sciences USA, Cat. No. F4403)
8. MagnetSeparator 104 II (Bruker Daltonics, Part No. 207151)
9. Serum samples (see blood collection)

2.3. Ultrafiltration

1. Microcon ultrafiltration units with MWCO 30 kDa (Millipore, MA)
2. Water CHROMASOLV Plus, for HPLC (Sigma-Aldrich)

2.4. MALDI Mass Spectrometry

1. α-Cyano-4-hydroxy-cinnamic acid (CHCA), 3.3 mg/ml (Bruker Daltonics) (*see* **Note 2**)
2. MTP AnchorChip ™600/384 T F (Bruker Daltonics, Part No. 209513)
3. Peptide calibration standard (Bruker Daltonics, Part No. 206195) (Store at −20°C)
4. Sample buffer: 5% acetonitrile with 0.1% TFA (47.5 ml water, 2.5 ml acetonitrile and 50 µL TFA)

3. Method

3.1. Blood Samples Collection and Serum Preparation

1. Blood samples collected in a BD Vacutainer "red-top" tube according to a standard manufacturer's protocol are allowed to clot for 60 min (*see* **Note 3**).
2. Serum is separated by centrifugation at 1,200 g for 10 min and aliquoted as soon as possible in a convenient volume for freezing at −80°C in NUNC Cryotubes (*see* **Note 4**).
3. At first thaw, serum is sub-aliquoted at 50 µL to store at −80°C until processing. All samples are processed at second thaw (*see* **Note 5**).
4. Thawing of serum aliquot is achieved by submersion in room temperature water bath; samples are processed as soon as possible after thawing.

5. Particulates from serum are removed by a spin in a tabletop centrifuge at ~10,000 g for 10–15 s.

3.2. Robotic Protocol

We describe a protocol using an SX-8G laboratory automation system dedicated to the handling of magnetic beads (Precision System Sciences USA, Inc., Livermore, CA). The SX-8G robot uses an 8-channel Magtration ® pipetting unit for separation of magnetic beads from sample volumes of 5 to 200 µL. We describe a program for a simultaneous handling of 8 samples (*see* **Note 6**).

3.2.1. Robot Preparation (Fig. 1)

1. Load the following materials and reagents in the appropriate positions on the robot
   - Five 8-tube thermo-strips on the PCR plate (row 1–5, each sample/tube, 5 tubes/run).
   - Pipette tips on the tip racks.
   - Small radioimmunoassay tubes into small reagent reservoir (S1 & S0). Add 15 µL acetonitrile to each tube on S1 and 16 µL magnetic beads to each tube on S0 (*see* **Note 7**).
   - Add water to the large reagent reservoir for tip wash.
   - Add Wash Solution into medium reagent reservoir 1.
   - Add Binding Solution into medium reagent reservoir 2.
   - Add water into medium reagent reservoir 3.
   - Attach a used pipette tip bag to the tip discard.
2. Load 15 µL serum into a thermo-strip tube in row 1 (8 serum samples/strip).
3. Turn on the robot and computer, load the robot software, and initiate the program.

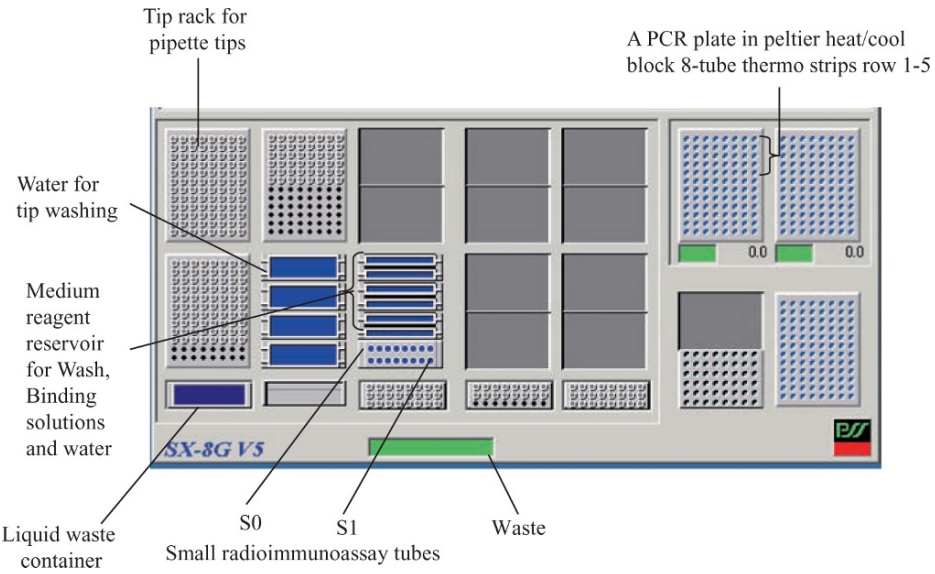

Fig. 1. Schematic of the robot.

3.2.2. Automated Steps

1. Robot picks up 10 µl water and transfers to tubes in Row 2.
2. Robot picks up 10 µl acetonitrile from tubes in S1 and transfers to the same tubes in Row 2 to generate 50% aqueous acetonitrile; the solvent is mixed three times by pipetting up and down.
3. Tips are rinsed once with water.
4. Robot picks up 200 µl Wash Solution and distributes 100ul each into tubes in Row 3 and Row 4 (*see* **Subheading 2.2**) **(***see* **Note 8)**.
5. Robot picks up 100ul Wash Solution and dispenses into tubes in Row 5.
6. Tips are rinsed once in water.
7. Robot picks up 35ul binding solution and mixes thoroughly with sera in Row 1.
8. The tips are changed.
9. Robot picks up 15 µL beads from each tube on S0 and mixes thoroughly with diluted serum; the sample is incubated for 2 min at room temperature (*see* **Note 9**).
10. Beads are captured by the magnet and the supernatant is discarded.
11. Beads are taken to the 8-tube thermo strip on Row 3–5 and washed in wash solution; beads are captured by the magnet and the supernatant is discarded.
12. Proteins/peptides are eluted from the beads at tubes in Row 2 with 20ul of 50% acetonitrile/water.
13. Beads are captured and discarded.
14. Take the strip out of the robot, place a cover on it, and spin briefly in a tabletop centrifuge.
15. Remove stray beads manually with the MagnetSeparator if needed.
16. Transfer eluates into Microcon filters for ultrafiltration.

3.3. Ultrafiltration

1. Pipette 150 µL of water into each assembled 30kDa filter (*see* **Note 10**).
2. Wash filter 5 min at 10,000 g and 10°C in a refrigerated centrifuge; repeat 3 times for a total of four washes.
3. Pipette 20 µL of dH_2O to the washed Microcon filters.
4. Add 20 µL MB eluate to the washed Microcon filters (final concentration 25% acetonitrile).
5. Spin for 10 min at 10,000 g and 10°C in a centrifuge (*see* **Note 11**).
6. Concentrate ultrafiltrate to dryness in a vacuum evaporator (*see* **Note 12**).

3.4. Manual Protocol

1. Add 15 µL of magnetic beads to each tube of the 8-tube thermo strip (*see* **Note 7**).
2. Add 35 µL Binding Solution and 15 uL serum to each tube; pipette up and down for 2 min.
3. Place thermo-strip on a MagnetSeparator; incubate for 1 min to capture the beads.
4. Aspirate supernatant and discard; peptides are bound to the beads.
5. Wash with 100 µL of Wash Solution (transfer strip on the magnet at least 6 times) and discard supernatant.

6. Repeat 2 more times for a total of three washes.
7. Elute peptides from beads using 20 µL of 50% Acetonitrile; incubate for 2 min (*see* **Note 13**).
8. Capture the beads on the magnet and place supernatant into Microcon filter tubes for ultrafiltration.

3.5. MS and Data Analysis

1. Resuspend peptides in 2 µL sample buffer (0.1%TFA/5% acetonitrile/water) (*see* **Note 14**).
2. Spot 2 µL sample on an Anchorchip® target and allow to dry partially (See Note 15).
3. Mix partially dried sample with 1 µL of matrix solution on the target plate and allow to dry completely (*see* **Note 16**).
4. Spot 1 µL of peptide calibration standard and mix on the target with 1 µL matrix then dry completely.
5. Analyze the plate using an Ultraflex MALDI TOF/TOF mass spectrometer (Bruker Daltonics) equipped with pulsed ion extraction ion source. Ionization is achieved by irradiation with nitrogen laser (λ = 337 nm) operating at 20 Hz. Ions are accelerated at +19 kV with an 80 ns of pulsed ion extraction delay. Each spectrum is detected in linear positive mode at m/z 800–10,000 and is externally calibrated using the Peptide calibration standards (Bruker Daltonics) (*see* **Notes 17** and **18**).
6. Mass spectra are exported using the Flex Analysis software (Bruker Daltonics); raw data are converted to text files for further analysis.
7. Data analysis is carried out as described in the following chapter.
8. **Fig. 2** shows the mass spectrum of a serum sample analyzed using the protocol described above.

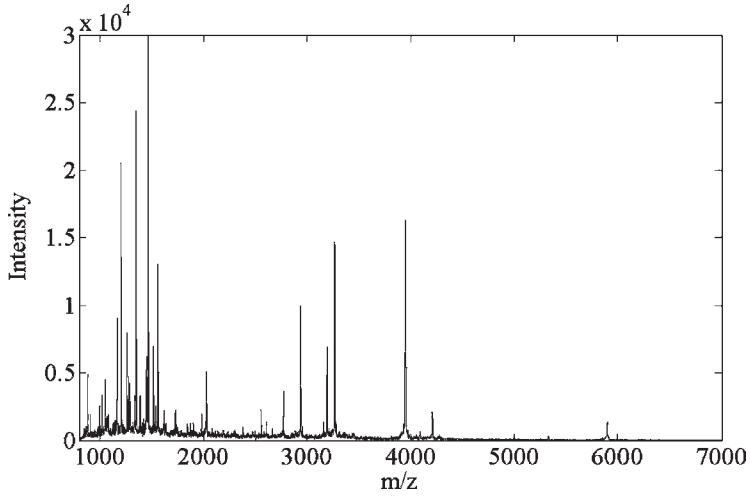

Fig. 2. MALDI-TOF mass spectrum of the C8 magnetic bead-ultrafiltration enriched serum.

4. Notes

1. Manual processing is possible with a skilled technician handling approximately 30 samples in a day. The amount of pipetting at this scale is substantial and difficult to maintain reproducibly over time. The manual handling is described in **Subheading 3.4.**
2. Dissolve CHCA at 5 mg/ml in 50% acetonitrile, aliquot 1mg/vial (0.2 ml), vacuum dry and desiccate at −20°C. For experiments, dissolve fresh in 50% acetonitrile (0.15 ml of water and 0.15 ml of acetonitrile) at a final concentration of 3.3 mg/ml. Protect matrix from exposure to daylight at all times.
3. Control time of clotting as closely as possible. Differences in clotting time may affect results. Follow SOP for hazardous biological materials.
4. Be careful not to disturb the interface between serum and red blood cell clot when aspirating serum. If the interface is disturbed, repeat the centrifugation step.
5. A. We use aliquots of approximately 1 ml further divided at first thaw into 50 µl subaliquots.
   B: It is advisable to keep track of the time from collection to centrifugation and of any lag between centrifugation and freezing.
   C: Avoid multiple freeze-thaw cycles. Freeze-thaw cycles of serum samples can cause degradation of peptides and consequently changes in the mass spectra.
6. Other convenient automation system can be used. Manual processing flow can be also used as described in **Subheading 3.4.**
7. Shake magnetic beads thoroughly to form a homogeneous suspension before transfer to the tubes. Beads are stable for several hours after shaking.
8. The Dynabeads RPC 18 (Invitrogen) can be used as an alternative. The Dynabeads are supplied in 20% ethanol. Make sure to recondition beads in 0.1% TFA before applying samples. 0.1% TFA in water can be used for wash solution, and for binding solution.
9. Pipette gently to avoid making air bubbles.
10. Be careful not to touch the membrane with the tip!!
11. Samples can spin at 4°C but we observe an occasional freezing of the sample at this temperature which could damage the filter membrane.
12. Dried peptides may be stored for several weeks desiccated at −80°C.
13. Disrupt the beads with the tip and pipette up and down, but try to avoid formation of bubbles.
14. Pipette at least 1 min up and down and swirl around the bottom to dissolve the samples well.

15. The plate surface can be slightly touched with the tip but wear gloves to handle the plate. Wait until the spot shrinks to approximately 25% of its original size (about 10 min), but do not dry the spot completely.
16. The spot is dry when yellowish (from the side) and not shiny (from the top). If continuously shiny, add 0.5 µL of matrix. The spot can also be dried in vacuum.
17. For identification of the peptides of interest by sequencing, the reflector mode of the MALDI-TOF-TOF instrument is used.
18. The C8 enriched peptides can be analyzed on other MALDI-TOF instruments such as ABI 4800 Mass Analyzer (Applied Biosystems, Foster City, CA). The 4800 MALDI TOF/TOF TM Analyzer is used in positive ion mode in both reflector and MSMS acquisitions with laser repetition rate at 200 Hz. In MSMS mode, 2 kV collision energy (with CID gas on) is used to fragment the peptides.

Computational Methods for Analysis of MALDI-TOF Spectra to Discover Peptide Serum Biomarkers

Habtom W. Ressom, Rency S. Varghese, and Radoslav Goldman

1. Introduction

The characterization of peptides in serum and plasma by mass spectrometry (MS) is one of the promising strategies for biomarker discovery ***(1,2).*** In addition to careful experimental design, improved mass spectrometric technology and sample preparation methods, innovative computational methods are needed to facilitate data interpretation and extract useful information from high-dimensional MS data. In this chapter, we describe computational methods for analysis of raw mass spectra generated by MALDI-TOF/TOF instrument (Bruker Daltonics, Billerica, MA) and exported as text files by the Flex Analysis software. We bin the text files using 'Protein Group Report Generator 1.6', which is a Visual Basic 6 application, and import the binned data into MATLAB, where we apply spectral preprocessing methods as well as statistical and machine learning methods to extract candidate peptide biomarkers.

The purpose of data preprocessing is to correct intensity and m/z values in order to: (1) reduce noise, (2) reduce amount of data, and (3) make the spectra comparable to each other. For example, binning reduces the dimension of a spectrum by grouping intensity measurements at adjacent m/z values into bins. Its aim is to preserve raw data information while performing a dimensional reduction for subsequent processing and mining phases. Smoothing is a process by which data points are averaged with their neighbors as in a time-series of data. Its main aim is to reduce noise, i.e., to increase signal to noise ratio. Baseline correction flattens the base profile of a spectrum to minimize the impact of varying baseline caused by the chemical noise in the matrix or by ion overloading; drifting baseline introduces serious distortion of ion intensities

without adequate correction. Normalization reduces systematic variation that may be caused by varying amounts of protein, sample degradation over time, or variation in the sensitivity of the MS ion detector. Normalization enables the comparison of different samples since the absolute peaks of different spectra could be incomparable. Peak detection deals with the identification of peaks that display a reasonable intensity compared to those that may be just noise. Hence, the main task of peak detection is separating real peaks (e.g. corresponding to peptides) from peaks representing noise. Although this task can be done visually by mass spectrometry experts, algorithms that do not require human intervention are needed for rapid and repeatable quantitative processing of spectra that often contain hundreds of discrete peaks. The simple peak finding (SPF) provides the locations of all local maximum peaks and their associated left-hand and right-hand bases ***(3)***. Peak calibration allows correction of drifts that do not reflect any real sample variation. Without peak calibration, the same peak (e.g. the same peptide) can have different m/z values across samples. To allow an easy and effective comparison of different spectra, peak alignment methods find a common set of peak locations (i.e. m/z values) in a set of spectra, in such a way that all spectra have common m/z values for the same biological entities. For example, dynamic programming can be used to align peaks across spectra ***(4)***. However, this approach and other peak detection tools such as Proteome Quest (Correlogics Systems, Bethesda, MD) deal with exact mass points (single peak). Hence, they do not address the existence of isotopes representing the same peptide, where the same peptide could have multiple peaks. It is important to take into consideration that each detected m/z value is affected by noise and isotopes causing the presence of a window in which the m/z ratio can be shifted. A window is defined here to indicate the range of potential m/z shifting for each peak location ***(5)***. To automate the creation of windows, neighboring peaks are coalesced, if they fall within a pre-specified mass separation ***(3)***. A mass separation cutoff is determined based on the instrument's tolerance.

Finally, peaks that best discriminate the subjects within a subgroup are selected via a feature selection algorithm. In mass spectral data analysis, the peak dimensionality is usually larger than or comparable to the sample size. This makes many standard pattern classification algorithms fail to address the high risk of overfitting. Thus, there is an algorithmic need for peak selection in addition to the biological need of discovering a manageable set of key disease biomarkers ***(6)***. A commonly used approach in peak selection is to apply statistical analyses such as t-test and weighting factor, employed in the weighted voting algorithm ***(7)*** that recognize differentially abundant peaks between two groups with multiple subjects. These peaks are then used as inputs to a pattern classification algorithm such as support vector machine (SVM). This approach has the following limitations: (a) it selects peaks based on "relevance criterion", not on the basis of their "usefulness" (i.e.,

prediction capability); (b) redundant peaks can exist; and (c) peaks that have strong discriminant power jointly, but are weak individually are ignored. The SVM recursive feature elimination (SVM-RFE) algorithm recursively classifies samples with SVM and select features according to their SVM weights ***(8).*** Benefiting from the good performance of SVMs in high dimensional gene-expression data, SVM-RFE is often considered as one of the best feature selection algorithms in the literature. SVM-RFE ranks the features once using all samples, and uses the top ranked features in the subsequent cross-validation. This will generate a biased estimation of errors and limits the search space by allowing only the top ranked features as candidate features. The goal is to search for a manageable combination of useful features from the entire set of peaks. However, due to the large number of peaks, a systematic method is required to select the best combination of peaks without examining all possible combinations. Stochastic global optimization methods such as genetic algorithms (GAs), simulated annealing, and swarm intelligence (SI) methods are ideal candidates for selecting features from a high-dimensional search space. The recent release of ClinProTools™ uses GAs to determine features for SVM classifiers. In this chapter, we provide codes that can be used to select the optimal peak set by combining SVM with a special type of SI method, ant colony optimization (ACO). ACO allows the integration of features selected on the basis of both "relevance" and "usefulness" criteria ***(9)***.

This chapter is organized as follows: Section 2 lists the software tools needed for MALDI-TOF MS data analysis including codes written by the authors of this chapter. Section 3 highlights the methodologies for spectral preprocessing and peak selection. Also, this section outlines the procedure to run the codes, in which the methodologies are implemented. Finally, **Subheading 4** provides additional notes and alternative procedures.

2. Materials

2.1. FlexAnalysis Software

FlexAnalysis software is provided by Bruker Daltonics (Billerica, MA). Raw mass spectra generated by MALDI-TOF/TOF instrument can be viewed and saved using this software.

2.2. Binning Software Tool

1. Protein Group Report Generator 1.6 (PGRG) (http://microarray.georgetown.edu/files/msdat.zip)
2. VB6 Run-time and VB6 Service Pack available at Microsoft website.

2.3. MATLAB Tools

1. MATLAB software (Windows version)
2. MATLAB Bioinformatics Toolbox

3. MATLAB Statistics Toolbox
4. OSU SVM Toolbox for MATLAB (http://sourceforge.net/projects/svm/)
5. MATLAB codes (http://microarray.georgetown.edu/files/msdat.zip). These codes include m-files the authors of this manuscript wrote and additional m-files from The Cromwell Package (http://bioinformatics.mdanderson.org/cromwell.html) and SVM-RFE files from (http://www.bo.infn.it/ masotti/software.html)

3. Methods

Figure 1 illustrates our methodology for peak selection. The spectra in the labeled set are used for peak selection. The resulting peaks and the associated SVM classifier is used to predict the disease state of the spectra in the blinded set. Spectral preprocessing (i.e., binning, baseline correction, normalization, peak detection, and peak calibration) and peak selection are performed on the labeled set by subjecting the entire process to cross-validation.

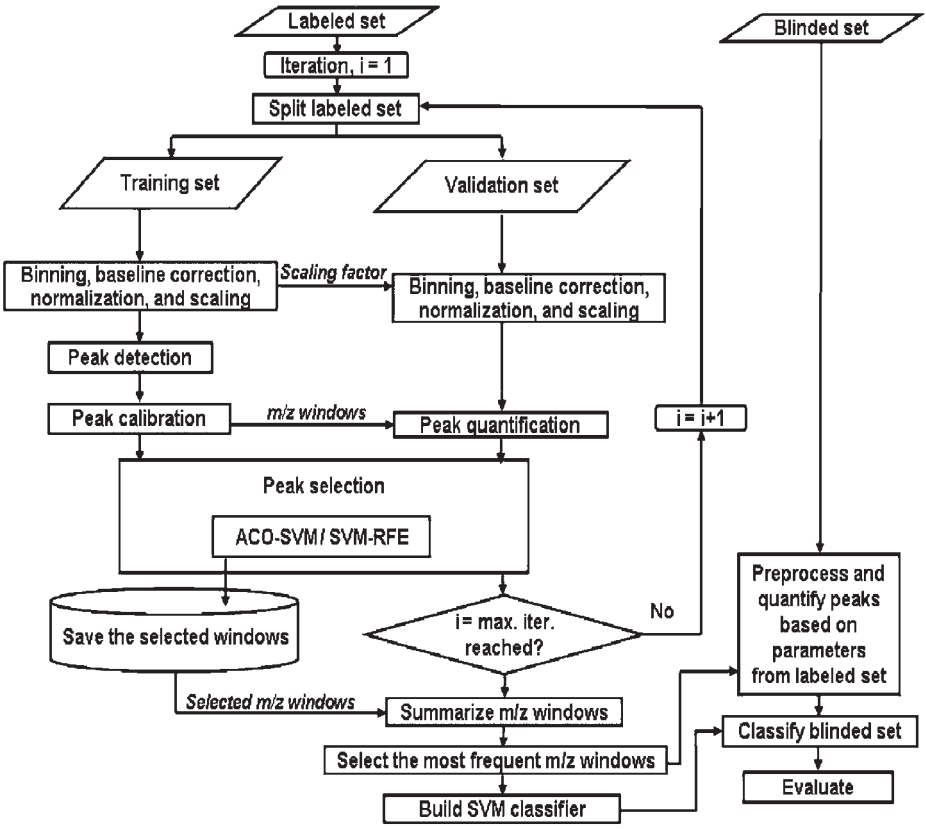

Fig. 1. Methodology for peak detection.

As illustrated in **Fig. 1,** the spectra in the labeled set are split into training and validation sets. The performance of the peaks selected from the training spectra are evaluated via validation spectra to guide the search for the optimal peak set. In the following, we describe briefly the specific methodologies we implemented for spectral preprocessing and peak selection.

3.1. Spectral Preprocessing

Binning reduces the dimension of a spectrum by grouping intensity measurements at adjacent m/z values into bins. Its aim is to preserve raw data information while performing a dimensional reduction for subsequent processing and mining phases

We estimate the baseline of a binned spectrum by obtaining the minimum value within a shifting window size of 50 bins and a step size of 50 bins of each spectrum. Spline approximation is applied to regress the varying baseline. The regressed baseline is smoothed using the lowess smoothing method. The resulting baseline is subtracted from the spectrum.

Each spectrum is normalized by dividing by its total ion current. After scaling the peak intensities of the normalized training spectra to an overall maximum intensity of 100, local maximum peaks above a specified threshold are identified and peaks that fall within a prespecified mass separation are coalesced into a single m/z window to account for drift in m/z location and to represent isotopic clusters by a single peak. The maximum intensity in each window is used as the variable of interest.

3.2. Peak Selection

We apply the hybrid ACO-SVM algorithm to search for a peak set that consists of a pre-specified number of peaks. ACO-SVM selects a peak set on the basis of its ability to distinguish the case and control spectra in the validation set. Note that the spectra in the validation set are not involved in the spectral preprocessing. They are binned, baseline corrected, normalized, and scaled on the basis of the parameter used to preprocess the spectra in the training set. These parameters include scaling factor that standardizes the peaks in the training set to have a maximum of 100. The peaks in the validation set are quantified at the selected m/z windows and are presented to SVM classifier previously trained using the peaks from the training set. The performance of the SVM classifier in predicting the disease state of the subjects in the validation set is used by ACO-SVM to guide its search for the optimal peak set.

Alternatively, the user can choose the SVM-RFE algorithm, which uses the labeled set to determine the most useful set of peaks.

The above steps (spectral preprocessing and peak selection) are repeated multiple times by randomly splitting the labeled spectra into training and

validation sets with resubstitution. The peaks selected in multiple iterations (I = 1,2,…) are summarized by merging overlapping m/z windows to determine the most frequently selected m/z windows. Note that the number of peaks detected and the size of the m/z windows could vary due to the change in the population set at each iteration.

To evaluate the peak selection process, we quantify the peak intensities at the m/z windows of the final peak set in both the labeled and blinded sets. Note that the blinded set is not used during the entire peak selection process, thus it serves as an independent set to evaluate the generalization capability of the selected peaks. Alternatively, if the disease state of the spectra in the blinded set is unknown, an SVM classifier built via the labeled set will be used for prediction. The spectra in the blinded set are binned, baseline corrected, normalized, and scaled on the basis of parameters used to preprocess the spectra in the labeled set.

3.3. Procedure

1. Place the provided *PGRG.exe* in any directory and create the following folders: "INPUT_GRP1", "INPUT_GRP2", and "OUTPUT"
2. Place input files (i.e., .TXT files from FlexAnalysis software) into either INPUT_GRP1 or INPUT_GRP2. Alternatively, split the TXT files into two phenotypic groups and place them in the two folders.
3. Run the PGRG.exe
4. Provide values for all the form fields

Note: Choose the CSV option for Output file. The Output File name should not contain characters like / : etc.

5. Choose either "Sum Intensity Values per Reported ID" or "Calculate Average Intensity per Reported ID."
6. Press the Generate Report button.

The application generates an Output File in the OUTPUT folder. PGRG uses data from all the TXT files stored in the INPUT_GRP1 or INPUT_GRP2 or both directories to generate the report. If only one of the INPUT folders contains input files, then a simple report will be generated. If both input folders contain input files, the generated report contains five more columns for group comparison purposes.

7. Copy the EXCEL file that has the binned data into a folder where the MATLAB files are copied.
8. Start MATLAB
9. Run the m-file *ProteomicAnalysis.m*, which will prompt you to provide the following information sequentially:

   9.1 Enter the name of the EXCEL file which has the training data. After it reads the data into MATLAB.

9.2 Choose a peak selection method; the options are "SVM-RFE" (default) and ACO-SVM.
9.3 Enter the number of features to be selected. The default is set to three. It is advised to use at least three features.
9.4 Enter the number of times (iterations) the reshuffling algorithm is to be done. The code will run through the baseline correction and normalization process, peak detection, and peak selection process.
9.5 Select the desired number of peaks. (Note that if the reshuffling is done only once, the number of peaks will be equal to the number entered in Procedure 9.3. However, for multiple iterations, a frequency plot will be provided to assist the user to select the number of desired peaks).
9.6 Enter a filename you wish to save the results as a MAT file. The result includes parameters used for normalization, along with the normalized train data, the SVM classifier built for the training data and the selected m/z windows. These will be saved as a MAT file in the name you have provided when prompted for.

10. To predict the disease state of spectra in a blinded set, bin the blinded spectra following steps 1 to 6. Run the M-file *PredictResults.m*. The m-file will prompt you to provide the following information sequentially:

    10.1 Enter the name of the EXCEL file which has the blinded data
    10.2 Enter the name of the saved MAT file (which has parameters used to analyze the labeled set) from the labeled data.

The code will perform baseline correction and normalization in the blinded dataset and then quantify the peaks/windows based on the selected peaks from the labeled data. It also uses the saved SVM classifier information and then gives you labels for the blinded dataset.

11. As an alternative to step 10, the m-file *SummarizeResults.m* allows you to choose a new set of summarized peaks from the previously trained spectra. Running this code prompts you to provide the following information sequentially:

    11.1 Enter the name of the EXCEL file which has the binned blinded data
    11.2 Enter the name of the saved MAT file that has parameters used by the labeled set. If the labeled set was shuffled more than once, a frequency plot will be displayed for the summarized peaks.
    11.3 Choose the number of peaks based on the frequency plot. These peaks will be used to design an SVM classifier which will then predict the labels for the blinded set.

4. Notes

1. As pointed out in Procedures 2 and 6, our binning tool can read .TXT files generated by the FlexAnalysis software either from a single input folder or two folders. If a single input folder is used, the output file will have one

column per subject. If the files are placed into two input folder, then the output file will provide the following additional five columns for group comparison purposes:

[GRP1] "Avrg Intensity" = an Average GRP1 intensity per row
[GRP1] "Val Count" = number of GRP1 intensity values per row
[GRP2] "Avrg Intensity" = an Average GRP2 intensity per row
[GRP2] "Val Count" = number of GRP2 intensity values per row
"GRP |Dif|" = the absolute difference between the [GRP1] and [GRP2]

2. If 'ACO-SVM' is chosen in Procedure 9.2, the algorithm will need a long time to perform the feature selection for multiple generations. The number of ants in this algorithm is set by default to 50 and the number of generations is set to 500. To change these options, the user needs to edit the m-files *PeakSelection_ACOSVM.m* and *peak_ACO_S2N.m*. However, the default peak selection algorithm in Procedure 9.2 (SVM-RFE) requires relatively less computational time.
3. If the feature selection algorithm is run only once (i.e., if number of reshuffling is set to 1 in Procedure 9.4), then frequency plot will not be provided. We suggest that the user performs multiple reshuffling (10–100 iterations) to determine the most frequently selected peaks.
4. If the feature selection algorithm is run for multiple iterations by reshuffling the labeled spectra, then a summarized set of peaks will be provided in Procedure 9.5. The summarization is needed because, when the samples are reshuffled, the number of peaks found for each run and the width of each peak may vary. Summarization allows us to merge overlapping peaks and to provide a frequency plot of the number of occurrence of each summarized peak in multiple iterations. The number of peaks needed for classification of a blinded set can be chosen based on a frequency plot, which assists users to estimate the optimal number of peaks. The frequency plot presents a bar plot with the number of occurrences versus the peaks sorted in the order of decreasing frequency. A commonly used approach is to select all peaks starting from the first until the frequency curve becomes flat (i.e. the change in frequency becomes low).
5. The MAT file saved following Procedure 9.6 consists of various training parameters including scaling factor, selected peaks, normalized labeled spectra, and an SVM classifier built based on the spectra in the labeled set. If multiple iterations are used in Procedure 9.4, the SVM classifier uses the peaks selected by the user on the basis of the frequency plot (Procedure 9.5). Otherwise, the number of peaks will be equal to the value entered in Procedure 9.3. The training parameters are used by *PredictResults.m* to

predict the disease state of the spectra in the blinded set. If the user wants to change the number of peaks without rerunning the peak selection process, previously saved training parameters from Procedure 9.6 can be used by *SummarizeResults.m* (Procedure 11) to display the frequency plot and to allow the selection of the number of peaks needed. Once the number of peaks are selected (Procedure 11.3), *SummarizeResults.m* predicts the disease state of the spectra in the blinded set.

Simple Tools for Complex *N*-Glycan Analysis

Anne-Catherine Fitchette, Meriem Benchabane, Thomas Paccalet, Loïc Faye, and Véronique Gomord

1. Introduction

Glycosylation is the most widespread post-translational modification encountered on secreted glycoproteins. In eukaryotes, glycosylation can be of two types: *N*- or *O*-glycosylation, depending on the linkage involved between the oligosaccharide and the protein backbone. The latter will not be detailed here.

N-glycosylation occurs exclusively on proteins that enter the secretory pathway of eukaryotic cells. It starts in the endoplasmic reticulum (ER) with the cotranslational transfer of an oligosaccharide precursor, $Glc_3Man_9GlcNAc_2$, onto specific asparagine residues constitutive of *N*-glycosylation sequences present on the nascent protein (Asn-*X*-Ser/Thr, where *X* can be any amino acid except proline). Then, processing of the $Glc_3Man_9GlcNAc_2$ precursor occurs along the secretory pathway as the glycoprotein moves from the ER through the Golgi apparatus to its final destination. Glycosidases and glycosyltransferases convert successively the oligosaccharide precursor into high-mannose-type *N*-glycans, ranging from $Man_9GlcNAc_2$ to $Man_5GlcNAc_2$, and to complex-type *N*-glycans (**Fig. 1**). This maturation pathway is common to most eukaryotic cells, including plant and human cells, up to the $Man_5GlcNAc_2$ structure (**Fig. 1**). Contrastingly, complex-type *N*-glycans differ according to the cell system in which they are matured. In plants, for example, the proximal GlcNAc of the core can be substituted with an α1,3-fucose, instead of an α1,6-fucose for human *N*-glycans. The β-mannose of the core can be substituted with a β1,2-xylose or a β1,4-GlcNAc in plants and humans, respectively. Moreover, glycan antennae are composed of a terminal β1,3-galactose and an α1,4-fucose linked to the terminal GlcNAc, forming the Lewis a structure, in plants (**Fig. 1**) ***(1)***. In mammals, especially

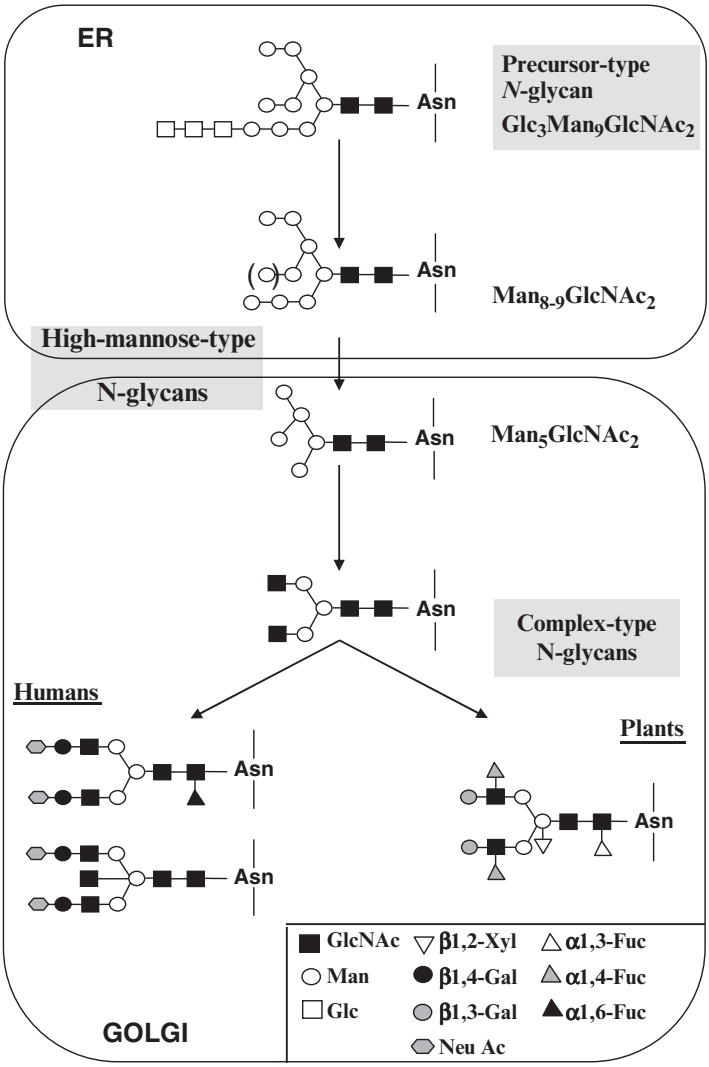

Fig. 1. *N*-glycan maturation pathway in humans and plants. (GlcNAc: N-acetylglucosamine, Man: mannose, Glc: glucose, Xyl: xylose, Gal: galactose, NeuAc: N-acetyl neuraminic acid, Fuc: fucose).

humans, terminal GlcNAc are substituted with β1,4-galactose to which neuraminic acid can be linked (**Fig. 1**).

This discrepancy between mammalian and plant complex *N*-glycans raises problems when a recombinant plant glycoprotein is to be used as a pharmaceutical in human. Indeed, the plant β1,2-xylose and the α1,3-fucose have been shown to be immunogenic in all laboratory mammals, with the exception of the

BALB/c mouse. The presence of xylose and fucose on a plant pharmaceutical will render this therapeutical protein insecure for injection to humans. Moreover, the differences existing between plant and human complex *N*-glycan structures can provoke a loss in biological activity and/or half-life of the plant pharmaceutical, once administrated. To circumvent these problems, several *in vitro* or *in vivo* strategies are being developped currently to humanize the *N*-glycans from plant pharmaceuticals (for recent review, see ***2***). In any case, *N*-glycosylation studies of a mammalian/human protein and its plant-expressed counterpart are generally undertaken to highlight the differences between the glycosylation status of these proteins.

In the present chapter, the authors propose simple methodologies to define whether and how a protein, expressed in mammal or plant, is glycosylated.

2. Materials

2.1. Is My Protein a Glycoprotein?

1. DIG Glycan Detection Kit (Roche Applied Science, Mannheim, Germany) (store at 2–8°C).

2.2. How Is My Protein Glycosylated?

2.2.1. Detection of N-Glycans by Western Blotting

2.2.1.1. Affinodetection with Lectins

1. TTBS buffer: 20 m*M* Tris-HCl, pH 7.4, containing 0.5 *M* NaCl and 0.1% Tween-20.
2. Lectin-biotin: GNA (*Galanthus nivalis* agglutinin)-biotin (Vector Labs/Abcys, France) (store at 2–8°C), (*Triticum vulgaris* agglutinin)-biotin (Sigma-Aldrich, Lyon, France) (store at 2–8°C), MAL II (*Maackia amurensis* lectin II)-biotin (Vector Labs/Abcys, France) (store at 2–8°C), RCA I or RCA_{120} (*Ricinus communis* agglutinin I)-biotin (Vector Labs/Abcys, France) (store at 2–8°C), SNA (*Sambucus nigra* agglutinin)-biotin (Vector Labs/Abcys, France) (store at 2–8°C).
3. Streptavidin-peroxidase conjugate (Amersham Biosciences/GE Healthcare, Uppsala, Sweden) (store at 2–8°C).
4. TBS buffer: 20 m*M* Tris-HCl, pH 7.4, containing 0.5 *M* NaCl.
5. 4-Chloro-1-naphtol (Bio-Rad, Hercules, CA) (store at −20°C).
6. 37% H_2O_2.
7. Ribonuclease B from bovine pancreas (Sigma-Aldrich) (store at 2–8°C).
8. Methyl α-D-mannopyranoside (Sigma-Aldrich) (store at room temperature).
9. Ovalbumin (Sigma-Aldrich) (store at 2–8°C).
10. TTBS* buffer: 20 m*M* Tris-HCl, pH 7.4, containing 0.5 *M* NaCl, 1 m*M* $CaCl_2$, 1 m*M* $MgCl_2$, and 0.1% Tween-20.
11. Concanavalin A (Sigma-Aldrich) (store at 5–8°C).
12. Horseradish peroxidase (HRP, Sigma-Aldrich) (store at 2–8°C).
13. Soybean agglutinin (Sigma-Aldrich) (store at 2–8°C).
14. Fetuin from fetal calf serum (Sigma-Aldrich) (store at 2–8°C).

15 Glycophorin from blood type B negative (Sigma-Aldrich) (store at 2–8°C).
16 Asialofetuin from fetal calf serum (Sigma-Aldrich) (store at 2–8°C).

2.2.1.2. Immunodetection with Specific Antibodies

1. TBS buffer: 20 m*M* Tris-HCl, pH 7.4, containing 0.5 *M* NaCl.
2. Gelatin (Bio-Rad).
3. Anti-HRP rabbit immunserum (Sigma-Aldrich) (store at 2–8°C).
4. Anti-*Apis mellifera* venom (honeybee venom; Sigma-Aldrich) (store at 2–8°C).
5. Mouse anti-human Lewis a monoclonal antibody (Calbiochem, Meudon, France) (store at −20°C).
6. TTBS buffer: 20 m*M* Tris-HCl, pH 7.4, containing 0.5 *M* NaCl and 0.1% Tween-20.
7. HRP-conjugated goat antibodies directed at mouse polyvalent immunoglobulins (Sigma-Aldrich) (store at −20°C).
8. HRP-conjugated goat antibodies directed at rabbit immunoglobulins (Bio-Rad) (store at 2–8°C).
9. Phospholipase A2 from honeybee venom (Sigma-Aldrich) (store at 2–8°C).
10. Bean phytohemagglutinin L (PHA-L, Sigma-Aldrich) (store at 2–8°C).

2.2.2. Analysis of the Protein after Enzymatic Glycan Release

1. 1% Sodium dodecyl sulfate (SDS).
2. 150 m*M* Sodium acetate buffer, pH 5.7.
3. Endo H: endoglycosidase H from *Streptomyces plicatus,* recombinant from *E. coli* (Roche Applied Science) (store at 2–8°C; *see* **Note 1**).
4. 0.1 *M* Tris-HCl buffer, pH 7.5, containing 0.1% SDS.
5. 0.1 *M* Tris-HCl buffer, pH 7.5, containing 0.5% Nonidet P40.
6. Nonidet P40 (called now IGEPAL; Sigma-Aldrich).
7. PNGase F: peptide-*N*-glycosidase F from *Flavobacterium meningosepticum* (Roche Applied Science) (store between −15°C and −25°C).
8. 10 m*M* HCl solution, pH 2.2.

2.2.3. In Vitro Enzymatic N-Glycan Sequencing Followed by SDS-Page Analysis

2.2.3.1. In Vitro Sequencing by Exoglycosidases

1. *Arthrobacter ureafasciens* neuraminidase (from EY Laboratories, Coger, France) (store at −20°C).
2. 90 m*M* sodium phosphate, pH 5.0.
3. β-galactosidase from *Aspergillus oryzae* (Sigma Aldrich) (store at −20°C).
4. SP-Sepharose Fast Flow (Amersham Biosciences/GE Healthcare) (store at 4°C).
5. Sephacryl S200 HR (Amersham Biosciences/GE Healthcare) (store at 4°C).
6. pNP-β-Gal: 2-nitrophenyl β-D-galactopyranoside (Sigma-Aldrich) (store at −20°C).
7. 10m*M* sodium acetate, pH 4.6.
8. 0.5 *M* NaCl.
9. 50 m*M* Tris-HCl, pH 7.5, containing 0.1 *M* NaCl.
10. 50 mM sodium acetate, pH 5.0.

2.2.3.2. In Vitro Modification with Glycosyltransferases

1. β1,4-Galactosyltransferase from bovine milk (Calbiochem) (store at −20°C).
2. UDP-Galactose (uridine 5′-diphosphogalactose disodium salt) (Sigma-Aldrich) (store at −20°C).
3. 100 m*M* Sodium cacodylate, pH 6.4, containing 5 m*M* UDP-galactose and 5 mM $MnCl_2$.

3. Methods

3.1. Is My Protein a Glycoprotein?

To determine if a protein can be *N*-glycosylated, a first point to check is the presence of potential *N*-glycosylation sites (Asn-*X*-Ser/Thr) within its sequence. This can be performed using the available programs Prosite Scan (http://npsa-pbil.ibcp.fr/cgi-bin/npsa_automat.pl?page=npsa_prosite.html) or NetNGlyc (http://www.cbs.dtu.dk/services/NetNGlyc/). The absence of the Asn-X-Ser/Thr motif within the sequence of a protein is insurance that it is not *N*-glycosylated. At the opposite, the presence of one or more of those motifs does not imply that the protein is a glycoprotein. This should be checked by the methods proposed hereunder.

Only one approach is available to answer the question globally: is my protein a glycoprotein? It necessitates the use of a general sugar detection kit that allows the detection and quantification of glycoproteins on blot. All the reagents necessary for such a determination are provided in a detection kit, the DIG Glycan Detection Kit commercialized by Roche Applied Science, which also includes the manufacturer's instructions. It should be noted that the only information the experimenter will get using this kit is that the proteins do bear at least one oligosaccharide moiety. No information will be provided about the type of glycan involved or its linkage to the protein backbone.

3.2. How Is My Protein Glycosylated?

Several strategies can be initiated to determine the nature of the glycan borne by a glycoprotein. The first one involves the use of probes specific for glycoprotein *N*-glycan moieties in Western blotting experiments. This strategy does not require any glycan cleavage or separation (*see* **Subheading 3.2.1.**). Alternatively, the *N*-glycan can be selectively cleaved from the purified glycoprotein by enzymatic treatment. The glycoprotein is then analyzed by electrophoresis prior to and after deglycosylation (*see* **Subheading 3.2.2**). The same strategy can be initiated on a crude protein extract. The glycoprotein of interest will be immunodetected, after SDS-PAGE migration and Western blotting, by specific antibodies. The removal of *N*-glycans from a glycoprotein induces an increase in its electrophoretic mobility. Roughly, a *N*-linked glycan has a molecular mass between 1,000 and 2,000 Da.

3.2.1. Detection of N-Glycans by Western Blotting

The detection of *N*-glycans borne by glycoproteins can be performed after Western blotting of either 1D or 2D electrophoresis gels. The probes used for this detection are of two types: lectins or antibodies.

3.2.1.1. Affinodetection with Lectins

Lectins are proteins able to bind oligosaccharide moieties specifically. Most lectins have been characterized on the basis of their affinity for mammalian glycoproteins. Only a few of them are available for the detection of plant glycans. They are presented in **Table 1** (*see* **Note 2**).

These lectins are commercially available in a biotinylated form. The recognition event between the lectin and the oligosaccharide is visualized on a blot using a streptavidin-peroxidase conjugate. An exception is the lectin concanavalin A, which is able to bind directly to horseradish peroxidase. The two protocols are detailed here.

The lectin-biotin/streptavidin-peroxidase procedure:

1. Separate the proteins to be studied by 1D or 2D electrophoresis and transfer onto a nitrocellulose membrane.
2. Saturate the blot with TTBS buffer for at least 1 h (*see* **Note 3**).
3. Incubate the blot in TTBS containing the lectin-biotin complex (0.1 mg/20 mL) for 2 h at room temperature.
4. Wash four times in TTBS, for 15 min each.
5. Incubate the blot with a streptavidin-peroxidase conjugate diluted 1:1000 in TTBS for 1 h at room temperature.
6. Wash the blot in TTBS (4 × 15 min) and once in TBS prior to development.
7. Prepare extemporaneously the peroxidase development mixture by dissolving, in a beaker, 30 mg of 4-chloro-1-naphtol in 10 mL cold methanol (−20°C), and mixing in another beaker 30 µL H_2O_2 with 50 mL TBS. Mix the two solutions just prior to pouring onto the membrane, and shake gently to optimize the development reaction.
8. Stop the reaction by discarding the development mixture and rinsing the blot several times with distilled water. Dry the membrane and store between 2 sheets of filter paper.
9. Suggested controls for the experiment are presented in **Note 4**.

The concanavalin A (ConA)-peroxidase procedure (modified from **ref. *3***):

1. Separate the proteins to be studied by 1D or 2D electrophoresis, and transfer onto a nitrocellulose membrane.
2. Saturate the blot for at least 1 h in TTBS at room temperature.
3. Incubate the membrane in TTBS* containing ConA (25 µg/mL) for 2 h at room temperature.
4. Wash the membrane four times for 15 min each in TTBS.

Table 1
Lectins used for *N*- linked glycan detection in Western blotting experiments

Lectin	Specificity	Detected oligosaccharides	Suggested positive controls	Sugar inhibitor	Ref
Concanavalin A from *Canavalia ensiformis*	αD – mannose αD - glucose	- Precursor structures: M9G3 to M9G1 - High-mannose structures: M9 to M5 In plants and animals	Soybean agglutinin Ovalbumin Ribonuclease B	methyl α-D-mannopyranoside	***3***
Galanthus nivalis agglutinin (GNA)	Terminal α1,3-mannose	- High-mannose structures: M8 to M5 In plants and Animals	Ribonuclease B	methyl α-D-mannopyranoside	***22*** ***23***
Wheat germ aggultinin (WGA) from *Triticum aestivum*	Terminal GlcNAc Internal chitobiose units	- All *N*-linked glycans In plants and animals	Ovalbumin	GlcNAc (*see* **Note 17**) Chitotriose Chitobiose	***24***
Ricinus communis agglutinin (RCA I, RCA120)	Terminal Gal α 1,4-GlcNAc	- Complex *N*-glycans devoid of NeuAc (in animals) - *N*-glycans from plants expressing human galactosyltransferase - *N*-glycans remodeled in vitro by neuraminidase or galactosyltransferase	Asialofetuin	Lactose	***25*** ***26; 27***
Maakia amurensis lectin (MAL II)	Terminal NeuAc-α 2,3-Gal– α 1,4-GlcNAc	- Complex *N*-glycans in animals	Fetuin	Lactose	***28***
Sambucus nigra agglutinin (SNA)	Terminal NeuAc-α 2,6-Gal- α1,4-GlcNAc	- Complex *N*-glycans in animals	Glycophorin	Lactose	***28***

5. Incubate the membrane in TTBS containing horseradish peroxidase (HRP, 50 µg/mL) for 1 h at room temperature.
6. Rinse the blot four times for 15 min each in TTBS and once in TBS for 15 min.
7. Develop the peroxidase reaction as described in the lectin-biotin/streptavidin-peroxidase procedure.
8. Controls have to be performed as presented in **Note 4**.

3.2.1.2. Immunodetection with Specific Antibodies

We have shown that the β1,2-xylose and the α1,3-fucose epitopes of plant *N*-linked complex glycans are highly immunogenic in rabbits ***(4)***. As a consequence, sera prepared against glycoproteins containing complex glycans generally contain antibodies directed at the β1,2-xylose and/or the α1,3-fucose. Some commercially available immunsera present the same characteristics as our home-made probes. For instance, immunsera directed against HRP can be used as probes specific for plant complex *N*-glycans with α1,3-fucose and β1,2-xylose residues. More specific is the immunserum raised against honeybee venom proteins, which can be used as a specific probe for α1,3-fucose-containing plant complex *N*-glycans ***(4)*** (*see* **Note 5**). We also raised in our laboratory rabbit antibodies specific for the terminal antennae of complex *N*-glycans, the trisaccharide Lewis a ***(1)***. Anti-Lewis a monoclonal antibodies are commercially available, although they are very expensive (*see* **Note 6**).

1. Separate the proteins by 1D or 2D electrophoresis and transfer onto a nitrocellulose membrane.
2. Saturate the blot with 3% gelatin prepared in TBS, for at least 1 h at room temperature.
3. Incubate the blot in TBS containing 1% gelatin and the immunserum at a convenient dilution for 2 h at room temperature. We used the commercial immunsera described above in **Subheading 2.2.1.2**. at the following dilutions:
   a. Anti-HRP rabbit immunserum, 1:300.
   b. Anti-honeybee venom rabbit immunserum, 1:200.
   c. Anti-Lewis a mouse monoclonal antibody, 1:100.
4. Wash the blot with TTBS buffer four times for 15 min each.
5. Incubate the blot in TBS containing 1% gelatin and the suitable conjugate, i.e., a goat anti-rabbit IgG conjugate coupled to HRP at a dilution of 1:2000, or HRP conjugated goat antibodies directed at mouse polyvalent immunoglobulins at a dilution of 1:500, for 1 h at room temperature.
6. Wash the blot four times with TTBS for 15 min each and once in TBS prior to development.
7. Develop the peroxidase reaction as described for the lectin-biotin/streptavidin-peroxidase procedure (*see* **Subheading 3.2.1.1.**).
8. For controls, *see* **Notes 7** and **8**.

3.2.2. Analysis of the Protein after Enzymatic Glycan Release

Further information can be obtained by treating the purified glycoprotein with glycosidases. Endoglycosidase H (Endo H) is only able to release high-mannose type *N*-glycans, from plant and mammalian glycoproteins, by hydrolyzing the glycosidic bond between the two GlcNAc residues on the core of the *N*-glycan (**Fig. 2**). Peptide *N*-glycosidases (PNGases) hydrolyze the bond between the Asn of the peptide backbone and the proximal GlcNAc of the oligosaccharide part, for both high-mannose type *N*-glycans and complex type *N*-glycans. However, PNGase F, which is widely used in the analysis of mammalian glycoproteins, is active on high-mannose and complex plant *N*-glycans, except those presenting an α1,3-fucose residue linked to the proximal GlcNAc. PNGase A is able to release all types of plant *N*-glycans (**Fig. 2**), but it is almost only efficient on glycopeptides and necessitates the proteolytic digestion of the glycoprotein prior to deglycosylation (***5, 6***) Therefore, this enzyme cannot be used to deglycosylate a glycoprotein before its electrophoretic analysis (*see* **Notes 9** and **10**). The deglycosylated protein or peptides can be analyzed for 1) an increased electrophoretic mobility, or 2) the loss of glycoprotein reactivity on blots with glycan-specific probes after Endo H or PNGase F treatment.

Deglycosylation with endoglycosidase H:

1. Prior to enzyme deglycosylation with Endo H, denature the purified protein by heating it to 100°C for 5 min in the presence of 1% SDS (w/v).
2. Dilute the sample fivefold with 150 m*M* sodium acetate, pH 5.7, and add then 10 mU Endo H per mg of protein to be analyzed. Incubate the mixture at 37°C for at least 6 h.
3. After the deglycosylation reaction, add an equal volume of twice concentrated electrophoresis sample buffer if the result of the digestion is followed by electrophoresis gel, affino-, or immunodetection (*see* **Subheading 3.2.1.**). The sample can also be desalted and analyzed by mass spectrometry.

Deglycosylation with PNGase F:

1. Dissolve the purified protein to be digested in 0.1 m*M* Tris-HCl, pH 7.5, containing 0.1% SDS.
2. Heat the sample for 5 min at 100°C to denature the protein. Let it cool down at room temperature and add an equal volume of 0.1 m*M* Tris-HCl, pH 7.5, containing 0.5% Nonidet P-40 (*see* **Note 11**).
3. Incubate the sample with PNGase F (1U enzyme for 100 µg protein) at 37°C during 24 h.
4. After digestion, precipitate, by 4 vol of cold ethanol, the deglycosylated protein overnight at −20°C or twice with shorter incubation time.
5. Wash the pellet 2 to 3 times with cold ethanol.

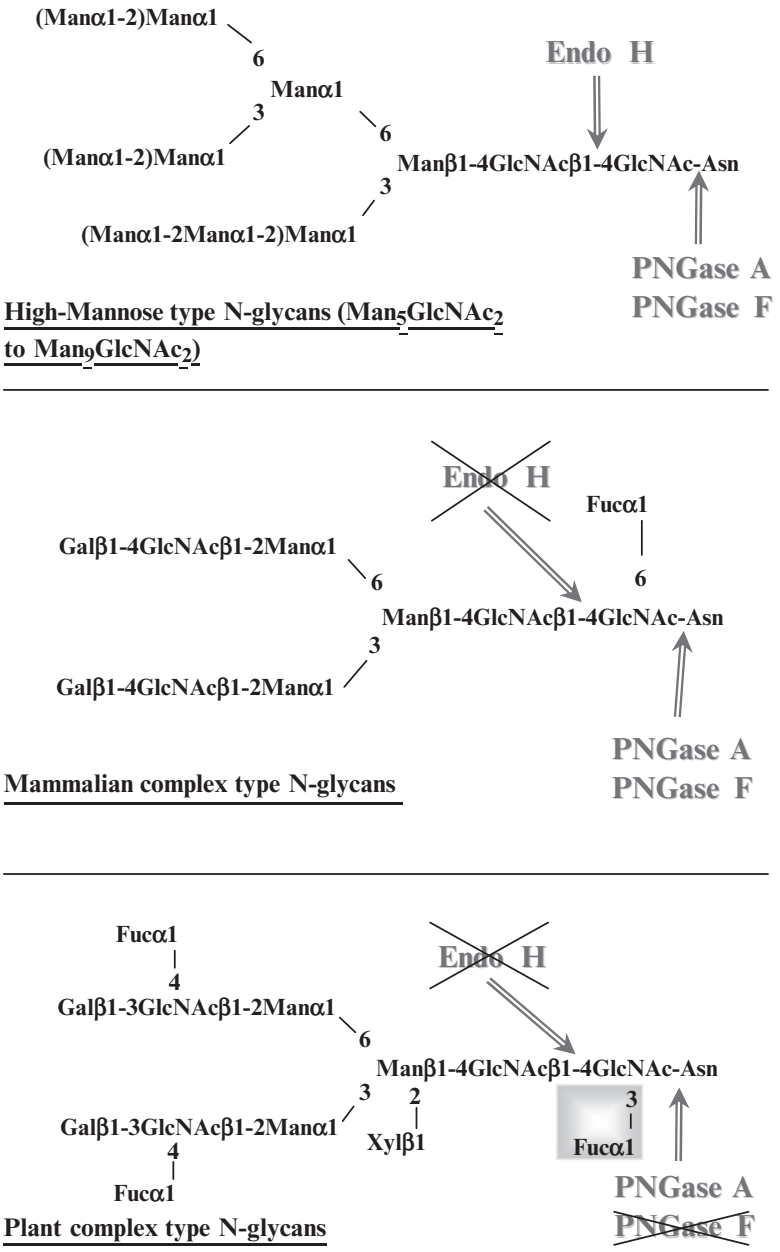

Fig. 2. Enzymatic deglycosylation of proteins bearing *N*-linked glycans. High-mannose type *N*-glycans can be cleaved by either endoglycosidase H (Endo H), peptide *N*-glycosidase A (PNGase A), or peptide *N*-glycosidase F (PNGase F). Mammalian complex type *N*-glycans can be removed using PNGase A and PNGase F. Plant complex type *N*-glycans can only be released by PNGase A, owing to the presence of α1,3-fucose linked to the core. It should be noted that PNGase A mostly acts on glycopeptides and is not efficient on a complete glycoprotein.

6. Centrifuge the sample. Recover the deglycosylated protein in the pellet and dissolve it in a suitable buffer for gel electrophoresis or mass spectrometry analysis.

3.2.3. In Vitro Enzymatic N-Glycan Sequençing Followed by SDS-Page Analysis

To specify the structure of a *N*-glycan linked to a glycoprotein, exoglycosidases and glycosyltransferases can be used. The formers specifically remove the last sugar residues present at the terminal non-reducing end of the *N*-glycan, while the latters add specifically terminal sugar residues. The resulting modified *N*-glycans are detected on blots with *N*-glycan-specific probes (*see* **Subheading 3.2.1**; *see* **Table 2**).

3.2.3.1. In Vitro Sequencing by Exoglycosidases

Many exoglycosidases can be used to sequence *N*-glycans, illustrated here for two of them. They are neuraminidase from *Arthrobacter ureafasciens* and β1,4-galactosidase from *Aspergillus oryzae*. The former removes any NeuAc present at the non reducing end of *N*-glycans, while the latter cleaves terminal β1,4-Gal (*see* **Table 2**; *see* **Note 12**).

Terminal neuraminic acid enzymatic hydrolysis (*see* **Note 13**):

1. Dissolve 5 µg of protein (*see* **Note 14**) in 20 µL of 90 m*M* sodium phosphate, pH 5.0, and incubate in the presence of 0.5 U neuraminidase for 3 h at 37°C.
2. Dilute then the sample in a suitable electrophoresis buffer prior to SDS-PAGE migration, Western transfer and detection with SNA I and/or RCA_{120} lectins (*see* **Subheading 3.2.1.1**).The loss of terminal NeuAc induces a lack or an increase of detection by SNA I and RCA_{120}, respectively. The removal of terminal NeuAc followed by lectin detection is illustrated by the on blot glycan analysis of human alpha 1 antichymotrypsin (**Fig. 3**).

Terminal β1,4-galactose enzymatic hydrolysis ***(7)***

The enzyme used for degalactosylation is a β-galactosidase from *Aspergillus oryzae* and is specific for terminal β1,4- and β1,6-galactoses ***(8)*** (*see* **Note 15**). *A. oryzae* β-galactosidase needs to be purified from the commercial preparation ***(8)***, prior to its use for *N*-glycan degalactosylation.

1. Purify *A. oryzae* β-galactosidase by applying it to an ion-exchange chromatography on S Sepharose Fast-flow column equilibrated in 10m*M* sodium acetate, pH 4.6. Elute β-galactosidase using a linear gradient of 0–0.5 *M* sodium chloride. Check the purity of the enzyme by gel filtration on Sephacryl S200 HR equilibrated in 50 m*M* Tris-HCl, pH 7.5, complemented with 0.1 *M* sodium chloride, or by SDS-PAGE. Evaluate the activity of the enzyme preparation by incubating a fraction of the purified *A. orizae* with 5 m*M* pNP-β-Gal in 50 mM sodium acetate, pH 5.0. One milliunit is defined as the amount of β-galactosidase inducing the liberation of 1 nmol of 4-nitrophenol per minute ***(9)***.
2. Dissolve 10 mg of glycoprotein (*see* **Note 16**) in 0.5 mL of 50 m*M* sodium acetate, pH 5.0, and incubate overnight with 4.2 U of purified β-galactosidase from *A. orizae*.

Table 2
Exoglycosidases and glycosyltranferases used for *N*-glycan sequencing prior to on blot detection

Enzyme	Action	Occurrence of the substrate	Detection	Information
Neuraminidase	Removal of NeuAc from: NeuAc-α2,3-GlcNAc- NeuAc-α2,6-GlcNAc-	Complex N-glycans in mammals	- Loss of reactivity with MAL II ou SNA. - Increased reactivity with RCA_{120}	Presence of terminal NeuAc
Galactosidase	Removal of Gal from: Gal-β1,4-GlcNAc-	Complex N-glycans in mammals Complex N-glycans in plants expressing a g alactosyltransferase	- Loss of reactivity with RCA_{120}	Presence of terminal Gal
Galactosyl transferase	Addition of a β1,4-Gal on a terminal β1,2-GlcNAc	Complex N-glycans in mammals and plants	- Gain of reactivity with RCA_{120}	Presence of terminal GlcNAc

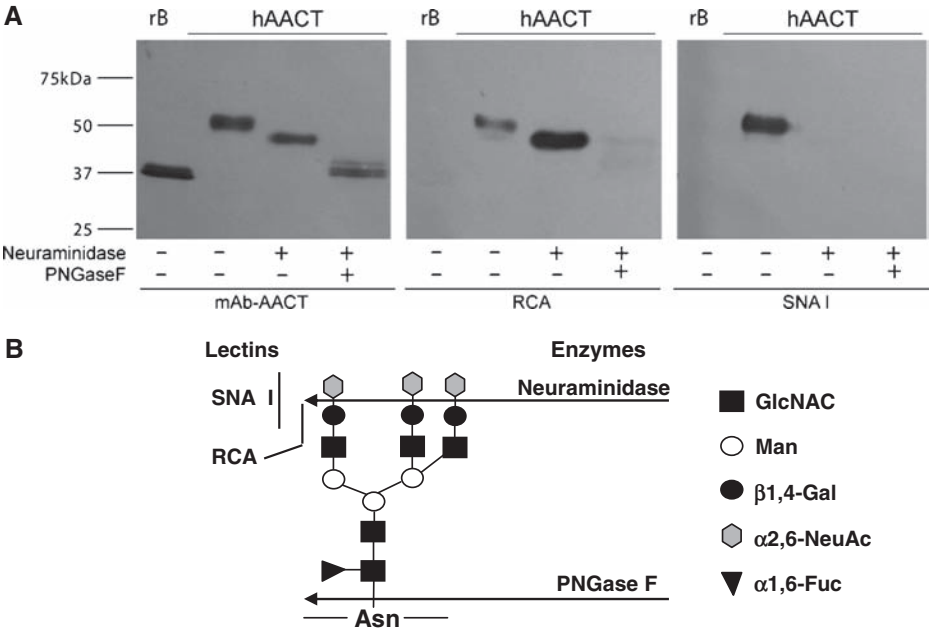

Fig. 3. Human α1 anti-trypsin (hAACT) is higly glycosylated with complex *N*-glycans containing sialic acids. (A) Human AACT (hAACT) was successively digested with neuraminidase and peptide *N*-glycosidase F (PNGase F). All samples were analysed by immuno- and affinodetection with AACT specific antibodies (mAb-AACT), *Ricinus communis* agglutinin (RCA) and *Sambucus nigra* lectin I (SNA I). Bacterial recombinant AACT (rb) was used as a non-glycosylated control. (B) Suggested *N*-glycan structure of AACT as supported by the exoglycosidase digestion combined to lectin binding assays.

3. Dilute then the sample in a suitable SDS-PAGE buffer prior to electrophoretic migration, Western blotting and detection using RCA_{120} (*see* **Subheading 3.2.1.1**). A correct degalactosylation induces a loss in RCA_{120} detection.

3.2.3.2. In Vitro Modification with Glycosyltransferases

Glycosyltranferases can also be used for the characterization of *N*-linked glycans. This is illustrated through the following exemple.

To specifically detect terminal GlcNAc, a Gal residue can be added to the non-reducing end of *N*-glycans by a β1,4-galactosyltransferase from bovine milk (*see* **Note 17**). The resulting *N*-linked glycan is detectable by RCA_{120} (*see* **Table 2**).

1. Dissolve 50 µg of glycoprotein (*see* **Note 18**) in 1 mL of 100 m*M* sodium cacodylate, pH 6.4, containing 5 m*M* UDP-galactose and 5 mM $MnCl_2$ (*see* **Note 19**). Incubate for 24h at 37°C.
2. Dilute then the sample in a suitable SDS-PAGE buffer prior to electrophoretic migration, Western blotting and detection using RCA_{120} (*see* **Subheading 3.2.1.1**). β1,4-Galactosylation of terminal GlcNAc residues renders the glycoprotein detectable by RCA_{120}.

4. Notes

1. Do not freeze Endo H as this inactivates the protein.
2. The experimenter should be careful in the blot interpretation, as WGA recognizes GlcNAc in *N*-linked glycans, as well as *O*-linked GlcNAc.
3. The solution used for blocking binding sites on the nitrocellulose needs to be devoid of glycoproteins. This is why we recommend using Tween-20 to coat the nitrocellulose ***(10)*** in this procedure.
4. Controls for specificity:
   a. It might be advisable to blot the proteins cited in **Table 1** on the membrane ("Suggested positive controls"), to get positive controls for the affinodetection.
   b. Lectin binding specificity must also be checked by running affinodetection in the presence of 0.3 *M* inhibitory sugar (**Table 1**).
5. Core α1,3-fucosylation has been shown to be reponsible for cross-reactions between *Drosophila melanogaster* neuronal proteins and horseradish peroxidase. Anti-horseradish peroxidase antibodies are used as markers for neurons of *D. melanogaster* ***(11)***.
6. No immunsera or antibodies are commercially available to detect mammalian *N*-glycans.
7. Control for *N*-glycan specificity of the immunodetection: it might be wise to check for the specificity of sera toward *N*-glycans attached to the protein studied. This can be done by performing a mild periodate oxidation on the blot prior to immunodetection. Mild periodate treatment oxidizes glycans and abolishes any recognition of the glycoprotein by the anti-glycan antibodies. Any remaining signal will be the consequence of a protein backbone antibody/recognition ***(12)***.
   a. After saturation with gelatin, incubate the blot in a 100 m*M* sodium acetate buffer, pH 4.5, containing 100 m*M* sodium metaperiodate for 1 h in the dark at room temperature, changing the incubation solution after 30 min.
   b. Incubate the blot in PBS containing 50 m*M* sodium borohydride for 30 min at room temperature.
   c. Rinse the blot with TBS, saturate for 15 min with TBS containing 1% gelatin, and perform the immunodetection, as described in **Subheading 3.2.1.1**.
8. Controls for fucose or xylose specificity: some proteins can be used as positive controls for the *N*-glycan immunodetection. Phospholipase A2 from honeybee venom contains the α1,3-fucose residue, and is devoid of β1,2-xylose ***(13)***. PHA-L is a glycoprotein containing both β1,2-xylose and α1,3-fucose ***(14)***.

9. Some authors have shown some success at deglycosylating an entire glycoprotein. The result of this experiment is glycoprotein-dependent and the researcher should be aware that most glycoproteins will not be deglycosylated by PNGase A, unless previously digested by a protease.
10. To overcome the problem caused by the presence of α1,3-fucose on a plant glycoprotein, the researcher can express it, if its cDNA is available, in a plant system devoid of complex *N*-linked glycans. Such a system can be the *cgl* mutant, an *Arabidopsis thaliana* mutant in which *N*-acetylglucosaminyltransferase 1, the enzyme responsible for the addition of the 1st terminal GlcNAc, has been impaired. This mutant accumulates secreted glycoproteins presenting *N*-glycans matured only to the Man5 form ***(15)***. Researchers can also express the glycoprotein of interest in *A. thaliana* or in the moss *Physcomytrella patens*, in which the genes encoding xylosyltransferase and fucosyltranferase, the two enzymes responsible for the addition of β1,2-xylose and α1,3-fucose, have been knocked-out (***16***; ***17***).
11. The role of Nonidet P40 is to complex free SDS.
12. Although several xylosidases and fucosidases are proposed by suppliers, they have been used only rarely in the literature, and never in our laboratory. Therefore, they will not be detailed here.
13. It is also possible to chemically eliminate the terminal NeuAc by incubationg the glycoprotein in 0.1 N HCl at 80°C for 1h.
14. The experiment has been settled on human alpha 1 antichymotrypsine (***29***), a glycoprotein bearing 4 *N*-linked glycans ***(18)***.
15. As β1,6-galactose occurs rarely in *N*-glycans, one can consider the β-galactosidase from *A. oryzae* specific for terminal β1,4-galactose residues.
16. The protocole has been established using human transferrin ***(7)***, a glycoprotein bearing 2 *N*-linked glycans ***(19)***.
17. β1,4-galactosyltranferase from milk adds a Gal preferentially on the β1,2-GlcNAc linked to the α1,3-mannose of the *N*-glycan core ***(20)***.
18. The protocole has been established using a mouse recombinant antibody expressed in plants ***(21)***.
19. The experiment presented here is a "cold" technique. The same method can be reproduced using radioactive UDP-Gal. The addition of galactose will visualized by autoradiography.
20. Free GlcNAc is a ligand of WGA and will displace the bound glycoproteins from the immobilized lectin.

Acknowledgments

We thank present and former colleagues from our lab who contributed to the development and optimization of the strategies described in this manuscript. Work on glyco-

biology at the University of Rouen is supported by the French Ministère de la Recherche and the Centre National de la Recherche Scientifique (CNRS). We also wish to thank Muriel Bardor for her contribution to **Fig. 2**.

A Lectin-Binding Assay for the Rapid Characterization of the Glycosylation of Purified Glycoproteins

Mohammad T. Goodarzi, Angeliki Fotinopoulou, and Graham A. Turner

1. Introduction

Most proteins have carbohydrate chains (glycosylation) attached covalently to various sites on their polypeptide backbone. These posttranslational modifications, which are carried out by cytoplasmic enzymes, confer subtle changes in the structure and behavior of a molecule, and their composition is very sensitive to many environmental influences ***(1–3)***. There is increasing interest in determining the glycosylation of a molecule because of the importance of glycosylation in affecting its reactivity ***(1, 4, 5)***. This is particularly true in the production of therapeutic glycoproteins by recombinant methods, in which glycosylation can be determined by the type of host cell used or the production process employed ***(2)***. Glycosylation is also important in disease situations in which changes in the carbohydrate structure can be involved in the pathological processes ***(3,6,7,8)***. Unfortunately, the glycosylation of proteins is very complex; there are variations in the site of glycosylation, the type of amino acid–carbohydrate bond, the composition of the chains, and the particular carbohydrate sequences and linkages in each chain ***(3, 4)***. In addition, within any population of molecules there is considerable heterogeneity in the carbohydrate structures (glycoforms) that are synthesized at any one time ***(1)***. This is typified by some molecules showing increased branching, reduced chain length, and further addition of single carbohydrate moieties to the internal chain.

To unravel completely the complexities of the glycosylation of a molecule is a substantial task, which requires considerable effort and resources. However, in many situations this is unnecessary, because only a limited amount of information,

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

on a single or a group of structural features, is needed. Lectins can be useful for this purpose. These substances are carbohydrate binding proteins with particular specificity ***(9)***. Although their specificity is not absolute, there is usually one carbohydrate or group of carbohydrates to which the lectin binds with a higher affinity than the rest of the group. The major carbohydrate specificity of a number of commonly used lectins is shown in **Table 1**.

Lectins have previously been used for investigating glycoprotein glycosylation by incorporating them into existing technologies such as affinity chromatography, blotting, and electrophoresis. Although these modifications give workable methods, they frequently use large amounts of lectin, which is expensive, requires considerable technical skill, cannot handle large numbers of specimens, and provides only semiquantitative results. For a more detailed discussion of these methods the reader should refer to a previous review ***(3)***.

Another approach is to use lectins in the familiar sandwich enzyme-linked immunosorbent assay (ELISA) technology in multiwell plates. Procedures of this type have been described for the measurement of particular carbohydrate structures in α-fetoprotein ***(10)***, glycodelin ***(11)***, haptoglobin (HP) ***(12)***, human chorionic gonadotrophin (hCG) ***(13)***, α1-acid glycoprotein (AGP) ***(14)***, fibronectin ***(15)***, c-*erb*-B2 ***(16)***, immunoglobulins (IgG) ***(17)***, mucins ***(18)***, plasminogen (Pg) activator ***(19)***, and transferrin (TF) ***(20)***. In this method, the lectin is used either to capture the molecule of interest or to identify it. An antibody is used as the other partner in the sandwich and the degree of binding is measured by the presence of an enzyme label on the identifier. Both configurations suffer from the disadvantage that the lectin may bind to carbohydrate determinants on the immunoglobulin used as the antibody. Furthermore, using the lectin as the capture molecule, the immobilized lectin may bind to glycans of other glycoproteins

Table 1
Specificity of Different Lectins

Lectin	Abbreviation	Specificity
Concanavalin A	ConA	Mannose α1–3 or mannnose α1–6
Datura stramonium agglutinin	DSA	Galactose β1–4 *N*-acetylglucosamine
Aleuria aurantia agglutinin	AAA	Fucose α1–6 *N*-acetylglucosamine
Lens culinaris agglutinin	LCA	Mannose α1–3 or mannose α1–6 (Fucose α1–6 GlcNAc is also required)
Lotus tetragonolobus agglutinin	LTA	Fucose α1–2 galactose β1–4 [Fucose α1–3] *N*-acetylglucosamine
Sambucus nigra agglutinin	SNA	*N*-acetylneuraminic acid α2–6 galactose
Maackia amurensis agglutinin	MAA	*N*-acetylneuraminic acid α2–3 galactose
Peanut agglutinin	PNA	Galactose β1–3 *N*-acetylgalactosamine on O-linked chains

in the sample and these will compete with the molecule of interest for the available binding sites. When immobilized antibody is used as the capture molecule, care must be taken to ensure that the antibody is not binding to the same determinant as that reacting with lectin.

The lectin binding assay (LBA) described herein ***(21)*** overcomes many of the disadvantages with the previous lectin immunoassays. It was developed from a previously reported procedure ***(22)***. A purified glycoprotein is absorbed onto the plastic surface of a well in a microtiter plate. After the unbound protein is removed by washing, uncoated sites on the plate are blocked using a non-ionic detergent. A lectin labeled with digoxigenin (DIG) or biotin is added and allowed to interact with the carbohydrate on the absorbed glycoprotein. Unbound lectin is removed by further washing and the amount of bound lectin is measured by adding an anti-DIG antibody or streptavidin conjugated to an enzyme. Streptavidin has a very high affinity for biotin. Following further washing, the bound enzyme is used to develop a color reaction by the addition of the appropriate substrates. The principle of the procedure is summarized schematically in **Fig. 1**.

Using this method it is possible to rapidly screen multiple specimens, with high sensitivity and excellent precision. In addition, very small amounts of

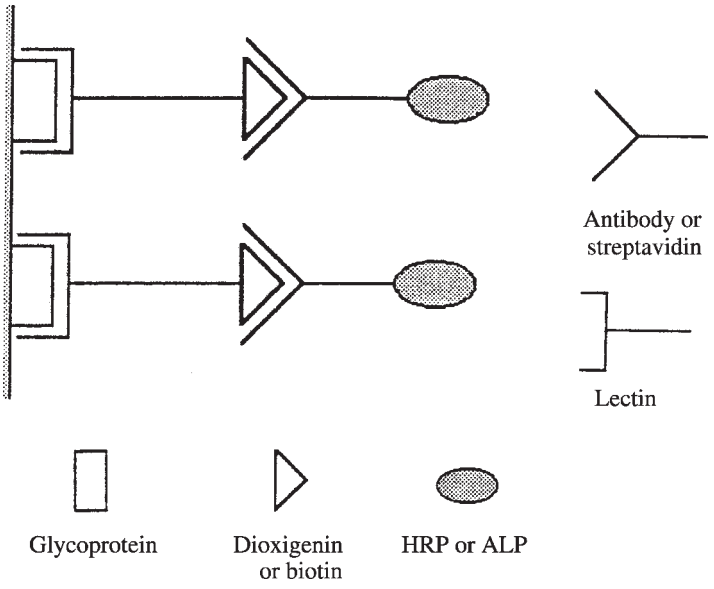

Fig. 1. Schematic diagram of the interactions in the LBA.

lectin are used, background absorbances are low, and the procedure does not require a high degree of technical skill other than some experience with micropipets and ELISA. Because such small amounts of glycoprotein are needed, a glycoprotein can be rapidly purified by a batch affinity chromatography method ***(23, 24)***. The LBA has successfully been applied to the investigation of the glycosylation of purified alpha-1-proteinase inhibitor (API) ***(24)*** and HP ***(25)*** using concanavalin A (ConA), *Maackia amurensis* agglutinin (MAA), and *Sambucus nigra* agglutinin (SNA). Other studies of API and HP have been carried out using *Lens culinaris* agglutinin (LCA) and *Lotus tetragonolobus* agglutinin (LTA) (unpublished observations). If a panel of lectins is used, an overall picture of the carbohydrate structure of a glycoprotein can be built up very quickly and cheaply. Furthermore, subtle differences in the glycosylation of the same glycoprotein in different situations can be identified, for example, different diseases ***(24, 25)*** or between different batches of a recombinant protein ***(26)***.

2. Materials

2.1. Reagents

1. Tris-buffered saline (TBS): 125 m*M* Tris-HCl, pH 7.5, containing 100 m*M* NaCl pH 7.5.
2. Control glycoprotein (*see* **Notes 1** and **2**).
3. Sample glycoprotein (*see* **Notes 2** and **3**).
4. Tween–TBS (TTBS): 125 m*M* Tris-HCl, pH 7.5, containing 100 m*M* NaCl and 0.1% (v/v) Tween 20.
5. Tris cations (TC): 1 m*M* Tris-HCl, pH 7.5, containing 1 m*M* $CaCl_2$, 1 m*M* $MgCl_2$, 1 m*M* $MnCl_2$, and 0.1% (v/v) Tween 20.
6. DIG-labeled lectins (Roche Molecular Biochemicals): Lectin-DIG dissolved in TC (*see* **Note 3**).
7. Biotin-labeled lectins (Sigma): LCA-biotin and LTA-biotin dissolved in TC (*see* **Note 3**).
8. Anti-DIG antibody conjugated with horseradish peroxidase (HRP) (Roche Molecular Biochemicals): 50 mU/mL (Fab fragment) in TTBS (*see* **Note 4**).
9. Streptavidin-alkaline phosphatase (SALP) (Sigma): 1 ng/µL (1.3 mU/µL) in TTBS.
10. Citrate buffer: 34.8 m*M* citric acid, 67.4 m*M* Na_2HPO_4, pH 5.0.
11. Diethanolamine buffer: 100 m*M* diethanolamine, pH 9.8, containing 1 m*M* $MgCl_2$. Store in the dark at 4°C and prepare monthly.
12. *O*-Phenylenediamine (OPD): 37 m*M* solution which is stored in 1 mL aliquots at −20°C.
13. *p*-nitrophenylphosphate (PNPP) (BDH, Atherstone, UK).
14. Hydrogen peroxide: 3% (v/v) solution prepared by diluting concentrated (30%) H_2O_2 1:10 with deionized water. Prepared monthly and stored at 4°C.

15. Color reagent:
    a. HRP: 9 mL citrate buffer + 1 mL of OPD + 50 mL of 10% H_2O_2. Make up fresh 10 min before use. H_2O_2 is added just prior to use.
    b. SALP: 20 mL of diethanolamine buffer + 20 mg of PNPP. Prepare fresh.
16. 1.25 *M* Sulfuric acid (H_2SO_4).
17. 1 *M* Sodium hydroxide (NaOH).

All other reagents were of analytical grade or better (BDH or Sigma), and prepared as required. All solutions were prepared with double-distilled deionized water (Millipore, Bedford, MA).

2.2. Equipment

1. Multiwell plastic plate: 96-Well plate (Immunolon 4, Dynex, Chantilly, VA).
2. Plate reader: Multiskan MCC/340 (Titerteck [McLean, VA]).
3. Multichannel micropipet: Finnpipet, Labsystem, Finland.

3. Methods

1. For each lectin add 100 µL of sample glycoprotein in triplicate to a multiwell plate, and for each batch of samples, add 100 µL of control glycoprotein or TBS in triplicate.
2. Incubate the plate for 2 h at 37°C. Pour off liquid by turning upside down, and tap on a pad of tissue paper to dry completely.
3. Add 200 µL of TTBS to each well, pour off liquid, and dry again. Repeat this operation 3×.
4. Add 200 µL of TTBS to each well and incubate for 1 h at 37°C and then overnight at 4°C.
5. Wash each well 3× with 200 mL of TC, removing liquid as described in **step 2**.
6. Add 200 mL of DIG-lectin or biotin-lectin to each well and incubate for 1 h at 37°C.
7. Wash each well 4× with 200 mL TTBS, removing liquid as described in **step 2**.
8. Add 150 mL anti-DIG/HRP or SALP to each well and incubate the DIG/HRP for 1 h at room temperature and the SALP for 1 h at 37°C.
9. Wash each well 4× with TTBS, removing liquid as described in **step 2**.
10. Add 100 µL of color reagent to each well as appropriate.
11. Leave plate for 10–30 min (*see* **Note 5**) at room temperature (in the dark for HRP).
12. Stop reaction:
    a. For HRP, add 100 µL of H_2SO_4 to each well.
    b. For SALP, add 100 µL of NaOH to each well.
13. Read the absorbance for each well with plate reader:
    a. For HRP, 492 nm.
    b. For SALP, 405 nm.
14. Calculate the mean of triplicate measurements and subtract the absorbance value (OD) of the blank from the values of all samples and controls.

4. Notes

1. A pool of purified glycoprotein that reacts with the lectin is recommended as a positive control in the assay and also for preliminary experiments to develop assay conditions. Various serum glycoproteins can be obtained commercially in a purified form for this purpose, but with other glycoproteins this may not be possible, and suitable material may have to be prepared in the laboratory.
2. Sample and control glycoproteins can be conveniently purified for assay by extracting with an antibody coupled to Sepharose. We have described a batch method that is very rapid, can handle many specimens, produces very pure protein, and works for a number of different glycoproteins ***(23,24)***. Although the yield from this procedure can be low (5–20%), this does not matter because only low amounts of glycoprotein are needed in the assay. A similar method could be equally well adapted for the extraction of other types of glycoprotein.
3. For each combination of lectin and protein, preliminary experiments are carried out to determine the optimum concentration of protein required to coat the well. This is done by coating the well with different amounts of protein (1–1000 ng) and probing with a lectin solution of 1 µg/mL ***(22)***. The protein concentration is chosen that gives an OD value of approx 1. If this value cannot be established, the lectin concentration is increased (e.g., 1.5 µg/mL) or decreased (e.g., 0.5 µg/mL) as required, and the protein is reassayed. **Table 2** shows the optimum glycoprotein concentrations for various lectins we have previously studied. The concentrations of Con A, LCA, LTA, MAA, and SNA used in these experiments were 1, 0.5, 1, 1.5, and 1 µg/mL, respectively.
4. The activity of anti-DIG HRP varies from batch to batch and should be routinely checked. This reagent is usually used at a dilution of 1:3000 to 1:6000.

Table 2
Optimum Protein Coating Concentration for Different Lectins and Different Serum Glycoproteins

	Optimum protein concentration, µg/mL			
Lectin	API	HP	TF	AGP
ConA	0.15	0.05	0.15	2.50
SNA	0.15	0.05	0.07	0.50
MAA	1.00	0.50	3.00	0.50
LCA	1.50	0.50	NR	ND
LTA	1.50	1.00	NR	ND
DSA	0.05	0.01	0.35	0.06

NR, no reactivity; ND, not determined.

5. The time required to develop the color reaction depends on the reactivity of lectin with the particular protein being investigated. For some lectins (e.g., Con A and SNA) it is between 10 and 30 min whereas for other lectins (e.g., LTA, MAA) it is as long as 120 min.
6. To minimize background, TBS and TTBS must be filtered through a 0.2-µm membrane (Tuffryn membrane). The absorbances (without glycoprotein but with all other reagents) for Con A, SNA, and MAA were (mean ± SD, no. of observations) 0.28 ± 0.02, 9, 0.16 ± 0.03, 9; 0.14 ± 0.02,9 respectively.
7. The method gives very good reproducibility. For example, in the case of API, the interassay precision using ConA, SNA, and MAA was 2.2%, 4.5%, and 6.4%, respectively, and the intraassay precision for this glycoprotein with the same lectins was 1.5, 3 and 5%, respectively.
8. The specificity of each lectin can be checked by assaying the glycoprotein in the presence of a competitive sugar. For example, in the presence of 100 m*M* α-D-methyl mannoside, a competitive inhibitor for ConA, the absorbance obtained for API is reduced from 2 to 0.09. Alternatively, glycoproteins can be used that are known to lack the carbohydrate grouping under investigation, for example, carboxypeptidase Y-MAA and TF-LTA.
9. The method is only semiquantitative, and if high absorbance values are obtained for a glycoprotein this suggests that it has high amounts of a particular carbohydrate grouping, and vice versa. Positive and negative controls must always be run in the assay, because it does not use standards. The method is at its most useful when comparing different samples in the same assay. This is illustrated in **Table 3**, which shows the lectin binding characteristics for Hp from healthy individuals and cancer patients. The results are interpreted according to the known properties of each lectin ***(27)***. Therefore, in cancer, the branching of Hp is increased, there is more α2–3 *N*-acetyneuraminic acid (Neu5A), and the α2–6 Neu5A content is unchanged. On the other hand, with API in cancer, the branching decreases, the α2–6 Neu5A con-

Table 3
Analysis of Purified API and Hp in the LBA using ConA, MAA, and SNA

		Lectin[b] ($OD_{492\ nm}$)

Table 4
Effect of Neuraminidase Treatment of Immobilized Glycoproteins on Their Lectin Binding Activity

	Lectin binding ($OD_{492\ nm}$)							
	Before NANase				After NANase			
Glycoprotein	ConA	MAA	PNA	SNA	ConA	MAA	PNA	SNA
Fetuin	0.81	1.15	0.04	2.78	1.08	0.09	1.23	0.08
IgG	1.61	0.06	—	1.62	1.29	—	0.11	0.34
Pg	1.45	1.37	0.53	1.13	0.99	0.32	1.24	0.25

Immobilized proteins were treated with 9 mU of neuraminidase (*Vibrio cholerae*, Roche Molecular Biochemicals) for 16 h at 37°C. After treatment the well was washed 4× with TC prior to measurement of lectin binding. Fetuin and IgG are from Sigma and Pg is from Biopool, Sweden.

tent increases, and the α2–3 Neu5A content decreases. All these changes are consistent with the reported monosaccharide composition of these specimens ***(23, 24)***, and the known carbohydrate structures present in *N*-glycans ***(4)***. It is important to emphasize that the method does not give an indication of the glycosylation of individual glycoforms in a population, but represents the overall glycosylation.

10. More information about carbohydrate structure can be obtained from the LBA by treating the immobilized glycoprotein with a glycosidase, for example, neuraminidase (NANase), galactosidase. **Table 4** shows the effect of NANase treatment (the glycosidase that removes terminal Neu5Ac from oligosaccharide chains] on the binding of ConA, MAA, PNA, and SNA to IgG, fetuin, and plasminogen (Pg). The presence of terminal α2–3 and α2–6 Neu5Ac can be clearly shown using lectins and NANase treatment. Furthermore, the presence of a cryptic grouping (galactose β1–3 *N*-acetylgalactosamine) on *O*-Linked chains can be demonstrated on fetuin and Pg with PNA after the removal of Neu5Ac. *O*-Linked chains were not detected on IgG, which appears also to lack α2–3 Neu5Ac.
11. Because OPD is carcinogenic, the noncarcinogenic substance, 3,3′,5,5′ -tetramethyl benzidine (dihydrochloride) can be used as a substrate for HRP ***(28)***.

128

Chemical Methods of Analysis of Glycoproteins

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

The first analysis of glycoconjugates that often needs to be carried out is to see if they indeed contain sugar. For glycoproteins in gels or oligosaccharides in solution, this can be readily achieved by periodate oxidation at two concentrations, the first to detect sialic acids, and the second, any monosaccharide that has two free vicinal hydroxyl groups ***(1)***. Periodate cleaves between the hydroxyl groups to yield reactive aldehydes, which can be detected by reduction with NaB^3H_4 or coupled to high sensitivity probes available in commercial kits, e.g., from Boeringher Mannheim (Mannheim, Germany) or Oxford GlycoSciences (Abingdon, UK). In solution, a quick spot assay can be carried out for the presence of any monosaccharide or oligosaccharide having a C-2 hydroxyl group by visualization with charring by phenol/sulfuric acid reagent ***(2)***. These methods are relatively specific for mono/oligosaccharides ***(3)***.

2. Materials

2.1. Periodate Oxidation

1. 0.1 *M* Acetate buffer, pH 5.5, containing 8 or 15 m*M* sodium periodate.
2. Ethylene glycol.
3. 0.1 *M* Sodium hydroxide.
4. Reducing agent: sodium borohydride, tritiated sodium borohydride, or sodium borodeuteride.
5. Glacial acetic acid.
6. Methanol.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2.2. Phenol Sulfuric Acid Assay

1. H_2O (HPLC-grade).
2. 4% Aqueous phenol.
3. Concentrated H_2SO_4.
4. 1 mg/mL galactose.
5. 1 mg/mL mannose.

3. Methods

3.1. Periodate Oxidation

1. Dissolve 0.1–1.0 mg glycoprotein in 2 mL of acetate buffer containing sodium periodate (15 m*M* for all monosaccharides, 8 m*M* for alditols, and 1 m*M* specifically for oxidation of sialic acids).
2. Carry out the periodate oxidation in the dark at room temperature for 1 h for oligosaccharides, or at 4°C for 48 h for alditols, or 0°C for 1 h for sialic acids (*see* **Note 1**).
3. Decompose excess periodate by the addition of 25 µL of ethylene glycol, and leave the sample at 4°C overnight.
4. Add 0.1 *M* sodium hydroxide (about 1.5 mL) until pH 7.0 is reached.
5. Reduce the oxidized compound with 25 mg of $NaB[^3H]_4$ at 4°C overnight (*see* **Note 2**).
6. Add acetic acid to pH 4.0, and concentrate the sample to dryness.
7. Remove boric acid by evaporations with 3 × 100 µL methanol (*see* **Note 3**).

3.2. Phenol/Sulfuric Acid Assay

1. Aliquot a solution of the unknown sample containing a range of approx 1 µg/10 µL into a microtiter plate along with a range of concentrations of a hexose standard (galactose or mannose, usually 1–10 µg).
2. Add 25 µL of 4% aquenous phenol to each well, mix thoroughly, and leave for 5 min (*see* **Note 4**).
3. Add 200 µL of H_2SO_4 to each well, and mix prior to reading on a microtiter plate reader at 492 nm (*see* **Note 5**).

4. Notes

1. It is important that the periodate oxidation is carried out in the dark to avoid unspecific oxidation. The periodate reagent has to be prepared fresh, since it is degraded when exposed to light.
2. The reactive aldehydes can also be detected by coupling to an amine-containing compound, such as digoxigenin ***(1)***.
3. Addition of methanol in an acidic environment leads to the formation of volatile methyl borate.
4. Do not overfill wells during the hexose assay, since the conc. H_2SO_4 will severely damage the microtiter plate reader if spilled.

5. Exercise care when adding the conc. H_2SO_4 to the phenol/alditol mature, since it is likely to "spit," particularly in the presence of salt.

Monosaccharide Analysis by HPAEC

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

Once the presence of monosaccharides has been established by chemical methods (*see* Chapter 128), the next stage of any glycoconjugate or polysaccharide analysis is to find out the amount of sugar and monosaccharide composition. The latter can give an idea as to the type of oligosaccharides present and, hence, indicate further strategies for analysis ***(1)***. Analysis by high-pH anion-exchange chromatography (HPAEC) with pulsed electrochemical detection, that is described here, is the most sensitive and easiest technique ***(2)***. If the laboratory does not have a biocompatible HPLC available that will withstand high salt concentrations, a sensitive labeling technique can be used with gel electrophoresis ***(3)***, e.g., that marketed by Glyko Inc. (Navato, CA) or Oxford GlycoSciences (Abingdon, UK), to include release of oligosaccharides/monosaccharides and labeling via reductive amination with a fluorescence label ***(4)***.

2. Materials

1. Dionex DX500 (Dionex Camberley, Surrey UK) or other salt/biocompatible gradient HPLC system (titanium or PEEK lined), e.g., 2 Gilson 302 pumps with 10-mL titanium pump heads, 802Ti manometric module, 811B titanium dynamic mixer, Rheodyne 7125 titanium injection valve with Tefzel rotor seal (Gilson Medical Electronics, Villiersle-Bel, France).
2. CarboPac PA1 separator (4 × 250 mm) and PA1 guard column (Dionex).
3. Pulsed amperometric detector with Au working electrode (Dionex), set up with the following parameters:
   a. Time = 0 s E = + 0.1 V
   b. Time = 0.5 s E = + 0.1 V
   c. Time = 0.51 s E = + 0.6 V

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

   d. Time = 0.61 s E = + 0.6 V
   e. Time = 0.62 s E = – 0.8 V
   f. Time = 0.72 s E = – 0.8 V
4. Reagent reservoir and postcolumn pneumatic controller (Dionex).
5. High-purity helium.
6. 12.5 *M* NaOH (BDH, Poole, UK).
7. Reagent grade sodium acetate (Aldrich, Poole, UK).
8. HPLC-grade H_2O.
9. 2 *M* Trifluoroacetic acid HPLC-grade.
10. 2 *M* HCl.
11. Dowex 50 W × 12 H^+ of cation-exchange resin.
12. 3.5-mL screw-cap septum vials (Pierce, Chester, UK) cleaned with chromic acid (2 L H_2SO_4/350 mL H_2O/100 g Cr_2O_3) (**Use care! extremely corrosive,** *see* **Note 1**), and coated with Repelcote (BDH, Poole, UK).
13. Teflon-backed silicone septa for 3.5-mL vials (Aldrich).

3. Method

1. Dry down the glycoprotein (10 µg) or oligosaccharide (1 µg) in a clean screw-top vial with Teflon-backed silicone lid insert (*see* **Note 2**).
2. Hydrolyze in an inert N_2 atmosphere for 4 h at 100°C with 2 *M* HCl.
3. Dry the hydrolyzate and re-evaporate three times with HPLC-grade H_2O.
4. Purify on a 1-mL Dowex 50 W × 12 H^+ column eluted in water.
5. Dry down the monosaccharides ready for injection onto the HPLC system.
6. Prepare the following eluants:
   Eluant A = 500 mL HPLC-grade H_2O.
   Eluant B = 500 mL of 50 m*M* NaOH, 1.5 m*M* sodium acetate.
   Eluant C = 100 mL of 100 m*M* NaOH.
7. Degas the eluants by bubbling through helium.
8. Place the postcolumn reagent in a pressurized reagent reservoir (300 mm NaOH) and use the pneumatic controller to adjust helium pressure to give a flowrate of 1 mL/min (approx 10 psi).
9. Equilibrate the column with 98% eluant A and 2% eluant B at a flowrate of 1 mL/min.
10. Add the postcolumn reagent between column and detector cell at a flowrate of 1 mL/min via a mixing tee.
11. Inject approx 100 pmol of monosaccharide and elute isocratically as follows: eluant A = 98%; eluant B = 2%; flowrate = 1 mL/min; for 30 min.
12. Calculate monosaccharide amounts by comparison with a range of known monosaccharide standards run on the same day with deoxyglucose as an internal standard. From this, it is possible to infer the type and amount of glycosylation of the glycoprotein.
13. Regenerate the column in eluant C for 10 min at 1 mL/min (*see* **Note 3**).
14. Re-equilibrate the column with 98%A/2%B before the next injection.

15. At the end of the analysis, regenerate the column in eluant C, and flush pumps with H_2O (*see* **Note 4**).

4. Notes

1. If required, an equivalent detergent-based cleaner may be used.
2. Use polypropylene reagent vessels as far as possible for HPAEC-PAD because of the corrosive nature of the NaOH, and to minimize leaching of contaminants from the reservoirs.
3. Some drift in retention times may be observed during the monosaccharide analysis. This can be minimized by thorough regeneration of the column and use of a column jacket to maintain a stable column temperature.
4. Failure to wash out the eluants from the pumps at the end of an analysis may result in crystallization and serious damage to the pump heads.

Monosaccharide Analysis by Gas Chromatography (GC)

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

Although the methods given in Chapter 129 can give an approximate idea of oligosaccharide amount or composition, they would not be able to distinguish the multiple monosaccharides and substituents present in nature. For this, the high resolution of gas chromatography (GC) is required ***(1,2)***. The most unambiguous results are provided by analysis of trimethylsilyl ethers (TMS) of methyl glycosides with on line mass selective detection (MS).

2. Materials

1. 0.5 *M* Methanolic HCl (Supelco, Bellefont, PA).
2. Screw-top PTFE septum vials.
3. Phosphorus pentoxide.
4. Silver carbonate.
5. Acetic anhydride.
6. Trimethylsilylating (TMS) reagent (Sylon HTP kit, Supelco: pyridine hexamethyldisilazane, trimethylchlorosilane; **use care; corrosive**).
7. Toluene stored over 3-Å molecular sieve.
8. GC apparatus fitted with flame ionization or MS detector and column, e.g., for TMS ethers 25 m × 0.22 mm id BP10 (SGE, Austin, TX) 30 m × 0.2 mm id ultra-2 (Hewlett Packard, Bracknell, Berkshire, UK).

3. Method

1. Concentrate glycoproteins or oligosaccharides containing 1–50 µg carbohydrate and 10 µg internal standard (e.g., inositol or perseitol) in screw-top septum vials. Dry under vacuum in a desiccator over phosphorus pentoxide.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2. Place the sample under a gentle stream of nitrogen, and add 200 µL methanolic HCl (*see* **Note 1**).
3. Cap immediately, and heat at 80°C for 18 h (*see* **Note 2**).
4. Cool the vial, open, and add approx 50 mg Silver carbonate.
5. Mix the contents, and test for neutrality (*see* **Note 3**).
6. Add 50 µL acetic anhydride, and stand at room temperature for 4 h in the dark (*see* **Note 4**).
7. Spin down the solid residue (*see* **Note 5**), and remove the supernatant to a clean vial.
8. Add 100 µL methanol, and repeat **step 7**, adding the supernatants together.
9. Repeat **step 8** and evaporate the combined supernatants under a stream of nitrogen.
10. Dry over phosphorus pentoxide before adding 20 µL TMS reagent.
11. Heat at 60°C for 5 min, evaporate remaining solvent under a stream of nitrogen, and add 20 µL dry toluene.
12. Inject onto a capillary GC column with 14 psi He head pressure and a temperature program from 130 to 230°C over 20 min and held at 230°C for 20 min.
13. Calculate the total peak area of each monosaccharide by adding individual peaks and dividing by the peak area ratio of the internal standard. Compare to standard curves for molar calculation determination.

4. Notes

1. The use of methanolic HCl for cleavage of glycosidic bonds and oligosaccharide-peptide cleavage yields methyl glycosides and carboxyl group methyl esters, which gives acid stability to the released monosaccharides, and thus, monosaccharides of different chemical lability can be measured in one run. If required as free reducing monosaccharides (e.g., for HPLC), the methyl glycoside can be removed by hydrolysis. The reagent can be obtained from commercial sources or made in laboratory by bubbling HCl gas through methanol until the desired pH is reached or by adding a molar equivalent of acetyl chloride to methanol.
2. An equilibrium of the α and β methyl glycosides of monosaccharide furanose (*f*) and pyranose (*p*) rings is achieved after 18 h so that a characteristic ratio of the four possible (fα, fβ, pα, pβ) molecules is formed to aid in unambiguous monosaccharide assignment.
3. Solid-silver carbonate has a pink hue in an acidic environment, and, therefore, neutrality can be assumed when green coloration is achieved.
4. The acidic conditions remove *N*-acetyl groups, which are replaced by acetic anhydride. This means that the original status of *N*-acetylation of hexosamines and sialic acids is not determined in the analysis procedure. If overacetylation occurs, the time can be reduced.
5. Direct re-*N*-acetylation by the addition of pyridine-acetic anhydride 1:1 in the absence of silver carbonate can be achieved, but this gives more variable results.

Determination of Monosaccharide Linkage and Substitution Patterns by GC-MS Methylation Analysis

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

The GC or GC-MS method discussed in Chapter 130 can distinguish substituted monosaccharides, but to characterize the position of acyl groups together with the linkages between the monosaccharides, a strategy has been developed to "capture" the substitution pattern by methylation of all free hydroxyl groups. The constituent monosaccharides are then analyzed after hydrolysis, reduction, and acetylation as partially methylated alditol acetates in a procedure known as methylation analysis ***(1–3)***.

2. Materials

1. DMSO.
2. Methyl iodide.
3. Sodium hydroxide (anhydrous).
4. Chloroform.
5. Acetonitrile.
6. Pyridine.
7. Ethanol.
8. Water.
9. V-bottomed reacti-vials (Pierce [Rockford, IL]) with Teflon-backed silicone lid septa.
10. Sodium borodeuteride.
11. Ammonium hydroxide.
12. Trifluoroacetic acid.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

13. Acetic acid.
14. GC-MS (e.g., Hewlett Packard 5890/5972A with ultra-2 or HP-5MS capillary column).

3. Method

1. Dry 20 nmol pure, desalted oligosaccharide into "V"-bottomed reacti-vials in a dessicator containing P_2O_5.
2. Resuspend samples into 150 µL of a suspension of powdered NaOH/anhydrous DMSO (approx 60 mg/mL) under an inert atmosphere (*see* **Note 1**).
3. Add 75 µL of methyl iodide (care) and sonicate for 15 min (*see* **Note 2**).
4. Extract the permethylated glycans with 1 mL $CHCl_3$ 3 mL H_2O, washing the aqueous phase with 3 × 1 mL $CHCl_3$. Wash the combined $CHCl_3$ washes with 3 × 5 mL H_2O (*see* **Note 3**).
5. Dry the $CHCl_3$ phase under N_2 after taking an aliqout for liquid secondary ion mass spectrometry (LSIMS) (*see* **Note 4**).
6. Hydrolyze for 1 h in 2 *M* TFA at 100°C.
7. Reduce samples with 50 m*M* $NaBD_4$/50 m*M* NH_4OH (*see* **Note 5**) at 4°C or 4 h at room temperature.
8. Evaporate once from AcOH and three times from 1:10 AcOH/MeOH.
9. Re *N*-acetylate samples with 50:50 acetic anhydride/pyridine 100°C, 90 min.
10. Analyze samples by GC-MS on low-bleed 5% capillary column (e.g., HP ultra-2 or HP5-MS or equivalent), with either on-column or splitless injection and a temperature gradient from to 50–265°C over 21 min, held for a further 10 min, and a constant gas flow of 1 mL/min into the MS. Ionization is in EI mode and a mass range of 45–400 (*see* **Note 6**).

4. Notes

1. The NaOH can be powdered either in a mortar and pestle or glass homogenizer and thoroughly vortexed with the DMSO prior to addition to the glycan.
2. If at the end of the methylation a yellow color is present, the reaction can be stopped by adding a crystal of sodium thiosulfate with aqueous extraction.
3. The permethylated oligosaccharides may also be purified on a Sep-Pak C_{18} column (Waters, Wafford, UK) by elution of permethylated oligosaccharides with acetonitrile or acetonitrile–water mixture.
4. The reaction with the NaOH/DMSO suspension deprotonates all the free hydroxyl groups and NH of acetamido groups forming an unstable carbanion. The addition of methyl iodide then rapidly reacts with the carbanions to form O-Me groups, and thus, permethylate the oligosaccharide. When subjected to LSIMS, these permethylated oligosaccharides will fragment about their glycosidic bonds particularly at hexosacetamido residues. This means each oligosaccharide generates a unique fragmentation pattern allowing the determination of the oligosaccharide sequence. For example, the

oligosaccharide Hex-HexNAc-HexNAc-Hex will generate the following fragments: Hex-HexNAc and Hex-HexNAc-HexNAc, where Hex denotes a hexose residue and HexNAc an *N*-acetylhexosamine.

5. The reduction can also be carried out with 50 m*M* NaOH, but this is not volatile and is harder to remove prior to further derivitization.
6. The hydrolysis step generates monosaccharides with the hydroxyl groups involved in the glycosidic linkages still retaining their protons. Reduction of these monosaccharides with $NaBD_4$ will break the ring structure to form monosaccharide alditols with the anomeric (C_1) carbon being monodeuterated. Acetylation of the free hydroxyls to *O*-acetyl groups completes the derivitization. The retention times of the PMAAs on the GC allow the assignment of the monosaccharide type (galactose, *N*-acetylgalactosamine, and so on). On-line mass spectrometric detection identifies fragment ions formed by the cleavage of C—C bonds of the monosaccharide alditols with the preference: methoxy-methoxy > methoxy-acetoxy > acetoxy-acetoxy. The resulting spectra are diagnostic for the substitution pattern, and hence, the previous position of linkage, e.g., a 2-linked hexose will produce a different set of ions to a 3-linked hexose, and a 2,3-linked hexose being different again. Selected ions from the spectra of all commonly occurring linkages can be used to analyze across the chromatogram (selected ion monitoring).

132

Sialic Acid Analysis by HPAEC-PAD

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

The most labile monosaccharides are the family of sialic acids, which are usually chain-terminating substituents. These are therefore usually released first by either mild acid hydrolysis or enzyme digestion, and can be analyzed with great sensitivity by high pH anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD ***[1, 2]***). The remaining oligosaccharide is analyzed as discussed in Chapter 131 to identify the position of linkage of the sialic acid.

2. Materials

1. HCl (0.01, 0.1, and 0.5 *M*).
2. 100 m*M* NaOH.
3. 1 *M* NaOAc.
4. HPLC and PA1 columns as described in Chapter 129.

3. Method

1. Dry the glycoprotein into a clean screw-top vial with a Teflon-backed silicone lid insert (*see* **Note 1**).
2. Release the sialic acids by hydrolysis with 0.01 or 0.1 *M* HCl for 60 min at 70°C in an inert N_2 atmosphere (*see* **Note 2**).
3. Dry down the hydrolysate, and wash three times with HPLC-grade H_2O.
4. Prepare 500 mL of 100 m*M* NaOH, 1.0 *M* sodium acetate (eluant A).
5. Prepare 500 mL of 100 m*M* NaOH (eluant B).
6. Degas eluants by bubbling helium through them in their reservoirs (*see* **Note 3**).
7. Regenerate the HPLC column in 100% eluant B for 30 min at a flow rate of 1 mL/min.
8. Equilibrate the column in 95% eluant B for 30 min at a flow rate of 1 mL/min (*see* **Note 4**).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

9. Inject approx 0.2 nmol of sialic acid onto the column, and elute using the following gradient at a flow rate of 1 mL/min:
   a. Time = 0 min; 95% eluant B.
   b. Time = 4 min; 95% eluant B.
   c. Time = 29 min; 70% eluant B.
   d. Time = 34 min; 70% eluant B.
   e. Time = 35 min; 100% eluant B.
   f. Time = 44 min; 100% eluant B.
   g. Time = 45 min; 95% eluant B; 1 mL/min.
10. Quantitate the sialic acids by comparison with known standards run on the same day.
11. When the baseline has stabilized, the system is ready for the next injection.
12. When the analyses have been completed, regenerate the column in eluant B, and flush pumps with HPLC-grade H_2O (*see* **Note 5**).

4. Notes

1. If problems with contaminants are encountered, it may be necessary to wash the vials with chromic acid overnight, wash them thoroughly with distilled water, and then treat with a hydrophobic coating, such as repelcoat (*see* Chapter 129).
2. 0.01 *M* HCl will release sialic acids with intact *N*- or *O*-acyl groups, but without quantitative release of the sialic acids. These can also be detected by HPAEC-PAD ***(3)***. At 0.1 *M* HCl, quantitive release is achieved, but with some loss of *O*- and *N*-acylation. At this concentration, some fucose residues may also be labile. Alternatively, the sialic acids can be released by neuraminidase treatment, which can be specific for α2–6 or α2–3 linkage, e.g., with α-sialidase of *Arthrobacter ureafacians* for α2–6 and α-sialidase of Newcastle disease virus for α2–3 using the manufacturer's instructions.
3. Use polypropylene reagent vessels as far as possible for HPAEC-PAD because of the corrosive nature of the NaOH, and to minimize leaching of contaminants from the reservoirs.
4. For maximum efficiency of detection, always ensure that the PAD reference electrode is accurately calibrated, the working electrode is clean, and the solvents are thoroughly degassed.
5. Failure to wash out the eluants from the pumps at the end of an analysis may result in crystallization and serious damage to the pump heads.

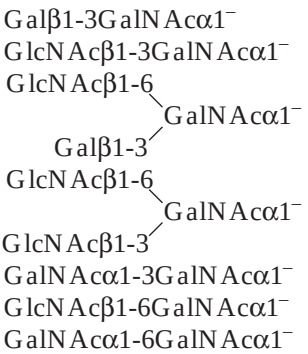
Chemical Release of *O*-Linked Oligosaccharide Chains

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

O-linked oligosaccharides having the core sequences shown below can be released specifically from protein via a β-elimination reaction catalyzed by alkali. The reaction is usually carried out with concomitant reduction to prevent peeling, a reaction caused by further β-elimination around the ring of 3-substituted monosaccharides ***(1).*** The reduced oligosaccharides can be specifically bound by solid sorbent extraction on phenylboronic acid (PBA) columns ***(2).***

O-linked protein glycosylation core structures linked to Ser/Thr:



2. Materials

1. 1 *M* $NaBH_4$ (Sigma, Poole, UK) in 50 m*M* NaOH. This is made up fresh each time from 50% (w/v) NaOH and HPLC-grade H_2O.
2. Methanol (HPLC-grade containing 1% acetic acid).
3. Acetic acid.
4. 1 mL Dowex H^+ (50 W × 12) strong cation ion-exchange column (Sigma, St. Louis, MO).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

5. Bond elute phenyl boronic acid column (Jones Chromatography, Hengoed, UK; activated with MeOH).
6. 0.1 *M* HCl.
7. 0.2 *M* NH_4OH.
8. 0.1 *M* Acetic acid.
9. Methanol.

3. Method

1. Dry the glycoprotein (100 µg to 1 mg) in a screw-topped vial and resuspend in 100 µL 50 m*M* NaOH containing 1 *M* $NaBH_4$ (*see* **Notes 1** and **2**).
2. Incubate at 55°C for 18 h.
3. Quench the reduction by the addition of ice-cold acetic acid until no further effervescence is seen.
4. Dry the reaction mixture down, and then wash and dry three times with a 1% acetic acid, 99% methanol solution to remove methyl borate.
5. Resuspend the alditols in H_2O, and pass down a 1-mL H^+ cation exchange resin. The alditols will not be retained and will elute by washing the column with water.
6. Dry the alditols and resuspend them in 100 µL of 0.2 *M* NH_4OH.
7. Activate a phenyl boronic acid (PBA) column with 2 × 1 mL MeOH.
8. Equilibrate the PBA column with 2 × 1 mL 0.1 *M* HCl, 2 × 1 mL H_2O, and 2 × 1 mL 0.2 *M* NH_4OH.
9. Add the sample in 100 µL 0.2 *M* NH_4OH and elute with 2 × 100 µL 0.2 *M* NH_4OH, 2 × 100 µL H_2O, and 6 × 100 µL 0.1 *M* Acetic acid. Collect these fractions and test for monosaccharide (Chapter 128) or combine and analyze according to Chapter 134.
10. Regenerate the PBA column with 0.1 *M* HCl and 2 × 1 mL H_2O before storing and reactivation in 2 × 1 mL MeOH.

4. Notes

1. The $NaBH_4$/NaOH solution is made up <6 h before it is required.
2. Reduction with NaB^3H_4 allows the incorporation of a radioactive label into the alditol to enable a higher degree of sensitivity to be achieved while profiling.
3. Protein degradation can be minimized by the omission of the $NaBH_4$, although this results in the degradation of sugar chains having a 3-substituted GalNAc-Ser/Thr, i.e., most types. The addition of 6 m*M* Cadmium acetate, 6 m*M* Na_2EDTA to the $NaBH_4$/NaOH solution reduces protein degradation without the loss of oligosaccharide alditol.

2. Stoll, M. S. and Hounsell, E. F. (1988) Selective purification of reduced oligosaccharides using a phenylboronic acid bond elut column: potential application in HPLC, mass spectrometry, reductive amination procedures and antigenic/serum analysis. *Biomed. Chromatogr.* **2,** 249–253.

134

O-Linked Oligosaccharide Profiling by HPLC

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

The several different core regions of *O*-linked chains (Chapter 133) can be further extended by Gal and GlcNAc containing backbones or by addition of blood group antigen-type glycosylation and the presence of sialic acid or sulfate. We sought a universal column that can be applied with high resolution to the various oligosaccharide alditols released from glycoproteins by β-elimination (*see* **Note 1**) and have pioneered ***(1, 2)*** the use of porous graphitized carbon (PGC). This is an alternative to C_{18} reversed-phase HPLC and normal-phase amino-bonded columns, which can be used together in the presence and absence of high-salt buffers ***(3)***.

2. Materials

1. Gradient HPLC system: e.g., 2 × 302 pumps, 802C manometric module, 811 dynamic mixer, 116 UV detector, 201 fraction collector, 715 chromatography system control software (all Gilson Medical Electronics, Villiers-le-Bel, France).
2. IBM PS-2 personal computer (or compatible model) with Microsoft Windows.
3. Hypercarb S HPLC Column (100 × 4.6 mm) (Shandon Scientific, Runcorn, Cheshire, England) or Glycosep H (100 × 3 mm, Oxford Glycosystems, Abingdon, UK).
4. HPLC-grade H_2O.
5. HPLC-grade acetonitrile.
6. HPLC-grade trifluoroacetic acid (Pierce and Warriner, Chester, UK).

3. Methods

1. Prepare eluant A: 500 mL of 0.05% TFA.
2. Prepare eluant B: 250 mL of acetonitrile containing 0.05% TFA.
3. Degas eluants by sparging with helium.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

4. Equilibrate the column in 100% eluant A and 0% eluant B for 30 min at 0.75 mL/min prior to injection samples.
5. Elute 10 nmol oligosaccharide alditol (obtained as in Chapter 133) with the following gradient at a flow rate of 0.75 mL/min and UV detection at 206 nm/0.08 AUFS.
   a. Time = 0 min A = 100%; B = 0%
   b. Time = 5 min A = 100%; B = 0%
   c. Time = 40 min A = 60%; B = 40%
   d. Time = 45 min A = 60%; B = 40%
   e. Time = 50 min A = 100%; B = 0%
6. The resulting oligosaccharide containing fractions are then derivatized for LSIMS and GC-MS or analyzed by NMR.

4. Note

1. The GalNAc residue linked to Ser/Thr in *O*-linked chains is normally substituted at least at C-3 and therefore the alkali catalyzed β-elimination reaction will also result in "peeling" of the released oligosaccharide. This is obviated by concomitant reduction to give oligosaccharide alditols ending in GalNAc-ol. Endo-α-*N*-acetylgalactosaminidase digestion at hydrazinolysis under mild conditions can be used to release intact reducing sugars, which will have longer retention times on HPLC ***(4)***.

135

O-Linked Oligosaccharide Profiling by HPAEC-PAD

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

Although it can often be an advantage to be able to chromatograph neutral and sialylated oligosaccharides/alditols in one run (*see* Chapter 134), the added resolution of HPAEC and sensitivity with PAD detection means that this is an additional desirable technique for analysis. Neutral oligosaccharide alditols are poorly retained on CarboPac PA1, but can be resolved on two consecutive columns ***(1)***. The carboPac PA1 column is ideal for sialylated oligosaccharides ***(2)*** and can also be used for sialylated alditols.

2. Materials

1. Dionex D500 (Dionex, Camberley Surrey, UK) or other salt/biocompatible gradient HPLC system (titanium or PEEK) lined, e.g., 2 Gilson 302 pumps with 10-mL titanium pump heads, 802Ti manometric module, 811B titanium dynamic mixer, Rheodyne 7125 titanium injection valve with Tefzel rotor seal, and Gilson 712 chromatography system control software (Gilson Medical Electronics, Villiers-le-Bel, France).
2. CarboPac PA1 separator (4 × 250 mm) and PA1 Guard column (Dionex).
3. Pulsed amperometric detector with Au working electrode (Dionex), set up with the following parameters:
   a. Time = 0 s E = +0.1 V
   b. Time = 0.5 s E = +0.1 V
   c. Time = 0.51 s E = +0.6 V
   d. Time = 0.61 s E = +0.6 V
   e. Time = 0.62 s E = −0.8 V
   f. Time = 0.72 s E = −0.8 V
4. Anion micromembrane suppressor 2 (AMMS2) (Dionex).
5. Autoregen unit with anion regenerant cartridge (Dionex).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

6. High-purity helium.
7. NaOH 50% w/v.
8. Reagent-grade sodium acetate (Aldrich, Poole, UK).
9. HPLC-grade H_2O.
10. 500 mL of 50 m*M* H_2SO_4 (reagent-grade).

3. Methods

1. Prepare eluant A: 100 m*M* NaOH, 500 m*M* Sodium acetate.
2. Prepare eluant B: 100 m*M* NaOH.
3. Prepare the column by elution with 50% A/50% B for 30 min at a flow rate of 1 mL/min.
4. Equilibrate column is 5% eluant A/95% eluant B at a flow of 1 mL/min.
5. Connect the AMMS2 to eluant out line and autoregen unit containing 500 mL of 50 m*M* reagent-grade H_2SO_4, and pump regenerant at a flow of 10 mL/min (*see* **Note 1**).
6. Inject 200 pmol of each oligosaccharide or sialylated oligosaccharide alditol (more if required for NMR or LSIMS), and elute with the following gradient at a flow of 1 mL/min:
   a. Time = 0 min A = 5%; B = 95%
   b. Time = 15 min A = 5%; B = 95%
   c. Time = 50 min A = 40%; B = 60%
   d. Time = 55 min A = 40%; B = 60%
   e. Time = 58 min A = 0%; B = 100%
7. Equilibrate the column in 5%A/95%B prior to the next injection.
8. At the end of the analyses, regenerate the column in 100%, and flush at the pumps with H_2O.
9. Desalt oligosaccharide-containing fractions by AMMS, and derivatize for LSIMS and GC-MS.

4. Notes

1. A better desalting profile may be achieved with an AMMS membrane (rather than AMMS2) if a flow rate of <1 mL/min can be used. In addition, it is important that the membranes of the suppressor remain fully hydrated and that the regenerant solution is replaced about once a week.

Release of *N*-Linked Oligosaccharide Chains by Hydrazinolysis

Tsuguo Mizuochi and Elizabeth F. Hounsell

1. Introduction

Hydrazinolysis is the most efficient method of releasing all classes of *N*-linked oligosaccharide chains from glycoproteins. Disadvantages compared to enzymic release (*see* Chapter 137) is the use of hazardous chemicals, break up of the protein backbone, and destruction of some chains. The first of these can be obviated by use of a commercial machine for hydrazinolysis—the Glyco Prep (Oxford GlycoSystems, Abingdon, UK), but this is expensive, and as long as caution is exercised, the following method is excellent ***(1)***.

2. Materials

1. Anhydrous hydrazine (*see* **Note 1**).
2. Toluene.
3. Saturated sodium bicarbonate solution prepared at room temperature.
4. Acetic anhydride.
5. 1-Octanol.
6. Lactose.
7. 1 *N* Acetic acid.
8. 1 *N* NaOH.
9. Methanol.
10. NaOH (0.05 *N*) freshly prepared from 1 *N* NaOH just before use.
11. Sodium borotritide (NaB^3H_4, approx 22 GBq/mmol) and approx 40 m*M* in dimethylformamide (silylation grade # 20672, Pierce Chemical Co., Rockford, IL).
12. 1-Butanol:ethanol:water (4:1:1, v/v).
13. Ethyl acetate:pyridine:acetic acid:water (5:5:1:3 v/v).
14. Dowex 50W-X12 (H^+ form, 50–100 mesh).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

15. Whatman 3MM chromatography paper.
16. Air-tight screw-cap tube with a Teflon disk seal.
17. Dry heat block capable of maintaining 100°C.
18. Vacuum desiccator.
19. High-vacuum oil pump.
20. Descending paper chromatography tank.

3. Method (*see* ref. 1)

1. Add the glycoprotein (0.1–100 mg) to an air-tight screw-cap tube with a Teflon disk seal, and dry *in vacuo* overnight in a desiccator over P_2O_5 and NaOH.
2. Add anhydrous hydrazine (0.2–1.0 mL) with a glass pipet. The pipet must be dried to avoid introducing moisture into the anhydrous hydrazine (*see* **Note 2**).
3. Heat at 100°C for 10 h using a dry heat block. Glycoprotein is readily dissolved at 100°C.
4. Remove hydrazine by evaporation *in vacuo* in a desiccator. To protect the vacuum oil pump from hydrazine, connect traps between the desiccator and the pump in the following order: cold trap with dry ice and methanol, concentration, H_2SO_4-trap, and NaOH-trap on the desiccator side. Remove the last trace of hydrazine by coevaporation with several drops of toluene.
5. To re-*N*-acetylate, dissolve the residue in ice-cold saturated $NaHCO_3$ solution (1 mL/mg of protein). Add 10 µL of acetic anhydride, mix, and incubate for 10 min at room temperature. Re-*N*-acetylation is continued at room temperature by further addition of 10 µL (three times) and then 20 µL (three times) of acetic anhydride at 10-min intervals. The total volume of acetic anhydride is 100 µL/1 mL of saturated $NaHCO_3$ solution. Keep the solution on ice until the addition of acetic anhydride to avoid epimerization of the reducing terminal sugar.
6. To desalt, pass the reaction mixture through a column (1 mL for 1 mL of the $NaHCO_3$ solution) of Dowex 50W-X12, and wash with five column bed volumes of distilled water. Evaporate the effluent to dryness under reduced pressure at a temperature below 30°C. Addition of a drop of 1-octanol is effective in preventing bubbling over.
7. Dissolve the residue in a small amount of distilled water, and spot on a sheet of Whatman 3MM paper. Perform paper chromatography overnight using 1-butanol:ethanol:water (4:1:1, v/v) as developing solvent (*see* **Note 3**).
8. Cut the area 0–4 cm from the origin, recover the oligosaccharides by elution with distilled water, and then evaporate to dryness under reduced pressure. On this chromatogram, lactose migrates <4 cm from the origin.
9. To label oligosaccharides with tritium, dissolve the oligosaccharide fraction thus obtained in 100 µL of ice-cold 0.05 *N* NaOH (freshly prepared from 1 *N* NaOH). Verify that the pH of the oligosaccharide solution is above 11 with pH test paper using a <1-µL aliquot. If not, adjust the pH paper as 0.05 *N* NaOH. After addition of NaOH solution, keep the oligosaccharide solution on ice; otherwise, part of the reducing terminal *N*-acetylglucosamine may be converted to *N*-acetylmannosamine by epimerization (*see* **Note 4**).

10. Add a 20 *M* excess of NaB^3H_4 solution to the oligosaccharide solution, mix, and incubate at 30°C for 4 h to reduce the oligosaccharides. Then, add an equal weight of $NaBH_4$ (20 mg/mL of 0.05 *M* NaOH, freshly prepared) as the original glycoprotein, and continue the incubation for an additional 1 h to reduce the oligosaccharides completely. Stop the reaction by acidifying the mixture with 1 *N* acetic acid. During the reduction, and addition of acetic acid, keep the reaction mixture in a draft chamber, since tritium gas is generated (*see* **Note 5**).
11. To desalt, apply the reaction mixture to a small Dowex 50W-X12 column, and wash with five column bed volumes of distilled water, and then evaporate the effluent under reduced pressure below 30°C. The volume of the column should be calculated based on the amount of NaOH and $NaBH_4$, and the capacity of the resin. Then, remove the boric acid by repeated (three to five times) evaporation with methanol under reduced pressure. Dimethyl formamide used to dissolve NaB^3H_4 is usually coevaporated during the repeated evaporation.
12. Dissolve the residue in a small amount of distilled water, spot on a sheet of Whatman 3MM paper, and perform paper chromatography overnight using ethyl acetate: pyridine:acetic acid:water (5:5:1:3, v/v) as developing solvent. This procedure is effective in removing the radioactive components originating from NaB^3H_4, which migrate a significant distance on the chromatogram.
13. Recover radioactive oligosaccharides, which migrate slower than lactitol (about 20 cm from origin), from the paper by elution with distilled water, and evaporate to dryness under reduced pressure.
14. Finally, subject the radioactive *N*-linked oligosaccharides thus obtained to high-voltage paper electrophoresis at pH 5.4 or HPLC to separate oligosaccharides by charge.

4. Notes

1. Anhydrous hydrazine is prepared by mixing 80% hydrazine hydrate (50 g), toluene (500 g), and CaO (500 g) and allowing to stand overnight. The mixture is refluxed for 3 h using a cold condenser and an NaOH tube. The mixture is then subjected to azeotropic distillation with toluene at 93–94°C under anhydrous conditions. Anhydrous hydrazine is collected from the bottom layer and stored in an air-tight screw-cap tube with a Teflon disk seal under dry conditions at 4°C in the dark. Commercially available anhydrous hydrazine (such as that from Aldrich Chemical Co., Inc., Milwaukee, WI) can also be used. It is important to check the quality with a glycoprotein of which the oligosaccharide structure has already been established before using for analysis, because contamination by trace amounts of water in some lots could modify the reducing terminal *N*-acetylglucosamine of *N*-linked oligosaccharides.

   Caution: Anhydrous hydrazine is a strong reducing agent, highly toxic, corrosive, suspected to be carcinogenic, and flammable. Therefore, great caution should be exercised during handling.

2. When stored in a small air-tight tube with a Teflon disk seal at −18°C, this NaB^3H_4 solution is stable for at least 1 yr. Dimethylformamide should be stored with molecular sieves in a small screw-cap bottle with a Teflon disk seal under dry conditions.
3. This procedure is indispensable for the next tritium-labeling step of the liberated oligosaccharides. This is because oligosaccharides larger than trisaccharides remain very close to the origin, whereas the degradation products derived from the peptide moiety, which react with NaB^3H_4, move a significant distance on the paper.
4. For quantitative liberation of intact *N*-linked oligosaccharides from glycoproteins by hydrazinolysis, great care should be taken to maintain anhydrous condition until the re-*N*-acetylation step. Introduction of moisture into glycoprotein samples or anhydrous hydrazine results in diverse modifications of reducing terminal *N*-acetylglucosamine residues, especially when unsubstituted with an Fucα 1–6 group, and causes the release of *O*-linked oligosaccharides accompanied with various degradations of the reducing end.
5. When oligosaccharides are reduced by NaB^3H_4 with high specific activity (e.g., 555 GBq/mmol), the sensitivity of detection of oligosaccharides increases about 20-fold. To label oligosaccharides with tritium at high efficiency, it is recommended to keep the concentration of NaB^3H_4 high in the incubation mixture by reducing the volume of 0.05*N* NaOH (e.g., to the same volume as the NaB^3H_4 solution). A 20 *M* excess of NaB^3H_4 solution is required for complete reduction of *N*-linked oligosaccharides, whereas a 5 *M* excess of NaB^3H_4 solution required for complete reduction of *N*-linked oligosaccharides derived from glycoprotein samples is roughly estimated from data on the carbohydrate content or amino acid sequence. If generation of tritium gas is to be avoided, continue the incubation for an additional 1 h with large amounts of glucose to absorb excess NaB^3H_4 before acidifying the mixture.

Enzymatic Release of *O*-and *N*-Linked Oligosaccharide Chains

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

Enzymes involved in both the synthesis and degradation of glycoconjugates are highly specific for monosaccharide, linkage position, and anomeric configuration factors further away in the oligosaccharide sequence or protein. Not withstanding this, endo- and exoglycosidases are extremely useful tools in structural analysis. The RAAM technique has automated the use of exoglycosidase digestion (Oxford Glycosystems, Abingdon, UK). Here we discuss the release of intact oligosaccharide chains from proteins that can be further analyzed for separate functions ***(1,2)***.

2. Materials

2.1. Desalting

1. mL Spectra/Chrom desalting cartridge (Orme, Manchester, UK) or Biogel P_{-2} minicolumn.
2. HPLC-grade H_2O.

2.2. Glycosidases

1. Endoglycosidase H (EC 3.2.1.96) (e.g., *E. coli,* Boehringer Mannheim, Lewes, UK). Digestion buffer: 250 m*M* sodium citrate buffer adjusted to pH 5.5 with 1 *M* HCl.
2. Test-neuraminidase (EC 3.2.1.18) (e.g., *Vibrio cholerae,* Behring Ag, Marburg, Germany). Made up as 1 U/mL enzyme in digestion buffer and stored at 4°C. Digestion buffer: 50 m*M* sodium acetate, 134 m*M* NaCl, 9 m*M* $CaCl_2$.
3. Peptide-*N*-glycosidase F (EC 3.2.2.18) (e.g., *Flavobacterium meningosepticum,* Boehringer Mannheim). Digestion buffer: 40 m*M* potassium dihydrogen orthophosphate (KH_2PO_4), 10 m*M* EDTA adjusted to pH 6.2 with 1.0 *M* NaOH.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

4. *O*-glycosidase (EC 3.2.1.97) (e.g., *Diplococcus pneunomiae,* Boehringer Mannheim). Digestion buffer: 40 m*M* KH_2PO_4/10 m*M* EDTA adjusted to pH 6.0 with 1.0 *M* NaOH.
5. Ice-cold ethanol.
6. Toluene.

3. Methods

3.1. Desalting

1. Wash the cartridge with 5 mL of HPLC-grade H_2O.
2. Load the sample onto the cartridge in a volume between 50 and 200 µL H_2O.
3. Elute the column with 200 µL of H_2O (including sample load).
4. Elute the glycoprotein in 350 µL of H_2O.
5. Elute the salt with an additional 1 mL of H_2O.

3.2. Glycosidase Digestions

1. Dissolve 1 nmol of glycoprotein in 100 µL of H_2O, and boil for 30 min to denature. Remove a 10% aliquot for sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), as a control for detection of enzyme digestion. Dry the remainder by lyophilization (*see* **Note 1**).
2. Resuspend the glycoprotein in 500 µL of Endo H digestion buffer and 5 µL of toluene. Add 1 mU of Endo H/l nmol glycoprotein, and incubate at 37°C for 72 h (*see* **Notes 2** and **3**).
3. Precipitate the protein with a twofold excess of ice-cold ethanol and centrifuge at 15,000g for 20 min. Wash the pellet three more times with ice-cold ethanol. Dry the protein pellet, take up in water, and aliquot 10% (relative to original amount) for SDS-PAGE.
4. Dry the remaining pellet, and resuspend in neuraminidase/neuraminidase digestion buffer at a concentration of 2 nmol of glycoprotein/10 µL of buffer. Incubate for 18 h at 37°C, and then ethanol-precipitate and aliquot as in **step 3**.
5. Resuspend the remaining glycoprotein in 500 µL of PNGase F digestion buffer, 5 µL toluene, and 1 U PNGase F/10 nmol glycoprotein. Incubate at 37°C for 72 h before precipitation and aliquoting as in **step 3** (*see* **Note 4**).
6. Digest the final pellet with *O*-glycosidase under the same conditions as for the PNGase F digestion. Precipitate the pellet from ethanol washing and dry.
7. Apply all the pellet to SDS-PAGE.
8. The supernatants containing *N*- and *O*-linked oligosaccharides can be analyzed as discussed in Chapters 111, 118, and 119.

4. Notes

1. The described procedure assumes approx 10% glycosylation of the glycoprotein. The amount of glycoprotein treated may have to be increased to obtain oligosaccharides for further analysis with less highly glycosylated glycoproteins.

2. PNGase F is stored at –20°C, and all other enzymes at 4°C. Endo H removes high-mannose oligosaccharide chains, but not complex type.
3. The toluene is added to prevent bacterial growth.
4. The PNGase F digestion can be performed directly on the boiled glycoprotein if all *N*-linked glycoprotein chains (both high mannose and complex) are required to be removed. Digests may also be performed in 0.2 *M* sodium phosphate buffer, pH 8.4, but this will result in the release of sialic acid residues as monosaccharides.

N-Linked Oligosaccharide Profiling by HPLC on Porous Graphitized Carbon (PGC)

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

The vast array of possible *N*-linked oligosaccharides demands high-resolution HPLC columns for their purification ***(1,2)***. Reverse-phase (C_{18}) and normal-phase (NH_2) columns have been used for the separation (singly or in concert) of many *N*-linked oligosaccharides. The porous graphitized carbon (PGC) column described in Chapter 134 for *O*-linked alditol separation will give improved *N*-linked oligosaccharide resolution over C_{18} columns, and has the advantage of using salt-free buffers for preparative work ***(3,4)***.

2. Materials

1. Biocompatible gradient HPLC system, e.g., 2 × 302 pumps, 802C manometric module, 811 dynamic mixer, 116 UV detector, 201 fraction collector, 715 chromatography system control software (all Gilson Medical Electronics, France).
2. IBM PS-2 personal computer (or compatible model) with Microsoft Windows.
3. Hypercarb S HPEC Column (100 × 4.6 mm) (Shandon Scientific, Runcorn, Cheshire, England) or Glyco H (OGS, Abingdon, Oxon, UK).
4. HPLC-grade H_2O.
5. HPLC-grade acetonitrile.
6. HPLC-grade trifluoroacetic acid (Pierce and Warriner, Chester, UK).

3. Methods

1. Prepare eluant A: 500 mL of 0.05% TFA.
2. Prepare eluant B: 250 mL of acetonitrile containing 0.05% TFA.
3. Degas eluants by sparging with helium.
4. Equilibrate the column in 100% eluant A, and 0% eluant B for 30 min at 0.75 mL/min prior to injection of samples.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

5. Elute 10 nmol oligosaccharides with the following gradient at a flow rate of 0.75 mL/min and UV detection at 206 nm/0.08 AUFS (*see* **Note 1**).
   a. Time = 0 min A = 100%; B = 0%
   b. Time = 5 min A = 100%; B = 0%
   c. Time = 40 min A = 60%; B = 40%
   d. Time = 45 min A = 60%; B = 40%
   e. Time = 50 min A = 100%; B = 0%
6. The resulting oligosaccharide containing fractions are then derivatized for LSIMS and GC-MS or analyzed by NMR.

4. Notes

1. Reverse-phase or normal-phase HPLC may also be required for the complete separation of some oligosaccharide isomers.
2. To prevent anomerization, the oligosaccharides can be reduced to their alditols (either after PNGase F digestion or hydrazinolysis). The inclusion of a ^{3}H-label on reduction will give increased sensitivity over UV. Alternatively, the oligosaccharides can be fluorescently labeled at their reducing terminus (with 2-amino-benzamide or 2-amino-pyridine) by reductive amination to give a fluorescent chromophore and increased sensitivity. Sensitivity of detection may also be increased by the postcolumn addition of 300 m*M* NaOH and pulsed amperometric detection as described for HPAEC-PAD.

N-Linked Oligosaccharide Profiling by HPAEC-PAD

Elizabeth F. Hounsell, Michael J. Davies, and Kevin D. Smith

1. Introduction

High-pH anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD) is a very powerful tool for the profiling of *N*-linked oligosaccharides ***(1, 2)***, only being limited by the concentrated sodium hydroxide and sodium acetate required to achieve the separation and sensitive detection. Oligosaccharides are separated on the basis of charge (i.e., the number of sialic acid residues) and the linkage isomers present. Neutral oligosaccharide alditols are most weakly retained, retention increasing with increasing sialylation, and NeuGc- and sulfate-bearing oligosaccharides being most strongly retained. Fucosylation results in a shorter retention. If the oligosaccharides can be effectively desalted after HPAEC-PAD, this remains the method of choice for oligosaccharide purification, and is a very powerful analytical tool.

2. Materials

1. Dionex DX300 or salt/biocompatible gradient HPLC system (titanium or PEEK lined), e.g., 2 Gilson 302 pumps with 10-mL titanium pump heads, 802Ti manometric module, 811B titanium dynamic mixer, Rheodyne 7125 titanium injection valve with Tefzel rotor seal, and Gilson 715 chromatography system control software (all Gilson Medical Electronics, Villiersle-Bel, France).
2. IBM PS-2 personal computer (or compatible model) with Microsoft Windows.
3. CarboPac PA100 separator (4 × 250 mm) and PA100 guard column (Dionex, Camberley, UK).
4. Pulsed amperometric detector with Au working electrode (Dionex), set up with the following parameters:

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

a. Time = 0 s E = +0.1 V
b. Time = 0.5 s E = +0.1 V
c. Time = 0.51 s E = +0.6 V
d. Time = 0.61 s E = +0.6 V
e. Time = 0.62 s E = −0.8 V
f. Time = 0.72 s E = −0.8 V

5. High-purity helium.
6. NaOH 50% (w/v).
7. ACS-grade sodium acetate (Aldrich, UK).
8. HPLC-grade H_2O.

3. Methods

1. Prepare eluant A: 100 m*M* NaOH, 500 m*M* sodium acetate.
2. Prepare eluant B: 100 m*M* NaOH.
3. Prepare the column by elution with 50% A/50% B for 30 min at a flow rate of 1 mL/min.
4. Equilibrate column in 5% eluant A/95% eluant B at a flow of 1 mL/min.
5. Inject 200 pmol of each oligosaccharide or sialylated oligosaccharide alditol (more if required for NMR or LSIMS) and elute with the following gradient at a flow of 1 mL/min:
   a. Time = 0 min A = 5%; B = 95%
   b. Time = 15 min A = 5%; B = 95%
   c. Time = 50 min A = 40%; B = 60%
   d. Time = 55 min A = 40%; B = 60%
   e. Time = 58 min A = 0%; B = 100%
6. Equilibrate the column in 5%A/95%B prior to the next injection.
7. At the end of the analyzes, regenerate the column in 100%B, and flush the pumps with H_2O.
8. Desalt oligosaccharide-containing fractions and derivatize for LSIMS, GC-MS, or NMR (*see* **Note 1**).

4. Notes

1. Desalting can either be achieved by means of a ion-suppression system (e.g., Dionex AMMS or SRS system) or by off-line desalting on Biogel P2 mini-columns or H^+ cation-exchange resins. Fractions containing multiply sialylated oligosaccharides will probably contain too much salt to be totally desalted by an ion-suppressor, and column methods will be required. This can lead to losses of minor oligosaccharides.
2. All previous notes for HPAEC-PAD methods in this volume also apply.

140

HPAEC-PAD Analysis of Monosaccharides Released by Exoglycosidase Digestion Using the CarboPac MA1 Column

Michael Weitzhandler, Jeffrey Rohrer, James R. Thayer, and Nebojsa Avdalovic

1. Introduction

Exoglycosidases are useful reagents for the structural determination of glycoconjugates. Their anomeric, residue, and linkage specificity for terminal monosaccharides have been used to assess monosaccharide sequence and structure in a variety of glycoconjugates ***(1)***. Their usefulness depends on the absence of contaminating exoglycosidases and an understanding of their specificity. Digestions of oligosaccharides with exoglycosidases give two classes of products: monosaccharides and the shortened oligosaccharides. Most assays of such reactions have monitored the reaction by following oligosaccharides that are labeled at their reducing ends. In these assays, after exoglycosidase digestion the shortened oligosaccharide retains the label at its reducing end. The other digestion product, the released monosaccharide, does not carry a label and thus cannot be quantified. Additionally, identification of any other monosaccharide that could be the result of a contaminating exoglycosidase activity would not be possible. Quantitative measurement of all products (all released monosaccharide[s] as well as the shortened oligosaccharide product) would be useful because it would enable the determination of any contaminating exoglycosidase activities by determining the extent of release of other monosaccharides. High pH anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD) detects the appearance of monosaccharide product(s), the shortened oligosaccharide product(s) as well as the disappearance of the oligosaccharide substrate(s) in a single chromatographic analysis without labeling. Thus, HPAEC-PAD has been used extensively to monitor the activities of several different exoglycosidases

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

on glycoconjugates, usually using the CarboPac PA1 column to separate the digestion products (*see* **refs.** *1–8*).

A problem encountered when using HPAEC-PAD to monitor exoglycosidase digestions is that *N*-acetylglucosamine (GlcNAc) is not baseline resolved from other glycoconjugate monosaccharides on the CarboPac PA1 column using the isocratic conditions that successively baseline resolve glycoprotein hydrolysis products: fucose, galactosamine, glucosamine, galactose, glucose, and mannose ***(9)***. We recently discovered that the CarboPac MA1 column, developed for the separation of neutral sugar alditols ***(10,11)***, gives an isocratic baseline separation of GlcNAc, GalNAc, fucose, mannose, glucose, and galactose, and simultaneously resolves many neutral oligosaccharides. This separation extends the usefulness of the CarboPac MA1 column to the assay of reducing monosaccharides released by exoglycosidases. In the following, an assay of exposed GlcNAc after β-*N*-acetylhexosaminidase treatment of a variety of glycoconjugates is shown.

To determine the suitability of HPAEC-PAD and the MA1 column for analyzing both released monosaccharide and oligosaccharide products in a single analysis, we subjected an asialo agalacto biantennary oligosaccharide standard (**Table 1**, structure 3; **Fig. 1A**, peak 3) and an asialo agalacto tetraantennary oligosaccharide standard (**Table 1**, structure 5; **Fig. 1B**, peak 5) to Jack bean β-*N*-acetylhexosaminidase digestion. In addition to differences in numbers of antennae (2 vs 4) and retention times (22.3 vs 25.2 min), these two oligosaccharides differ in that the tetraantennary oligosaccharide has terminal GlcNAc linked to mannose β(1→4) and β(1→6) in addition to the β(1→2) linkages present in the biantennary oligosaccharide standard.

The complete disappearance of the asialo agalacto biantennary substrate is indicated by the disappearance of peak 3 (**Fig. 1A**; compare dashed vs solid line in bottom tracing). The complete disappearance of the asialo agalacto tetraantennary substrate is indicated by the disappearance of peak 5 (**Fig. 1B**; compare dashed vs solid line in bottom tracing). The expected digestion products of both structures 3 and 5 would be the released monosaccharide GlcNAc, (*see* **Fig. 1A,B**; peak at 15.6 min) and the released, shortened oligosaccharide product, $Man_3GlcNAc_2$ (**Table 1**, structure 1; *see* **Fig. 1A,B**, peak at 17.5 min).

In addition to being useful for monitoring the β-*N*-acetylhexosaminidase release of terminal GlcNAc from isolated oligosaccharides, HPAEC-PAD and the MA1 column can be used to directly monitor the presence of terminal GlcNAc on glycoproteins. Such an assay could be useful for monitoring terminal carbohydrate modifications in therapeutic glycoproteins; these modifications have been shown to affect the stability and efficacy of therapeutic glycoproteins ***(12)***. The β-*N*-acetylhexosaminidase release of terminal GlcNAc from a monoclonal IgG is shown in **Fig. 2A** (bottom tracing; compare solid vs dashed line). Additionally, the absence of contaminating exoglycosidases is apparent by the absence of release of any other monosaccharides.

Table 1
Oligosaccharide Substrates for Exoglycosidase Analyses

Structure	Retention Time
1. *$Man_3GlcNAc_2$*: Manα(1→6) ↓ Manβ(1→4)GlcNAcβ(1→4)GlcNAc ↑ Manα(1→3)	17.5 min.
2. *Fucosylated $Man_3GlcNAc_2$*: Manα(1→6) Fucα(1→6) ↓ ↓ Manβ(1→4)GlcNAcβ(1→4)GlcNAc ↑ Manα(α1→3)	13.7 min
3. *Asialo agalacto biantennary*: GlcNAcβ(1→2)Manα(1→6) ↓ Manβ(1→4)GlcNAcβ(1→4)GlcNAc ↑ GlcNAcβ(1→2)Manα(1→3)	22.3 min.
4. *Asialo agalacto biantennary, Core Fuc*: GlcNAcβ(1→2)Manα(1→6) Fucα(1→6) ↓ ↓ Manβ(1→4)GlcNAcβ(1→4)GlcNAc ↑ GlcNAcβ(1→2)Manα(1→3)	18.7 min.
5. *Asialo agalacto tetraantennary*: GlcNAcβ(1→6) ↓ GlcNAcβ(1→2)Manα(1→6) ↓ Manβ(1→4)GlcNAcβ(1→4)GlcNAc ↑ GlcNAcβ(1→2)Manα(1→3) ↑ GlcNAcβ(1→4)	25.2 min.

To assess whether the released GlcNAc was derived from a GlcNAc-terminated *N*-linked oligosaccharide, the monoclonal IgG was treated with peptide-*N*-glycosidase (PNGase F), an amidase that nonspecifically releases *N*-linked oligosaccharides from glycoproteins. The *N*-linked oligosaccharide map of the monoclonal IgG is shown in **Fig. 2B** (bottom tracing; solid line).

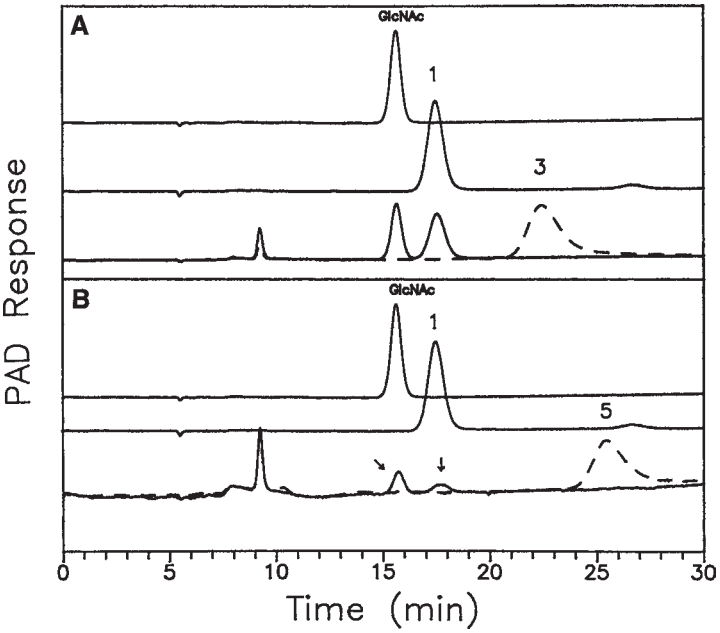

Fig. 1. HPAEC-PAD of β-*N*-acetylhexosaminidase digests of oligosaccharide standards. **(A)** Digestion of an asialo agalacto biantennary oligosaccharide standard. **(B)** Digestion of an asialo agalacto tetraantennary oligosaccharide standard. Peaks 1, 3, and 5 refer to structures 1, 3, and 5 identified in **Table 1**. (Bottom tracings in **A** and **B**: dashed line, chromatography of substrate; solid line, chromatography of digestion products.)

The major PNGase F product peak eluted between 18.5 and 19 min with a retention time similar to a core fucosylated asialo agalacto biantennary oligosaccharide standard (18.7 min, *see* **Table 1**, structure 4; *see also* **Fig. 2B**, peak 4). The second PNGase F released peak had a retention time of 21 min and could represent a monogalactosylated, biantennary oligosaccharide with core fucosylation, as has been reported in other monoclonal IgGs *(7)*. To assess whether the PNGase F released oligosaccharides were terminated with GlcNAc, the PNGase F released oligosaccharides were treated with β-*N*-acetylhexosaminidase.

The results of β-*N*-acetylhexosaminidase treatment of the PNGase F released oligosaccharides are depicted in **Fig. 2B** (second from bottom tracing). Both peaks corresponding to PNGase F released oligosaccharides disappeared and two new peaks appeared. The two new peaks had retention times corresponding to released GlcNAc (15.6 min) and to a fucosylated $Man_3GlcNAc_2$ standard (17.5 min, *see* **Table 1**, structure 2; *see also* **Fig. 2B**, peak 2). Thus, the two *N*-linked oligosaccharide peaks released from the monoclonal IgG are fucosylated and have terminal GlcNAc. To obtain further structural information

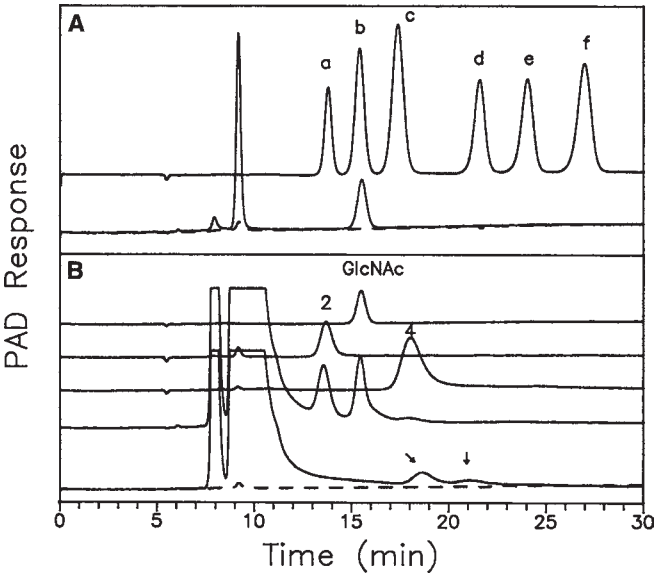

Fig. 2. HPAEC-PAD of β-*N*-acetylhexosaminidase digests of a monoclonal IgG **(A)** Bottom tracing is β-*N*-acetylhexosaminidase digests of a monoclonal IgG (dashed line, chromatography of IgG substrate; solid line, chromatography of digestion products). Top tracing is chromatography of monosaccharide standards; Peak a, fucose; b, GlcNAc; c, GalNAc; d, mannose; e, glucose; f, galactose. **(B)** Bottom tracing is PNGase F digest of a monoclonal IgG (dashed line, chromatography of IgG substrate; solid line, chromatography of PNGase F-released *N*-linked oligosaccharides from the monoclonal IgG; arrows indicate oligosaccharide peaks). β-*N*-acetylhexosaminidase treatment of PNGase F-released *N*-linked oligosaccharides is shown in the second to bottom tracing. Note appearance of product peaks corresponding to GlcNAc and fucosylated $Man_3GlcNAc_2$. Peaks 2 and 4 represent chromatography of oligosaccharide standards corresponding to structures 2 and 4 in **Table 1**.

regarding GlcNAc linkages, one could use the *Streptococcus pneumoniae* β-*N*-acetylhexosaminidase, an exoglycosidase which shows much more efficient cleavage of the GlcNAcβ(1 → 2)Man if the Man residue is not substituted with GlcNAc at the C-6 ***(13)***. This method is also useful for monitoring the β-*N*-acetylhexosaminidase preparation for contaminating exoglycosidase activities as other monosaccharide digestion products would be readily discernible.

2. Materials

1. HPLC grade deionized water (*see* **Note 1**).
2. 50% NaOH solution (w/w) (Fisher Scientific, Pittsburgh, PA) (*see* **Note 2**).
3. Reference-grade monosaccharides (Pfanstiehl Laboratories, Waukegan, IL).
4. Oligosaccharide standards $Man_3GlcNAc_2$ (**Table 1**, structure 1) fucosylated $Man_3GlcNAc_2$ (**Table 1**, structure 2), asialo agalacto biantennary (**Table 1**, structure 3),

asialo agalacto biantennary, core fucose (**Table 1**, structure 4), and asialo agalacto tetraantennary oligosaccharide (**Table 1**, structure 5) (Oxford GlycoSciences, Abingdon, UK).
5. β-*N*-acetylhexosaminidase, Jack bean (Oxford GlycoSciences) (*see* **Note 3**).
6. PNGase F (New England BioLabs, Beverly, MA) (*see* **Note 4**).
7. 25-mL Plastic pipets (Fisher Scientific).
8. 1.5-mL Polypropylene microcentrifuge tubes, caps, and O rings (Sarstedt, Newton, NC).
9. Autosampler vials: 12- × 32-mm disposable, limited-volume sample vials, Teflon/silicone septa, and caps (Sun Brokers, Wilmington, NC).
10. Nylon filters (Gelman Sciences, Ann Arbor, MI).
11. The chromatograph (Dionex, Sunnyvale, CA) consists of a gradient pump, a PAD II or PED, and an eluent degas module (EDM). The EDM is used to sparge and pressurize the eluents with helium. The system was controlled and data were collected using Dionex AI450 software. Sample injection was accomplished with a Spectra Physics SP8880 autosampler (Fremont, CA) equipped with a 200-µL sample loop. The Rheodyne (Cotati, CA) injection valve is fitted with a Tefzel rotor seal to withstand the alkalinity of the eluents. We also used a DX 500 BioLC system (Dionex) configured for carbohydrate analysis with PeakNet software (Dionex).

3. Methods

3.1. β-N-Acetylhexosaminidase Digestion

1. Reconstitute approx 2 µg each of the neutral agalacto biantennary and agalacto tetraantennary oligosaccharides (**Table 1**, structures 3 and 4, respectively) in 10 µL of 25 m*M* sodium citrate-phosphate buffer, pH 5.0.
2. Add 0.1 U of Jack bean β-*N*-acetylhexosaminidase in 2 µL of 25 m*M* sodium citrate-phosphate buffer, pH 5.0.
3. Incubate the digest for 20 h at 37°C.
4. Inject 10 µL of each digest directly onto the column.

3.2. PNGase F Digestion

1. Reconstitute approx 100 µg of a monoclonal IgG in 10 µL of 25 m*M* sodium citrate-phosphate buffer, pH 5.0.
2. Add 2 µL of the PNGase F preparation.
3. To an identifical PNGase F digest of the same monoclonal IgG, add 0.1 U of Jack bean β-*N*-acetylhexosaminidase in 2 µL of 25 m*M* sodium citrate-phosphate buffer, pH 5.0.
4. Separately inject 10 µL of each digest directly onto the column.

3.3. Chromatography and Detection of Carbohydrates

Separations of monosaccharides and oligosaccharides can be achieved using a Dionex BioLC system equipped with a CarboPac MA1 column (4 × 250 mm) and a CarboPac MA1 guard column working at an isocratic concentration of

480 m*M* NaOH and a flow rate of 0.4 mL/min at ambient temperature over 35 min. Separated mono- and oligosaccharides are detected by PAD with a gold electrode and triple-pulse amperometry (E_1 = 0.05 V, t_1 = 420 ms; E_2 = 0.80 V, t_2 = 360 ms; E_3 = −0.15 V, t_3 = 540 ms), measuring at 1000 nA full scale. Alternatively, a more recently described quadruple potential waveform can be used (Dionex Technical Note 21; Waveform A). (E1 = +0.1 V, t1 = 400 ms. The first 200 ms is t del and the second 200 ms is t det; E2 = −2.0 V, t2 = 10 ms; E3 = +0.6 V, t3 = 40 ms; E4 = −0.1 V, t4 = 60 ms).

4. Notes

1. It is essential to use high quality water of high resistivity (18 MeΩ) and to have as little dissolved carbon dioxide in the water as possible. Biological contamination should be absent. The use of fresh Pyrex glass-distilled water is recommended. The still should be fed with high-resistivity (18 MeΩ) water. The use of plastic tubing in the system should be avoided, as plastic tubing often supports microbial growth. Degas appropriately.
2. It is extremely important to minimize contamination with carbonate. Carbonate, a divalent anion at pH ≥ 12, binds strongly to the columns and interferes with carbohydrate chromatography. Thus carbonate is known to affect column selectivity and produce a loss of resolution and efficiency. Commercially available NaOH pellets are covered with a thin layer of sodium carbonate and should NOT be used. Fifty percent (w/w) sodium hydroxide solution is much lower in carbonate and is the preferred source for NaOH. Diluting 104 mL of a 50% NaOH solution into 2 L of water yields a 1.0 *M* NaOH solution. Degas appropriately.
3. This enzyme has a broad specificity, cleaving nonreducing terminal β-*N*-acetylglucosamine residues (GlcNAc) and β-*N*-acetylgalactosamine (GalNAc) with 1–2,3,4, and 6 linkages.
4. PNGase F is an amidase from *Flavobacterium meningosepticum*. The enzyme cleaves between the innermost GlcNAc and asparagine residues of high mannose, hybrid, and complex oligosaccharides from *N*-linked glycoproteins.

Acknowledgment

We thank Sylvia Morris for her work on the manuscript.

Microassay Analyses of Protein Glycosylation

Nicky K. C. Wong, Nnennaya Kanu, Natasha Thandrayen, Geert Jan Rademaker, Christopher I. Baldwin, David V. Renouf, and Elizabeth F. Hounsell

1. Introduction

The majority of secreted and cell surface proteins are glycosylated. To characterize accurately the carbohydrate moieties of oligosaccharide chains in glycosylated proteins, it is necessary to distinguish exactly which types of oligosaccharide are present and at which sites in the protein. The goal of the microassays presented here is to determine oligosaccharide structure and occupancy using lectin overlay assays. Lectins are multivalent binding proteins with the ability to bind specifically to certain sugar sequences in oligosaccharides and glycopeptides ***(1)***. Lectin overlay assays take advantage of the ability of lectins to distinguish between different types of glycoproteins by virtue of their ability to recognize terminal sugars, thus allowing the chain type and peripheral antigenic components to be determined. In addition, the assay is important as it provides structural information of protein glycosylation prior to conformational analysis and identification of antigenically and biologically active oligosaccharides. The lectin overlay, in the form of a microassay, can be developed to give a high level of sensitivity for glycan detection. The specificities of the lectins in such assays appears to vary from previous studies using lectin affinity chromatography and hence must be characterized further.

Three microassays are standardized here: The first is the analysis of non-protease-treated intact glycoproteins blotted onto nitrocellulose membranes (NCMs). Second, glycopeptides are released by prior digestion of the glycoprotein with a suitable protease that will cleave it into glycopeptides of ideally 5–15 amino acids and then separated by high performance liquid chromatography (HPLC) prior to lectin assay. Glycopeptides do not usually adhere to gels or membranes and therefore the latter need to be modified. Third, oligosaccharide chain structure has been characterized by the release of sugars from glycoproteins by endoglycosidase

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

digestion or hydrazinolysis and coupling them to a multivalent support followed by lectin overlay analysis. Coupling of oligosaccharides is achieved by reductive amination. This reaction takes advantage of the availability of reducing sugars in the open chain aldehydo form for reductive amination with primary amino groups, for example, εNH_2 of lysine in proteins. The base is stabilized by Schiff base formation via reduction in sodium cyanoborohydride. We have used this method, for example, to characterize the structure and antigenicity of a series of reducing *O*-linked oligosaccharides released from pigeon mucin ***(2)***.

2. Materials

1. Glycorelease *N*- and *O*-glycan recovery kit (Oxford GlycoSystems; Abingdon, UK).
2. Porous graphitized carbon (PGC) column (Hypersil Hypercarb, 100 mm × 4.6 mm, 7 µm, Hypersil; Runcorn, UK).
3. Reagents used in reverse-phase (RP)-HPLC (*see* **Subheading 3.2.**): acetonitrile and trifloroacetic acid (TFA) (Merck & Co.; Hoddesdon, UK).
4. Rat Thy-1 protein obtained by immunoaffinity purification and the lipid moiety removed by phospholipase C ***(3)***.
5. Pigeon intestinal mucin obtained from the intestines of freshly killed pigeons by CsCl density gradient ***(4)***.
6. Bovine fetuin, asialylated bovine fetuin, bovine serum albumin, chicken ovalbumin, ExtraAvidin peroxidase conjugate, 4-chloro-1 naphthol, poly-L-lysine, ammonium carbonate, and all reagents used in the modification and activation of NCM (*see* **Subheading 3.4.**): divinyl sulfone, dimethylformamide, sodium hydrogen carbonate, disodium carbonate, ethylenediamine, glutaraldehyde, and methanol (Sigma; Poole, UK).
7. Bovine pancreatic RNase B (Oxford GlycoSystems; Abingdon, UK).
8. Immobilon-P nitrocellulose membranes (0.2-µm and 0.45-µm pore size) (Millipore Corp.; Bedford, MA, USA).
9. Digoxigenin-labeled lectins of the glycan differentiation kit (Boehringer Mannheim; Mannheim, Germany).
10. Biotinylated lectins (Vector Labs, Peterborough, UK).
11. Benchmark microplate reader (Bio-Rad Lab. Ltd.; Hemel Hempstead, UK).

3. Methods

All procedures are carried out at room temperature unless otherwise stated.

3.1. Hydrozinolysis for Release of N- and O-Linked Oligosaccharides (e.g., O-Linked Glycoproteins) Using the Glycorelease Kit

1. Directly prior to hydrazinolysis, lyophilize glycoproteins overnight in a screw-capped) vial and store in a desiccator in the presence of phosphorus pentoxide for 24 h.
2. Add 5 mL of anhydrous hydrazine to the vial, seal, and heat in a heating block at 60°C for 4 h for *O*-linked glycans (95°C for 5 h for *N*-linked glycans).

3. Cool the reaction vessel to room temperature and remove excess hydrazine by centrifugal evaporation under reduced pressure (*see* **Note 1**).
4. Acetylate the released oligosaccharides by addition of 0.5 mL of ice-cold acetylation buffer and 50 µL of acetylating reagent (supplied with the kit). Incubate mixture for 20 min at 4°C and then 30 min at room temperature.
5. Desalt oligosaccharides on a cation-exchange resin and lyophilize using a centrifugal evaporator.
6. Dissolve dried samples in a minimal amount of pure water. Purify the released glycans from peptide material by ascending paper chromatography using high-purity butanol–ethanol–water (16:4:1 by vol). Elute oligosaccharides at and a few centimeters in front of the origin using water. Filter through a 0.2-µm PTFE filter. Evaporate to dryness and finally dissolve in 100 µL of water and store at −80°C.

3.2. Glycopeptide Preparation and RP-HPLC on Porous Graphitized Carbon Column

3.2.1. N-Linked Sugars

1. Dissolve 1 mg of trypsin in 500 µL of digestion buffer (500 m*M* NH_4CO_3, pH 8.5) immediately before it is required.
2. Dissolve either native or reduced carboxymethylated glycoprotein in enzyme–buffer solution at 20 µg of enzyme/1 mg of glycoprotein with 5 µL of toulene to prevent bacterial growth. Incubate for up to 72 h at 37°C, with an addition of enzyme (10 µg of enzyme/1 mg of glycoprotein) after 24 h.
3. Wash the digest 3× with 0.1 mL of water.
4. Lyophilize the digest by evaporation prior to chromatography.
5. Redissolve dried sample in 0.1% aqueous TFA and inject onto an HPLC column of PGC ***(5)***.
6. Run a starting eluent for 2 min at 2% buffer A (0.1% TFA in acetonitrile) in buffer B (0.1% aqueous TFA) followed by a linear gradient to 82% buffer A for 78 min at a flow rate of 1 mL/min.
7. Collect 2-mL fractions up to 70 min and then lyophilize each fraction. Spot samples onto NCM modified to bind peptides and glycopeptides as described in **Subheading 1.4.1** (adapted from the method of **ref.** *6*) (*see* **Notes 2** and **3**).

3.2.2. O-Linked Sugars

1. Lyophilize *O*-linked sugars released by hydrazinolysis (*see* **Subheading 3.1**).
2. Redissolve dried sample in 100 µL of 0.1% TFA and inject onto an HPLC column of PGC.
3. Run a gradient of 0.1% TFA in water (buffer A) and 0.1% TFA in acetonitrile (buffer B) at a flow rate of 1 mL/min with 0–60% buffer B for 60 min, 60% buffer B for 10 min, and 60–0% buffer B for 2 min. Collect 70 fractions of 1 mL and then lyophilize each faction.
4. To assay the amount of hexose present, redissolve each lyophilized fraction by addition of 60 µL of water.

5. Pipet 10 µL of each fraction into a microtiter plate along with a range of concentrations of a hexose standard (Gal or Man, usually 1–10 µg). To each well, add 50 µL of 2% aqueous phenol, mix thoroughly, and leave for 5 min. Add 200 µL of concentrated sulfuric acid to each well and mix prior reading on a benchmark microplate reader at 490 nm (*see* **Note 4**).

3.3. Coupling of Oligosaccharides to Poly-L-Lysine (PLL) to Reintroduce Multivalency (see Note 5)

1. To each oligosaccharide fraction recovered from RP-HPLC on PGC (assuming 20 µg of oligosaccharide in each tube), add 50 µL of 0.092 *M* sodium phosphate, pH 7.4, containing 32 µg/mL of PLL (200 pmol in 50 µL) and incubate at 37°C for 2 h.
2. After incubation, add to each fraction 60 nmol of $NaCNBH_3$ (4µg in 5 µL of water) and incubate for 16 h.
3. Prior to lectin overlay analysis, dilute samples 1:2 in phosphate-buffered saline (PBS), and spot 2 × 1 µL of each sample, 1 cm apart, onto a nonmodified NCM (0.2-µm pore size) (*see* **Note 6**).

3.4. Modification and Activation of NCM

3.4.1. Modification of NCM

1. To modify the NCM (0.2-µm pore size) for adherence of peptides and glycopeptides, incubate the membrane with 1:2 divinyl sulfone in dimethylformamide dissolved for 1 h in 0.5 *M* $NaHCO_3$–Na_2CO_3, pH 10.0.
2. Wash the membrane with distilled water and then incubate in 1% aqueous ethylenediamine for 30 min, followed by a wash with water.
3. Incubate the membrane in 1% glutaraldehyde in 0.5 *M* $NaHCO_3$–Na_2CO_3 buffer, pH 10.0, for 15 min.
4. Wash the membrane with water and air dry. The membrane is ready for use for post-HPLC tryptic-digest fractions.

3.4.2. Activation of NCM for Glycoprotein Adhesion

1. To hydrophilically activate NCM without modification (0.45-µm pore size), incubate the membrane in 100% methanol for 5 min.
2. Wash the membrane in distilled water for 1 min and 50 m*M* Tris–0.15 *M* NaCl (TBS) buffer for an additional 1 min and then air dry. The membrane is now ready for loading intact glycoproteins samples.

3.5. Spotting of Samples on the NCM

1. Spot (1 µL) intact non-protease-treated glycoproteins (total protein concentration ranging from 2 µg to 10 ng) or HPLC fractions containing peptides and glycopeptides from the tryptic digests 1 cm apart either onto the activated or modified NCM, respectively (*see* **Notes 7** and **8**).
2. Allow samples to air dry for at least 10 min before identification of glycans (*see* **Note 6**).

3.6. Dot-Blot Lectin Overlay Analysis

3.6.1 Digoxigenin-Labeled Lectins

1. Block the surface of the activated membrane by incubating in the blocking solution (supplied with the kit) for 30 min with gentle shaking (*see* **Notes 9–11**).
2. Wash the membrane twice (5 min each) with at least 50 mL of TBS, pH 7.5.
3. Incubate with the respective lectin solutions: *Datura stramonium* agglutinin (DSA), *Galanthus nivalis* agglutinin (GNA), *Maackia amurenisis* agglutinin (MAA), and *Sambucus nigra* agglutinin (SNA) (an aliquot of the digoxigenin-labeled lectin in 50 m*M* Tris containing 1 m*M* $MgCl_2$ and 1 m*M* $CaCl_2$) for 1 h (*see* **Note 12**).
4. After incubation, wash the membrane 3× with TBS (10 min each).
5. Incubate with anti-digoxigenin (polyclonal sheep anti-digoxigenin Fab fragments conjugated with alkaline phosphatase) (supplied with the kit) in TBS for 1 h.
6. After washing extensively in TBS, develop the membranes using a freshly prepared staining solution of 4-nitroblue tetrazolium chloride–5-bromo-4-chloro-3-indolyl phosphate (NBT/X-phosphate) (supplied with the kit) in buffer (0.1 *M* Tris-HCl, 0.05 *M* $MgCl_2$, 0.1 *M* NaCl, pH 9.5) (*see* **Notes 13** and **14**).
7. Stop the reaction by washing the membranes extensively (at least 20 changes) in distilled water and leave to air dry (*see* **Note 15**).
8. Scan the membrane using a Hewlett-Packard flat bed scanner (*see* **Notes 16** and **17**).

3.6.2. Biotinylated Lectins

1. Wash the activated or modified membrane twice (5 min each wash), in PBS containing 0.1% Tween 20 (PBS-T) (*see* **Notes 9** and **10**).
2. After washing, block the membrane in PBS-T containing 5% Bovine serum albumin (PBS–T-BSA) for 1 h and wash for a further 4× (5 min each) with at least 50 mL of PBS-T.
3. Dilute in 5 µg/mL of PBS–T-BSA the following biotinylated lectins: *Aleuria aurantia* (AAL), *Lotus tetragononolobus* (LTL), *Lycopersicon esculentum* (LEL), *Maackia amurensis* (MAL-1), *Maclura pomifera* (MPL), soybean agglutinin (SBA), *Sophora japonica* (SJA), *Ricinus communis* agglutinin (RCA-1), *Ulex europeus* II (UEA-II), and wheat germ agglutinin (WGA). Apply respective lectin solutions (50 mL to membranes and incubate for 2 h (*see* **Note 9**).
4. Wash the membranes 4× (5 min each) with at least 50 mL of PBS-T.
5. Incubate in ExtraAvidin peroxidase conjugate, diluted 1:500 in PBS–T-BSA, for 45 min.
6. Wash the membranes 3× in PBS-T and twice in PBS and then incubate in developing solution (60 mg of 4-chloro-1 naphthol dissolved in 20 mL of cold methanol, 80 mL of cold PBS, and 60 mL of 6% hydrogen peroxide) until spots appear on the membrane.
7. Stop the reaction by washing the membranes extensively (at least 20 changes) in distilled water and leave to air dry (*see* **Note 15**).
8. Scan the membrane using a Hewlett-Packard flat bed scanner (*see* **Notes 17** and **18**).

4. Notes

1. For safety, the evaporator is vented to a fume cupboard and kept on overnight after the sample had been dried.
2. To identify and study the site occupancy of individual glycans of glycoproteins, the protein is first cleaved with proteases. The relative hydrophobicities *(7, 8)* of the trypsin digest are calculated to predict the elution of the HPLC column as shown for disulfide-bonded Thy-1 (**Table 1**). We have shown earlier that in HPLC of peptides and glycopeptides using a PGC column *(5)*, the main determinator of retention is peptide and not oligosaccharide; thus, glycopeptides will elute in the same relative order as their peptides. The predicted hydrophobicities of the peptides containing each *N*-glycosylation site had large differences in value (**Table 1**) as mirrored in the time of elution between the glycopeptide HPLC fractions.
3. As an example for Thy-1, of the 35 fractions collected from the HPLC purification, the lectin-DSA (specific for Galβ1–4GlcNAc linkages present in complex and hybrid chains) bound well to fractions 13 and 14 and not as well to fractions 2 and 3. Staining with the lectin-GNA (specific for nonreducing terminal Man present in high mannose and hybrid chains) showed binding to fraction 10 and fractions 8, 9, and 11. This suggested that the least hydrophobic glycopeptide containing site $_{98}$NKT (**Table 1**) had complex chains (factions 2 and 3), the glycopeptide containing $_{23}$NKT has high mannose chains (fractions 8–10), and the most hydrophobic glycopeptide containing $_{74}$NFT had complex chains (fractions 13 and 14). There was some evidence (*not shown*) for staining of fractions 12–14 with GNA as well as DSA, suggesting that hybrid chains could also be present at this site. The GPI anchor glycan attached to the C-terminal tryptic peptideμs) was not expected to interact well with either of the lectins, but may possibly have added to the binding of GNA in the fractions 8–10 due to the Manα1–2Man shown near the protein.
4. The hexose assay is used to quantitate the amount of material after coupling to PLL (*see* **Subheading 3.3**) an dialysis during optimization of the reaction. Do not overfill wells during the hexose assay, as concentrated sulfuric acid will severely damage the microtiter plate reader if spilled.
5. To screen for lectin and antigenic activity to multiple oligosaccharides released from mucin glycoproteins by hydrazinolysis, the oligosaccharides are coupled to PLL, which provides a multivalent molecule to which dot blots adhere throughout washing procedures required for lectin overlay. This is a convenient "one-pot" reaction before purification and detailed quantitative studies of active oligosaccharides can be done.
6. Take care to allow the samples to air dry completely before the second application on the NCM.

7. To avoid unnecessary cross-contamination between samples, a 96-well dot-blotter (Bio-Rad) was used instead of spotting the samples directly onto the membrane. Prior to activation or modification of the NCM, cut the membrane to size for placing onto the dot blotter cassette. Once the membrane is in a fixed position, apply respective samples as indicated in **Subheading 3.5**. After loading samples remove membrane from dot blotter and leave to air dry. Once dried, mark the membrane with a pencil to indicate the order of the samples. Also, draw a grid on paper to indicate the location of samples.
8. When applying respective samples onto the membrane, always use fresh Gilson tips for each sample to avoid contamination.
9. All incubations in the lectin overlay analysis are carried out on a rocking table at room temperature.
10. During the lectin overlay analysis, use gloves and avoid direct contact of the membrane with skin. Handle the membrane carefully with a flat-ended twiser to avoid damage.
11. For a clearer background, the blocking solution can be incubated with the membrane for overnight at 4°C. After, incubate the membrane with the blocking solution for a further 30 min at room temperature prior to washing.
12. For convenience, use large Petri dishes to incubate each membrane with respective lectin solutions. Make sure that the lectin solution always covers the membrane surface during incubation.
13. In contrast to the manufacturer's instructions the staining reaction can be extended until significant staining could be observed (1–18 h).
14. Standard glycopeptides should also spotted onto the membrane to monitor the progress of staining.
15. To protect the membrane from dust and damage, place a clear plastic film over the membrane and store in the dark.
16. **Table 2** presents a summary of results of a series of whole non-protease-treated glycoproteins (at various concentrations) analyzed for lectin specificity and sensitivity by dot-blot lectin overlay. The results from this assay

Table 2
The Sensitivity Levels of Commercial Lectins on Glycoproteins by Lectin Overlay Analysis

Lectin	Fetuin	Asialylated fetuin	Bovine serum albumin	Chicken ovalbumin	RNase B
MAA	10 ng	1 µg	NB	NB	NB
SNA	0.1 µg	NB	NB	NB	NB
DSA	0.1 µg	0.1 µg	NB	NB	NB
GNA	1 µg	1 µg	2 µg	1 µg	NB

NB, No binding of lectin detected to sample.

clearly show that three lectins (MAA, SNA, and DSA) recognize Bovine fetuin (BF) at high sensitivity protein levels ranging from 10 ng to 0.1 µg. Asialylated BF (ABF) were detected by lectins MAA and DSA but not SNA. As expected, all three lectins showed no binding to Bovine serum albumin (BSA), which is not glycosylated. According to the lectin specificity as published by the manufacturer, GNA should stain positive for RNase B and ovalbumin but not the other glycoproteins/proteins; however, negative results with RNase B were shown even after repeated tests such as using increased concentrations of RNase B (up to 20 µg). The sugar of RNase B was analyzed by hexose assay and shown to contain the expected 3%; thus the specificity of GNA is not as published, and the lectin can distinguish between ovalbumin and RNase B glycosylation.

17. **Table 3** shows the binding preferences of the lectins used. From the results obtained, the sensitivity of lectins can detect protein concentrations down to 10 ng. The choice between the commercial digoxigenin-labeled and biotinylated lectins used relate to their recognition of a range of defined and limited sugar structures depending on the samples tested. One drawback to the procedure is that because a number of structurally distinct oligosaccharides interact identically with certain lectins, this suggests that the structural heterogeneity frequently encountered with glycoproteins may not always be reflected in the interactions of these moieties with lectins.
18. For pigeon intestinal mucin ***(2)*** 8 of the 10 lectins (AAL, LEL, LTL, MAL-1, MPL, RCA-1, SBA, SJA, UEA-II, and WGA) reacted specifically with a different spectrum of PLL-oligosaccharide conjugates. LTL stained the entire blot, suggesting that this lectin interacted with the nitrocellulose. SJA reacted with all of the fractions and controls, indicative of nonspecific interaction with PLL itself. For the other lectins there was a wide range of activities with the various HPLC fractions. Difference in staining patterns between the lectins demonstrated that oligosaccharides of varying structure have been released from pigeon mucin by hydrazinolysis and have successfully been coupled to PLL, thus allowing binding to the NCM. Optimization of conditions at the macro-level included both neutral and sialylated oligosaccharides, with the chosen conditions giving maximum yield of both. The principle of this assay is derived essentially from enzyme-linked immunosorbent assay (ELISA) and commercial kits are available, where lectins are already linked to antibodies or other methods for detection.

Polyacrylamide Gel Electrophoresis of Fluorophore-Labeled Carbohydrates from Glycoproteins

Brian K. Brandley, John C. Klock, and Christopher M. Starr

1. Introduction

Prior to 1980, most methods for analysis of glycoprotein carbohydrates utilized column, thin-layer, and paper chromatography, gas chromatography, mass spectroscopy, and rarely nuclear magnetic resonance spectroscopy. These methods required relatively large amounts of materials (micromoles), specialized training and experience, and in some cases, significant capital equipment outlays. Because of these restrictions, convenient carbohydrate analysis on small samples was not available to most biologists. Recently, improvements in chromatographic methods, labeling methods for carbohydrates, carbohydrate-specific enzymes, and higher resolution electrophoresis methods have allowed carbohydrate analysis to be done on nanomolar amounts of material. Because of these improvements, today's biologist now has an improved ability to evaluate the role of carbohydrates in their research and development work.

Polyacrylamide gel electrophoresis (PAGE) of fluorophore-labeled carbohydrates has also been referred to as fluorophore-assisted carbohydrate electrophoresis, or FACE®. The technique was first developed in England by Williams and Jackson ***(1–4)*** and utilizes reductive amination of carbohydrates by low molecular weight, negatively charged or neutral fluorophores and electrophoresis on 20–40% polyacrylamide slab gels. This method permits separation of charged or uncharged sugars or oligosaccharides with high resolution and can detect single hydroxyl anomeric differences between mono- and oligosaccharides of sugars with otherwise identical molecular weight, charge, and sequence. The separation of sugars by electrophoresis is largely empirical, and it is not always possible to predict relative mobilities of structures. For the most part the success

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

of this approach has been based on experimental observations and the use of highly specific reagents, enzymes, and standards.

What follows in this chapter are descriptions of the materials and methods required to perform two of the most common manipulations of oligosaccharides used in biologic research today. The method with some modification is useful for analysis of a variety of carbohydrates including reducing and nonreducing sugars, substituted and unsubstituted monosaccharides, and oligosaccharides from glycoproteins, proteoglycans, glycolipids, and polysaccharides. In this chapter only profiling of *N*-linked and *O*-linked glycoprotein oligosaccharides is discussed. The method is also useful for a variety of other manipulations including structure–function studies, preparative work, and synthesis of oligosaccharides that are not discussed in detail here. Other reviews of this technique have been published previously ***(5,6)*** and a number of research studies have been performed using this method ***(7–31)***.

2. Materials

2.1. N-linked Oligosaccharide Analysis

For profiling of Asn-linked oligosaccharides released by peptide *N*-glycosidase F.

1. *N*-linked Gels: 10 × 10 cm low fluorescence glass plates with 0.5 mm spacers and 8-well combs filled with 20% T acrylamide:bis in 0.448 *M* Tris-acetate buffer pH 7.0 and containing a 5-mm stack of 10% polyacrylamide in the same buffer (gels should be made fresh or obtained precast from a commercial source).
2. Releasing enzyme: peptide *N*-glycosidase F (from commercial sources).
3. Running buffer: 50 m*M* Tris tricine buffer (pH 8.2).
4. Enzyme buffer: 100 m*M* sodium phosphate buffer (pH 7.5).
5. Labeling dye: 1 *M* 8-aminonaphthalene-1,3,6-trisulfonic acid (ANTS) in 15% acetic acid (reagent is stable for 2 wk at–70°C in the dark).
6. Reducing agent: 1 *M* sodium cyanoborohydride ($NaBH_3CN$) in dimethyl sulfoxide (DMSO) (reagent is stable for 2 wk at–70°C).
7. Sample loading solution: 25% glycerol with thorin 1 dye (store at 4°C).
8. Tracking dye: Mixture of Thorin 1, Bromphenol blue, Direct red 75, and Xylene cyanole in water.
9. Electrophoresis gel box (with 2-sided cooling).
10. Deionized or distilled water.
11. Assorted pipeting devices including a 0–10 μL positive displacement pipet (e.g., Hamilton syringe).
12. Centrifugal vacuum evaporator.
13. Oven or water bath at 45°C and 37°C.
14. Sodium dodecyl sulfate (SDS), 5%.
15. β-Mercaptoethanol (βME).
16. 7.5% nonidet P-40 (NP-40).
17. 100% Cold ethanol (undenatured).

18. Microcentrifuge tubes (1.5 mL).
19. Microcentrifuge.
20. Chicken trypsin inhibitor control (optional).
21. Maltotetraose or partially hydrolyzed starch standard (optional).

2.2. O-linked Glycoprotein Oligosaccharide Analysis

For profiling of Ser/Thr-linked oligosaccharides released by hydrazine.

1. *O*-linked gels: 10 × 10 cm low fluorescence glass plates with 0.5-mm spacers and eight-well combs filled with 35% T acrylamide:bis in 0.448 *M* Tris-acetate buffer and containing a 5-mm stack of 16% polyacrylamide in the same buffer (gels should be made fresh or obtained as precast gels from a commercial source).
2. Gel running buffer: 50 m*M* Tris-glycine (pH 8.2).
3. *O*-linked cleavage reagent: anhydrous hydrazine, 1 mL amp. **Hydrazine is toxic and flammable; discard ampoule and residual contents after using once; dispose of safely according to your institution's regulations.**
4. Re-*N*-acetylation reagent: acetic anhydride.
5. Re-*N*-acetylation buffer: 0.2 *M* ammonium carbonate, pH 9.4.
6. Desalting resin: Dowex AG50X8.
7. Tracking dye: Mixture of Thorin 1, Bromphenol blue, Direct red 75, and Xylene cyanole in water.
8. Sample loading solution: 25% glycerol with Direct red 75 (store at 4°C).
9. Labeling dye: 1 *M* 8-aminonaphthalene-1,3,6-trisulfonic acid (ANTS) in 15% acetic acid (reagent is stable for 2 wk if stored in the dark at –70°C).
10. Reducing agent: 1 *M* sodium cyanoborohydride ($NaBH_3CN$) in DMSO (reagent is stable for 2 wk at –70°C).
11. Distilled-deionized water.
12. Microcentrifuge tubes (2-mL, glass-lined).
13. Assorted pipeting devices including a 0–100 µL capillary positive displacement pipet.
14. Centrifugal vacuum evaporator.
15. Oven or water bath set at 37°C.
16. Sand filled heat block set at 60°C.
17. Vacuum dessicator.
18. Microfuge.
19. Phosphorus pentoxide (P_2O_5).
20. Bovine submaxillary mucin control (optional).
21. Maltotetraose or partially hydrolyzed starch standard (optional).

3. Methods

3.1. Principle

Using fluorescent PAGE, individual oligosaccharides can be quantified to obtain molar ratios, to obtain degree of glycosylation, and to detect changes in the extent or nature of glycosylation. Oligosaccharide profiling involves four steps:

1. Release of the oligosaccharides from the glycoprotein enzymatically or chemically;
2. Labeling of the mixture of released oligosaccharides with a fluorescent tag;
3. Separation of the fluorophore-labeled oligosaccharides by PAGE; and
4. Imaging of the gel either on a UV lightbox to obtain qualitative band information or using a commercial imaging system to determine the amount of oligosaccharide present in each band and the relative mobility of the bands.

Once separated on the gel, individual oligosaccharide bands can also be purified for further study.

3.2. Preparation of Glycoprotein

1. Isolate the glycoprotein according to your usual procedures. The sample should be relatively salt-free and contain no extraneous carbohydrates (e.g., sephadex-purified material contains large amounts of glucose) (*see* **Note 1**).
2. If the volume of the glycoprotein solution required is >100 µL, dry the glycoprotein in a 1.5-mL microcentrifuge tube. Generally 50–200 µg of glycoprotein is required for *N*-linked analysis (*see* **Note 2**). For analysis of *O*-linked oligosaccharides 100–500 µg of glycoprotein may be required.
3. For the *N*-linked oligosaccharide control (*see* **Note 3**) remove 100 µg of the chicken trypsin inhibitor in a 45 mL aliquot, and place it in a 1.5 mL microfuge tube. Proceed with the enzymatic digestion as described below. For the *O*-linked oligosaccharide control remove 50 µL (100 µg) of Bovine submaxillary mucin, and place it in a reaction vial. Proceed with lyophilization, P_2O_5 drying and process along with the sample glycoprotein (*see* **Subheading 3.4.2.**). Store remaining glycoproteins at 4°C for future use.

3.3. Release of Asn-Linked Oligosaccharides with Peptide N-Glycosidase F

1. Add an equal volume of enzyme buffer to the glycoprotein in solution or dissolve the dried glycoprotein in 22.5 µL of water and add 22.5 µL enzyme buffer.
2. SDS is often required to completely denature the glycoprotein prior to enzymatic digestion. To denature the protein add SDS to 0.1% (1.0 µL of 5% SDS to 45 µL reaction) and β-ME to 50 m*M* (1.5 µL of a 1:10 dilution of 14.4 *M* stock β-ME to 45 µL reaction). Boil for 5 min (*see* **Note 4**), cool to room temperature and add NP-40 to 0.75% (5 µL of 7.5% NP-40 into 45 µL). Mix with finger flicks.
3. Add 2.0 µL (5 U of peptide-*N*-glycosidase F or as specified by the manufacturer) of enzyme to the glycoprotein sample. Mix with finger flicks and centrifuge for 5 s. Store remaining enzyme at 4°C.
4. Incubate sample for 2 h at 37°C.
5. Precipitate protein by adding 3 vol of cold 100% ethanol.
   Keep samples on ice for 10 min. Spin samples in microcentrifuge for 5 min to pellet protein.
6. Remove the supernatant and transfer to a clean 1.5-mL microcentrifuge tube.
   IMPORTANT! Do not discard the supernatant. It contains the released carbohydrates!

7. If a large amount of protein was digested (>250 µg) 5–10% of the released oligosaccharides may remain in the pellet. The recovery of these oligosaccharides can be accomplished by drying the pellet completely in a centrifugal vacuum evaporator or lyophilizer. Add 50 µL H_2O to resuspend, then 150 µL 100% cold ethanol and precipitate on ice. Centrifuge and combine the supernatants.
8. Dry the supernatants in a centrifugal vacuum evaporator or lyophilize to a translucent pellet. At this point samples may be stored at −20°C or proceed with the fluorophore labeling procedure described in **Subheading 3.4.2**.

3.4. O-Linked Oligosaccharide Release Using Hydrazine

3.4.1. Isolation of Glycoprotein

1. Isolate glycoprotein according to your usual procedures. The purified glycoprotein should be prepared in a non-Tris buffer containing a minimum amount of salt. The presence of nonvolatile salts may cause the breakdown of the oligosaccharides during hydrazinolysis. If the glycoprotein is in a buffer containing salt it is recommended that the sample be dialyzed against distilled water to remove salts prior to chemical digestion.

3.4.2. Hydrazinolysis

1. Dry 100–500 µg of glycoprotein in a glass-lined reaction vial, using a centrifugal vacuum evaporator or lyophilizer. The actual amount of glycoprotein required will depend on the size of the protein and the extent of glycosylation (*see* **Note 2**).
2. The sample must be completely dry before hydrazinolysis. Following lyophilization, dry the sample overnight under vacuum in the presence of P_2O_5 to remove all traces of H_2O. Place samples in a dessicator flask with a beaker containing a small amount of P_2O_5. Attach the dessicator directly to the pump without a cold-trap—any water remaining in the sample will be trapped by the P_2O_5.
3. Open a fresh ampoule of anhydrous hydrazine *O*-linked cleavage reagent. Add 50 µL of hydrazine to the dried sample using a glass transfer pipet, or a positive displacement capillary pipet (metal or plastic should not be used). Resuspend the dried sample. Overlay the sample with dry nitrogen and cap tightly. **Hydrazine is very hygroscopic. Discard unused hydrazine according to your hazardous waste regulations. Do not reuse**.
4. Incubate samples for 3 h in a sand bath or dry heat block set at 60°C (do not use a water bath) to release *O*-linked oligosaccharides (higher temperatures may result in the degradation of *O*-linked sugars or in the release of non-*O*-linked sugar chains, such as *N*-linked sugars, from the sample if they are present).
5. Dry samples in vacuum evaporator on low heat setting.

3.4.3. Re-N-Acetylation Procedure

1. Add 30 µL of Re-*N*-acetylation buffer to the dried pellet from **step 5** in **Subheading 3.4.2.**
2. Resuspend by vortexing. Spin 2 s in a microfuge.
3. Add 2 µL of re-*N*-acetylation reagent to the solution. Mix well. Spin 2 s in a microfuge.

4. Incubate tubes on ice for 15 min.
5. Following the 15 min incubation, stop the reaction by adding 60 µL of the desalting resin. Desalting resin is prepared by adding 0.5 g of Dowex AG50X8 to 0.7 mL water. Invert or vortex the resin immediately prior to removing the 60 µL for each tube. Incubate the resin with the sample at room temperature for 5 min mixing by placing the tube on a shaker or by continuously inverting the tube to keep the resin suspended.
6. Briefly centrifuge to pellet the resin, remove the supernatant (save supernatant) and wash the resin 2× with 120 µL of water for 2 min each (save supernatant).
7. Combine the resin supernatants in a 1.5-mL microcentrifuge tube.
8. Dry the supernatants in a vacuum evaporator on low heat setting.

3.5. Labeling Oligosaccharides

3.5.1. Preparation of Samples and Standards

If quantitation of the oligosaccharide bands in the samples is required, then one must compare the intensity of an internal standard (e.g., maltotetraose) band with the intensity of sample bands and it is, therefore, essential that the standard is present on each gel used (*see* **Note 5** for preparation and use of this material).

3.5.2. ANTS Labeling

1. Prepare the labeling dye as 1 *M* ANTS in 15% acetic acid (dye solution can be stored in the dark at −70°C for up to 2 wk).
2. Prepare 1 *M* solution of $NaBH_3CN$ in DMSO and mix well by vortexing until crystals are completely dissolved (this reducing agent can be stored for 2 wk at −70°C).
3. Add 5 µL of labeling dye to each dried oligosaccharide pellet. Mix well until the oligosaccharide pellet is dissolved.
4. Add 5 µL of reducing agent. Mix well by vortexing. Centrifuge 5 s in microcentrifuge.
5. Incubate samples at 45°C for 3 h (temperatures higher than 45°C or times longer than 3 h can destroy or modify carbohydrates, e.g., sialic acids). Greater than 90% of the oligosaccharides are labeled under these conditions. As a convenient alternative samples can be labeled at 37°C (not 45°C) overnight (or approx 16 h). These latter conditions result in labeling of >90% of the oligosaccharides (*see* **Note 6**).
6. After labeling, dry the samples in centrifugal vacuum evaporator for approx 15 min or until the sample reaches a viscous gel stage.

3.6. Electrophoresis

3.6.1. Preparation of a Sample for Electrophoresis

1. Resuspend the dried fluorophore "labeled" oligosaccharide in 5–20 µL H_2O. The actual volume of H_2O used to resuspend the sample will depend on the amount of oligosaccharide present in the sample (start with 10 µL, this will enable the sample to be diluted further if necessary).

2. Remove an aliquot of the sample (generally 1–2 µL) and dilute it with an equal volume of sample loading solution. Load the entire aliquot into one lane of a gel. Best results are obtained by loading 4 µL/lane on a 10 × 10 cm gel with eight lanes.

3.6.2. Electrophoresis

1. For *N*-linked analysis chill the running buffer to 4–6°C prior to use. For *N*-linked analysis perform electrophoresis at a buffer temperature of 5–8°C. All *O*-linked gels are run at 15–20°C.
2. For *N*-linked analysis set up electrophoresis with a recirculating chiller and place the electrophoresis tank containing a stir bar on a mechanical stirrer. Connect the gel box cooling chamber to a refrigerating circulator. Turn on the circulator and stirrer and set the coolant temperature to 5°C.
3. For *N*-linked analysis pour the precooled running buffer into the electrophoresis tank up to the appropriate level. The temperature of the buffer should be monitored during the run using a thermometer inserted through the hole in the lid or other method. The temperature will probably increase a few degrees during electrophoresis, but should not exceed 10°C. For *O*-linked gels the temperature should not exceed 23°C.
4. Determine the number of gels required for the samples prepared. Each gel should contain eight lanes. The outside lanes should be used for the tracking dye and glucose polymer standard leaving the six inner lanes for samples and quantitation standard (maltotetraose).
5. Gently remove the comb(s) from the gel(s). To avoid distorting the wells, gently wiggle each comb to free the teeth from the gel, then lift up slowly until the comb is released.
6. Place the gel cassette(s), one on each side of the center core unit of the gel apparatus with the short glass plate against the gasket. Be sure the cassette is centered and that the cassette is resting on the "feet" at the bottom of the apparatus. If only one gel is being run place the buffer dam on the other side.
7. It is essential that the wells of the gel are thoroughly rinsed out with the running buffer from the upper buffer reservoir prior to sample loading. This is best accomplished by using a syringe with a blunt needle (a Pasteur pipet is not recommended because of the possibility of breakage into the wells).
8. With the core unit containing the gels placed securely on the bench, load samples into the wells by underlaying the upper buffer. Use flat sequencing pipet tips to load by delivering the sample to the bottom of each well. Optimal resolution will be achieved by using 4 µL of sample per lane.
   Note: For the most reliable quantitation of oligosaccharide bands the use of a positive displacement pipet (e.g., Hamilton syringe) is recommended.
9. Load 4 µL of the standard in a lane when prepared as described in **Note 5**.
10. Load 2 µL of tracking dye in a lane directly from the vial.
11. Load 4 µL of each labeled oligosaccharide sample in a lane. Samples should be diluted 1:1 in the sample loading solution (*see* **Note 7**).

12. To prevent possible lane distortions as a result of different loading volumes it is recommended that **4** µL of Sample Loading Solution be loaded in any unused lanes. Best results are obtained when the same volume of sample is added to each lane.
13. Place the core unit containing the loaded gels into the electrophoresis tank and connect the power cords to the electrophoresis tank then connect the power supply.
14. Place the thermometer into the lower buffer chamber through the hole in the lid. For *N*-linked analysis the initial temperature of the lower buffer must be 5–8°C; for *O*-linked analysis 15–20°C is optimal.
15. Turn on the power supply and select the proper current. Gels should be run at a constant current of 15 mA/gel (30 mA for 2 gels; 15 mA for 1 gel and 1 buffer dam). Limits on the power supply should be set for 1000V and 60W. These run conditions will result in voltages of 100–400V at the beginning of the run and may approach 800–1000V at the end of the run. If the initial voltage is significantly different check to be sure that the leads are connected properly and that the buffers are at the recommended levels (*see* **Notes 8** and **9**).
16. Most *N*-linked oligosaccharides fall in the $Glucose_4$–$Glucose_{12}$ range (also referred to as G4–G12 or DP4–DP12), so the time of electrophoresis should be adjusted to optimize the separation of this region of the gel. Most *O*-linked oligosaccharides run in the G1–G6 range (DP1–DP6).
17. Monitor the electrophoresis by following the migration of the fast moving thorin dye (orange band). Generally, electrophoresis of *N*-linked oligosaccharides is complete when the orange dye just exits the bottom of the gel in approx 1 to 1¼ h. For the *O*-linked oligosaccharides the gel run is complete when the orange dye is 1 cm above the bottom of the gel. In a darkened room, the migration of the labeled oligosaccharides can be monitored directly during electrophoresis by turning off the power supply, removing the leads and the gel box cover and holding a hand-held UV light over the gels. The run can be continued by repositioning the gel in the electrophoresis box and reconnecting the power supply as described in **step 15**. The amount of time the current is off should be as short as possible (<5 min) to minimize diffusion of the oligosaccharides in the gel.
18. When the electrophoresis is complete, turn off the power supply. Disconnect the power cords from the power supply and the electrophoresis tank. Turn off the refrigerated cooler and discard the buffer (*see* **Note 10**).

3.7. Gel Imaging

CAUTION: UV protective eyeware or faceshield should be worn. Avoid prolonged exposure to UV light.

1. Allow UV lightbox to "warm-up" for at least 2 min in order to get maximum intensity output. The lightbox must be long-wave UV and have a peak output at approx 360 nm; this is *not* the type of box typically used for ethidium bromide-stained DNA gels.
2. Remove the tape from the gel cassette, which may be fluorescent, and clean the surfaces of the cassette if it is required to image the gel within the cassette.

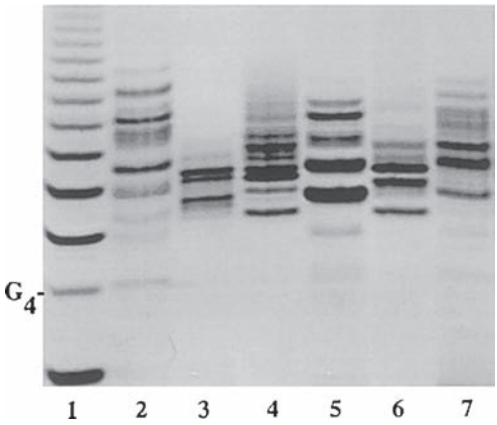

Fig. 1. Profiles of *N*-linked oligosaccharides from several glycoproteins. ANTS-labeled oligosaccharides released by peptide *N*-glycosidase (PNGase F) from six different glycoproteins are shown. *Lane 1* contains an oligosaccharide ladder standard of partially hydrolyzed wheat starch with G4 representing glucotetraose; *lane 2*, chicken trypsin inhibitor; *lane 3*, bovine fetuin; *lane 4*, human α-acid glycoprotein; *lane 5*, bovine ribonuclease B; *lane 6*, human chorionic gonadotropin (hCG); and *lane 7*, chicken ovalbumin. The profiles show a wide variety of different glycosylation patterns, indicating the minimum number (some oligosaccharides will comigrate) of different types of oligosaccharide present and their relative quantities. The images presented in this review were obtained by imaging the gels following electrophoresis using a CCD (charge-coupled-device)-based imaging system (Glyko).

The cassette glass must be of special low-fluorescence type to obtain an image of a gel within the cassette. If the glass is not of a low fluorescence type and if the type of gel cassette being used permits disassembly, remove the gel completely from the cassette and place it on the UV lightbox (*see* **Notes 11** and **12**).

3. An electronic image of the *N*-linked oligosaccharides from several glycoproteins is shown in **Fig. 1**; an electronic image of the *O*-linked oligosaccharides from several different glycoproteins is shown in **Fig. 2**. In each image you can also see the position of maltotetraose and a ladder of maltooligosaccharides from partially hydrolyzed wheat starch (*see* **Notes 9**, **10**, **13–16** for problems with bands).

3.8. Gel Handling

1. If the gel is no longer needed it should be properly discarded.
2. Following imaging of the oligosaccharide gels, the glass plates can be separated and the gels dried on a flat bed gel drier between sheets of Teflon™ membrane at 80°C for 1 h. After the gel is dry, carefully peel the Teflon sheets away from the gel. Gels dried in this manner can be stored indefinitely in a dark dry location and can reimaged at any time with minimal bleaching.

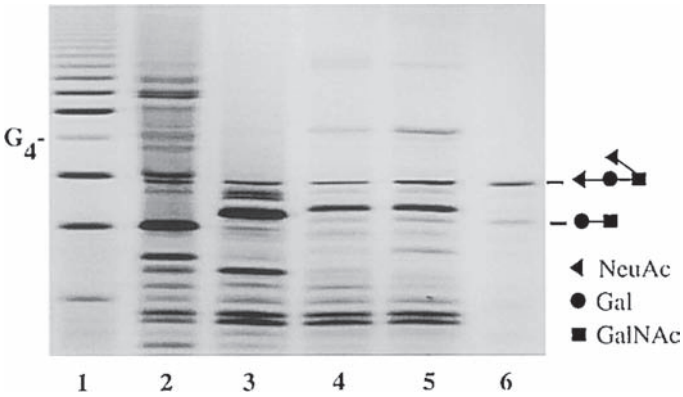

Fig. 2. Profiles of *O*-linked oligosaccharides from several glycoproteins. ANTS-labeled Ser/Thr-lined oligosaccharides released using hydrazine at 60°C from four different glycoproteins are shown. *Lane 1* contains an oligosaccharide ladder standard of partially hydrolyzed wheat starch with G4 representing glucotetraose; *lane 2*, porcine stomach mucin, Type II; *lane 3*, bovine submaxillary mucin, Type I; *lane 4*, bovine fetuin; and *lane 5*, human chorionic gonadotropin (hCG). *Lane 6* contains the NeuAc(α2–3)Gal(β1–3)[NeuAc(α2–6)]GalNAc and Gal(β1–3)GalNAc standards. The images presented in this review were obtained by imaging the gels following electrophoresis using a CCD-based imaging system (Glyko).

3. Following imaging, the gel cassette can be placed back in the electrophoresis apparatus and the run continued in order to improve the resolution of the oligosaccharide bands. In this case, the *upper* buffer should be saved and reused until the run is finally terminated. Note that diffusion of carbohydrate bands and subsequent poor resolution will occur if the time between electrophoresis and imaging exceeds 15 min.

4. Notes

1. The glycoprotein sample should ideally first be dialyzed against distilled water and stored lyophilized in a 1.5 mL microfuge tube. If the sample needs to be in a buffered solution, one can place the sample in 50 m*M* sodium phosphate buffer, pH 7.5, at a final concentration of at least 100 µg/50 µL or 2 mg/mL. Best results are obtained if the total salt concentration of the solution is <100 m*M*. The use of a Tris-based buffer is not recommended. If a detergent is required, the sample may be suspended in up to 0.1% SDS, 0.75% NP-40, or 1% n-octyl β-D-glucopyranoside. If desired, the sample may also contain 0.05% sodium azide.
2. We recommend that you use at least 250 µg of glycoprotein for analysis. The actual amount of glycoprotein required for profiling will depend on the size of the protein, the amount of glycosylation, and the degree of oligosac-

charide heterogeneity. In general, the amount of glycoprotein required increases with the size of the protein or the degree of heterogeneity and decreases with the percent of glycosylation. As a general guideline, one would start with approx 50–100 µg to profile the *N*-linked oligosaccharides of a 60 kDa glycoprotein that contains 10–20% carbohydrate by weight. For *O*-linked oligosaccharide analysis we suggest 100–500 µg of starting glycoprotein. This amount would normally provide sufficient material for several electrophoretic runs. For isolation of individual oligosaccharides, and carrying out sequencing, additional material will be required.

3. The control for *N*-linked profiling consists of trypsin inhibitor that is used as a control for enzyme digestion and fluorophore labeling. This control should be included in the analysis for the following reasons:
   a. If this control is used for the first time it will help the user to become familiar with the procedures;
   b. If the profile obtained looks appropriate then this assures the user that things are working properly; and
   c. In an unknown sample that may not contain *N*-linked oligosaccharides, the user can be certain that the reagents are good and that the release and labeling procedures were performed properly.

   Similarly a control for *O*-linked profiling such as Bovine submaxillary mucin should be used.
4. Some proteins will precipitate when boiled, i.e., immunoglobulins. The following procedure should be used if your protein precipitates: Add SDS/ -ME at the recommended concentration and incubate for 5 min at room temperature, add NP-40 according to directions, and then add PNGase F and incubate overnight.
5. The quantitation control consists of maltotetraose (Glucose 4). This control should be prepared so that once prepared 5 µL will contain 200 pmol of maltotetraose (standards prelabeled with ANTS are also available commercially). Accurate quantitation will be achieved when using an electronic imaging system. If using a commercial imaging system, refer to the manual for a detailed description of the quantitation procedures.
6. The stoichiometry of labeling is such that only one molecule of fluorophore is attached to each molecule of oligosaccharide. When labeling 20 nmol or less of total sugar using the reagents and labeling conditions described, the fluorophore labeling efficiency is >95% (5). Labeling more than 20 nmol in each reaction will result in reduced labeling efficiency. When labeling >20 nmol it is recommended that an internal labeling control is included.
7 Sample handling and storage:
   a. Always avoid exposing labeled samples and dyes to light or excess heat;

b. Labeled samples are stable when stored for 3 mo at −70°C in the dark;
c. Unused solutions of the dye and reducing agent can be stored for as long as 2 wk at −70°C. Thaw immediately before use.

8. Band distortion in gels caused by vertical streaking or smearing may result if the sample is overloaded. Use a maximum of 1/5 of the volume of the labeling reaction for each lane. The sample may have a high concentration of salt. Remove salts by dialysis, desalting column, and so on, prior to enzymatic digestion. Distorted sample wells in gel may be caused by tearing of wells when the comb was removed. Remove the comb slowly using a gentle back and forth rocking motion and lift vertically. Alternatively, gels may have been in contact with upper buffer too long prior to sample loading. Samples should be loaded within 5 min of placing the gel in the upper buffer tank.
9. Voltage and/or current leaks can result when high voltages are used. If at the beginning of the run the voltage is >400V or readings are unstable, turn the power off before checking the following: possible electrical leak, check for cracks in glass plates. Remove inner core assembly and check for buffer leak between gaskets and cassette plates. If leaks are evident check that the plates are clean and not cracked or chipped, and that they are installed properly.
10. Buffers should not be reused as they have fluorophore contamination after use. Reuse of buffers may result in no bands being visible on the gel owing to "washout" of the fluorophore-labeled oligosaccharides.
11. Accurate quantification is essential for detailed carbohydrate analysis. Although oligosaccharide patterns on PAGE gels can be viewed and photographed on a standard laboratory UV lightbox, it is not reliable for accurate quantification. Images of gels can be recorded using a Polaroid camera. The proper choice of light source, filters, and film must be made. A filter must be fitted to the camera lens that completely covers the glass of the lens (stray UV contacting the lens will cause it to fluoresce and subsequently lower the sensitivity of the film). A suitable filter will have no inherent fluorescence, peak transmission at approx 500 nm and bandwidth of 80 nm FWHM. A medium speed, medium resolution, Polaroid film is recommended. Use Polaroid 53 film for cameras which use single 4 × 5″sheet film; use Polaroid 553 film for cameras that use 8 sheet film cartridges.

    To visualize the carbohydrate banding patterns, the low fluorescent glass cassette containing the gel (or the gel removed from the casette) is placed on a longwave UV lightbox with a peak excitation output at approx 360 nm.

    Photograph the gel using the lowest practical f-stop setting on the lens with the gel filling as much of the frame as possible. E.g., exposures at f5.6

using Polaroid 53 film have ranged from 5–40 s using the equipment specified above. Keep UV exposure of the gel to a minimum to prevent bleaching.

Develop the film according to the manufacturer's instructions.

12. For electronic archiving and quantitation, several types of imaging systems are available. To give best results these systems must have an illumination source with an excitation wavelength of 365 nm and a 520 nm emission filter placed in the light path between the gel and the image capturing device. The use of an internal standard in the gels is also required for quantitation.

    Following electrophoresis, the gel is inserted into the imager under long-wave UV excitation, and an electronic image of the fluorescent carbohydrate banding pattern of the gel is acquired by the imager's CCD as a digital image. The gel image is displayed on a computer screen using the imaging software. The imaging system should allow for detection and quantification of individual carbohydrate bands into the low picomole range of 1.6–300 pmol. In practice, the most useful and accurate range of the imager for band quantification is between 5 and 500 pmol of carbohydrate and this range was used for the experiments described in this chapter.
13. You may have "smile effect" gel distortions at both sides of the gel. This can happen if the gel is not being cooled uniformly. Check that the cooling system is on and working properly. Check the buffer temperature. Check that the power supply is set for the proper current level.
14. You may have band distortions or "fuzzy bands." This can be caused by wells that may have not been rinsed thoroughly with electrophoresis upper buffer prior to loading samples, or the current may have not been set properly, i.e., the current was too high.
15. Incomplete re-N-acetylation may result in little or no labeling of the released oligosaccharides, presumably by the hydrazide interfering with the reductive amination using ANTS. To check the re-N-acetylation reagents you can use glucosamine that will migrate at a DP of approx 2.5 on the gel when N-acetylated and below DPI when unacetylated. You can also use N-acetyl-glucosamine as an internal control at the beginning of the experiment and take it through hydrazinolysis and re-N-acetylation expecting the same migrations as stated.
16. Oligosaccharides are small molecules that can diffuse rapidly in the gel matrix. Band diffusion and resulting broad or "fuzzy" bands can occur if:
    a. Electrophoresis is run too slowly;
    b. Electrophoresis is run at higher than optimal temperatures;
    c. Electrophoresis is stopped and started repeatedly; and
    d. The gel is removed for visualization for longer than 10 min and then re-electrophoresed.

HPLC Analysis of Fluorescently Labeled Glycans

Tony Merry and Sviatlana Astrautsova

1. Introduction

The study of the glycan chains (oligosaccharides) of glycoproteins presents a number of analytical problems that generally make their analysis more difficult than that of the peptides to which they are attached. A number of different analytical techniques have been applied to the study of glycans. Definitive characterization has traditionally been performed using nuclear magnetic resonance spectroscopy (NMR) and this still remains the only way to unequivocally assign the structure to novel glycans, but the techniques do require relatively large amounts of material (generally in the milligram range). In addition, access to the sophisticated equipment and the expertise required for the interpretation of data mean that the technique is available only to specialized dedicated laboratories. Another technique, which has also been applied extensively to studies of glycan structure, is that of mass spectrometry in various forms. A number of structures have been solved by means of fast atom bombardment (FAB-MS) ***(1,2)*** although generally further information from linkage analysis by gas chromatography-MS of permethylated alditol acetates (PMAA ***(3–5)***) or by use of specific exoglycosidase enzymes ***(6)*** is required. Other techniques for mass spectrometric analysis are becoming more widely used as a result of recent developments in instrumentation ***(7–9)***. Both matrix-assisted laser desorption mass spectrometry with time-of-flight detection ***(8)*** (MALDI-TOF) and electrospray coupled to post source decay ***(9)*** to produce fragmentation ions are now becoming routinely used. The instrumentation is still expensive, however, and requires skilled operation and interpretation.

Another technique that is also used is capillary electrophoresis, which can offer rapid characterization but that can also be difficult to optimize ***(10)***. Polyacrylamide gel electrophoresis of fluorescently labeled glycans, a technique

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

that requires no expensive instrumentation or specialized expertise, may also be used for screening or profiling. Although this is very useful for routine screening of a large number of samples, detailed characterization or sequencing of complex mixtures is problematic.

High-performance liquid chromatography (HPLC) techniques with fluorescent detection offer a compromise in that they give the capability of full characterization of complex glycan mixtures relatively quickly, and although they do require good instrumentation this is considerably less expensive than mass spectrometry or NMR. HPLC is therefore the method of choice for routine analysis of glycosylation of protein, which have glycans of a type that have been previously characterized. Even when the glycan type is novel it is a technique that is compatible with others that can give further structural information, in particular mass spectrometry with LC-MS techniques now becoming fully integrated. The development of HPLC has presented several problems, which are unique to glycan analysis. In particular they generally do not possess a strong chromophore or fluorophore for detection. In addition they may not be charged and different glycans may have very similar composition and physicochemical properties. Therefore, their study has required the development of techniques for their derivatization and also for their separation, which differ from those used for peptides.

When the glycans are released with a free reducing terminus, by either hydrazinolysis or endo-glycosidase, or endo-glycopeptidase enzymes, they may be derivatized by the relatively simple reaction of reductive animation ***(11)***. It is desirable that the derivatization is nonselective to achieve quantitative analysis and it should not cause structural changes such as desialylation. The incorporation of tritium into the C1 position of the reducing terminal monosaccharide fulfils these requirements most effectively, and many studies have been performed by this technique ***(12–14)***. This technique does, however, require the use of relatively large amounts or radioactivity and the use of scintillation counting for high sensitivity work and is not widely used now. Fluorescent labels may also be introduced into the C1 position by similar reductive amidation reactions and a number of these have now been described including 2-amino pyridine ***(15–17)***, 2-aminoacridone ***(18)***, 3-(acetylamino)-6-aminoacridine (AA-Ac) ***(19)***, 2-aminoanthanilic acid ***(20,21)***, and 2-aminobenzoic acid (2-AB) ***(20)***.

A number of chromatographic systems have been developed for separation including gas–liquid chromatography ***(22)*** size-exclusion chromatography on polyacrylamide based beads, notably the BioGel P4 series ***(24,24)***, ion-exchange chromatography on standard matrices ***(25)***, and the development of specialized matrices for anion-exchange (high-performance anion-exchange chromatography [(HPAEC]) ***(26–29)***. They have been used in a large number of studies on protein glycosylation but these techniques have certain drawbacks. Low-pressure size-exclusion chromatography requires great care in column packing

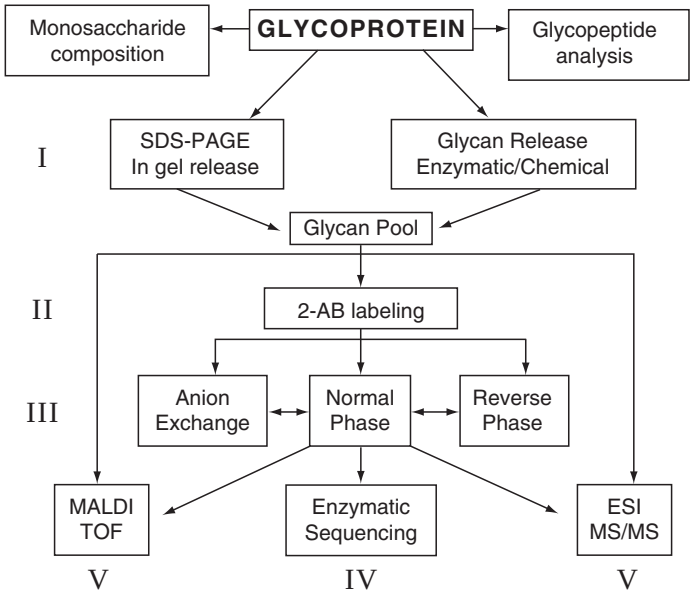

Fig. 1. The steps involved in complete analysis are shown diagrammatically. The Roman numerals relate to the stages given in the Introduction.

and the run times are long, HPAEC requires the use of high-pH and high-salt buffers that have to be removed before further analysis of separated glycans, such as exoglycosidase sequencing. The use of glycans labeled with a fluorescent tag such as 2-AB ***(20)*** and separated on suitable HPLC matrices ***(30,31)*** provides a convenient and sensitive means of profiling and sequencing of glycoprotein glycans ***(30,32,33)*** that can now be performed in many laboratories.

The analysis of glycans by this technique proceeds in a number of stages:

1. Release of glycans from the glycoprotein.
2. 2-AB labelling of the glycans.
3. Initial HPLC profiling.
4. Enzymatic sequencing of glycans.
5. Conformation of structures by mass spectrometry.

This approach is summarized in **Fig. 1**. The glycan release techniques may be adapted according to the source and purity of the proteins under study.

2. Materials

2.1. Equipment

1. HPLC system: High-pressure mixing two-solvent system capable of delivering 0.1–1.0 mL/min with shallow gradient (*see* **Note 1**).
2. Solvent degasser: Additional solvent degasser aids reproducibility.

3. Detector fluorescent detector capable of excitation at λ_{330nm} and emission at λ_{420nm} (*see* **Note 2**).
4. Computer system for data collection and analysis.
5. Data acquisition software, for example, Waters Millenium™.
6. Curve-fitting software, Microsoft Excel™ or Proprietary software from Instrument Vendor (*see* **Note 3**).

2.2. Reagents

1. Anhydrous hydrazine was prepared by distillation from reagent grade hydrazine (Pierce Aldrich 21515-1) by mixture with calcium oxide and toluene as previously described ***(34)*** (*see* **Note 4**). This is available commercially from Ludger Ltd, Abingdon, UK
2. Acetic anhydride (ACS reagent, Sigma).
3. Anion-exchange resin: Bio-Rad AG50 X12.
4. Acetonitrile: HPLC grade with low background fluorescence such as E Chromosolv® (Reiedel-de-Haën, from Sigma).
5. Formic acid Aristar grade (BDH).
6. 26% Extra pure ammonia solution (Reiedel-de-Haëen, from Sigma).
7. Water MilliQ or equivalent, sub boiling point double distilled water (for mass spectrometric analysis).
8. Whatman no. 3 chromatography paper.
9. 2-Aminobenzamide labelling kit (*see* **Note 5**).
10. Pro-Mem Filter, 0.45 µm cellulose nitrate (R. B. Radley and Co. Ltd., Shire Hill, Saffron Walden, Essex, UK).
11. 3-([3-Cholamidopropyl)dimethylammonio)-1-propanesulfonate (CHAPS) detergent buffer: 50 m*M* ammonium formate, pH 8.6, 1.29. w/v CHAPS, 0.1 *M* EDTA.

2.3. Enzymes

1. "PNGase F" is available from Ludger Ltd, Abingdon, UK) PNGQA-BioTM (PNGase F Peptide-N4-(acetyl-ß-glucosaminyl)-asparagine amidaseN-Glycosidase F.)
2. Exoglycosidase enzymes

Sequencing grade enzymes were obtained from Prozyme (Palm Desert, California – distributed in Europe by Ludger Ltd (Abingdon) unless specified and were used with the buffers supplied as shown in **Table 1**. The following enzymes were used for exoglycosidase sequencing and given the abbreviations shown below along with their specificities.

a) ABS α2–6 + 2,3 Specific sialidase (Arthrobacter ureafaciens).
b) NDVS α2–3 Specific sialidase (Newcastle disease virus).
c) BTG β1–3 (>β1,4 or 6) Specific galactosidase (bovine testes).
d) SPG β1–4 Specific galactosidase (*Streptococcus pneumoniae*).
e) AMF α1–3 Specific fucosidase (almond meal).
f) BKF α1–6 (>α1,2 or 3 or 4) Specific fucosidase (bovine kidney).

g) JBH β1–2,3, 4 or 6 Specific hexosaminidase (GlcNAc or GalNAc, Jack Bean).
h) SPH β1,3 or 6 to Gal β1,2,3 or 6 to Man *N*-acetylglucosaminidase (*Streptococcus pneumoniae*).
i) JBM α1–2, 1–3, 1–6 Specific mannosidase (Jack Bean).
j) HPM β1–4 Specific mannosidase (*Helix pomatia*).

2.4. Standards

1. Partially hydrolyzed dextran (glucose oligomer standard) (Ludger Ltd, Abingdon UK).
2. Arabinose oligomers (monomer to octamer are available from Dextra Labs, Reading, UK).
3. 2-AB labeled glycan standards, all available from Ludger Ltd (Abingdon UK):
   a. Biantennary galactosylated.
   b. Biantennary galactosylated (with core 1,6-linked fucose).
   c. Biantennary galactosylated (with bisecting GlcNAc).
   d. Biantennary sialylated.
   e. Triantennary.
   f. Tetraantennary.
   g. Oligomannose (Man 5,6,7,8,9).
   h. Type 2 core *O*-glycan.

3. Methods

3.1. Glycan Release

3.1.1. Enzymatic Release with PNGaseF from Glycoproteins in Solution (Method from **ref. 35**)

1. PNGaseF solution at 1000 U/mL (Boehringer Mannheim).
2. Isolate the glycoprotein according to your usual procedures.
3. The sample should be relatively salt free and contain no extraneous carbohydrates (e.g., Sepharose-purified material contains large amounts of free carbohydrate that should be removed by dialysis using a 15–18,000 mol wt cut-off membrane)
4. If the volume of the glycoprotein solution required is >100 µL, dry the glycoprotein in a 1.5-mL microcentrifuge tube. Generally 50–200 µg of glycoprotein is required.
5. The incubation of a control glycoprotein with known glycosylation alongside experimental samples is recommended (*see* **Note 6**).
6. Proceed with the enzymatic digestion as described in **Subheading 3.1.2**.
7. Store remaining glycoprotein at 4°C for future use.
8. Dissolve sample in 50 µL of 50 m*M* ammonium formate, pH 8.6, 0.4% sodium dodecyl sulfate (SDS).
9. Incubate for 3 min at 100°C.
10. Cool and add 50 µL of CHAPS detergent buffer.
11. Add 1 U of PNGaseF (1 µL).
12. Incubate for 24 h at 37°C (add 5 µL of toluene to prevent bacterial growth).

Table 1
Incubation Conditions for Exoglycosidase Enzymes

Enzyme	Specificity	Buffer	Concentration & Incubation Time*
Sialidase Arthrobacter Ureafaciens EC	α2-3, 6, 8 sialic acid	50mM sodium acetate pH 5.5	1μU/μl 3-16hrs
Sialidase From Newcastle Disease virus Recombinant EC 3.2.1.26	α 2,3 sialic acid only	50mM sodium phosphate pH 6.0	1μU/μl 16hrs
β-galactosidase Bovine Testes EC	β1,3 or 4 Gal	100mM citrate-phosphate pH 5.0	1mU/μl 3-16hrs
β-galactosidase Streptomyces Pneumoniae EC	β1,3 Gal	100mM Sodium Acetate pH 6.0	80μU/μl 16hrs
β-N acetylhexoseaminidase Recombinant	β1,3 or 4 GlcNAc or GalNAc	100mM Na citrate-phosphate pH 6.0	10μU/μl 16hrs
β-N-acetylglucosaminidase	β1,3 4 GlcNAc	100mM Na citrate/ phosphate	120μU/μl 16hrs pH 6.0

α-fucosidase Almond Meal	α1-4, 6 Fuc	50 mM NaAc pH 5.0	1mU/µl 16hrs
α-fucosidase Bovine Kidney	α1–3, Fuc	100 mM Na citrate pH 6.0 16hrs	1mU/µl
α-mannosidase Jack Bean	α1-2, 4 Man	100 mM sodium acetate, 2 mM Zn, pH 5.0	67 mU/µ l Requires 2× 16hrs incubations
Endo β-galactosidase B. fragilis	β1-3,4Gal in poly N-acetyl lactosamine 	50mM Sodium Acetate pH 5.8	100µU/µl 3 hrs

* It should be noted that for most of these exoglycosidases the enzyme concentration and the incubation times have not been optimised for the type of glycan or the amount used in studies with fluorescent glycans. The conditions are generally those which can be expected to give complete digestion of the particular linkages. In practice lower enzyme concentrations and shorter incubation times could often be used. It is advisable to check any enzymes against known standard glycans of different types before use in sequencing.

13. Remove 5 µL and analyze the reaction mixture by SDS-polyacrylamide gel electrophoresis (SDS-PAGE).
14. If sample is completely deglycosylated proceed with step otherwise continue with incubation (*see* **Note 8**).
15. Filter samples through protein binding membrane or perform gel filtration.
16. Dry sample in vacuum centrifuge.

3.1.2. Enzymatic Release with PNGaseF from Glycoprotein Bands in SDS-PAGE Gels

Suitable for analysis of low microgram amounts of protein or for unpurified proteins separated by SDS-PAGE or 2-dimensional electrophoresis. Method of Kuster et al. ***(36)***. See Royle et al. ***(37)*** for later modifications

1. Destain Coomassie Blue stained gels in 30% methanol–7.5% acetic acid.
2. Cut out gel pieces with band of interest using a washed scalpel blade, keeping pieces as small as possible.
3. Put into 1.5-mL tubes and wash with 1 mL of 20 m*M* $NaHCO_3$, pH 7.0, twice using a rotating mixer.
4. Add 300 µL of $NaHCO_3$, pH 7.0.
5. Add 20 µL 45 m*M* dithiothreitol (DTT).
6. Incubate at 60°C for 30 min.
7. Cool to room temperature and add 20 µL of 100 m*M* iodoacetamide.
8. Incubate for 30 min at room temperature in the dark.
9. Add 5 mL of acetonitrile–20 m*M* $NaHCO_3$, pH 7.0.
10. Incubate for 60 min to wash out reducing agents and SDS.
11. Cut gel into pieces of 1 mm^2.
12. Place in a vacuum centrifuge to dry.
13. Prepare PNGaseF solution at 1000 U/mL (Boehringer Mannheim): Add 30 U 30 µL of PNGaseF in 20 m*M* $NaHCO_3$, pH 7.0.
14. Allow gel to swell and then add a further 100-µL aliquot of buffer.
15. Incubate at 37°C for 12–16 h.

3.1.3. Release by Hydrazinolysis

Suitable for analysis of *N*- or *O*-linked glycans where the amount of protein is limited, where steric hindrance to enzymatic release is known, or where selective release of glycans by enzymatic means is suspected.

3.1.3.1. Preparation of Samples for Hydrazinolysis

Desalt and dry the samples completely as follows (*see* **Note 8**).

1. Dissolve the sample in 0.1% trifluorocetic acid (TFA) in as small a volume as possible.
2. Set up dialysis at 4°C. A microdialysis system is recommended.
3. Dialyze for a minimum of 48 h in a microdialysis apparatus fitted with a 6000–8000-Dalton cut-off membrane.

4. Recover sample from dialysis membrane. Wash membrane with 0.1% TFA to ensure recovery.
5. Transfer to a suitable tube for hydrazinolysis (*see* **Note 9**).
6. Lyophilize sample for 48 h.
7. For *O*-glycan analysis further drying is recommended (*see* **Note 10**).
8. Remove sample from lyophilizer immediately prior to addition of hydrazine.

3.1.3.2. Hydrazinolysis Procedure

Suitable for analysis of *N*- and *O*-linked glycans when expertise and equipment for the procedure are available ***(34)***.

1. Remove tubes from drying immediately prior to hydrazine addition.
2. Flush tube with argon, taking care not to dislodge lyophilized protein.
3. Rinse dried syringe fitted with stainless steel needle with anhydrous hydrazine.
4. Take up fresh hydrazine and dispense onto sample. A 0.1-mL volume of hydrazine is sufficient to dissolve up to 2 mg of glycoprotein. For larger amounts add more hydrazine.
5. Flame seal the tube. (note reaction may be performed in suitable air tight vials – e.g.
6. Gently shake tube—the protein should dissolve.
7. Place in an incubator (do not use water bath).
8. For release of *N*-linked glycans incubate at 95°C for 5 h; for *O*-glycan release incubate at 60°C for 6 h.
9. Allow to cool and remove hydrazine by evaporation.
10. Add 250 µL of toluene and evaporate. Repeat 5×.
11. Place tube on ice and add 100 µL of saturated sodium bicarbonate solution.
12. Add 20 µL of acetic anhydride.
13. Mix gently and leave at 4°C for 10 min.
14. Add a further 20 µL acetic anhydride.
15. Incubate at room temperature for 50 min.
16. Pass solution through a column of Dowex AG50 X12 (H^+ form)—0.5 mL bed volume.
17. Wash tube with 4 × 0.5 mL of water and pass through a Dowex column.
18. Evaporate solution to dryness. This should be done in stages by redissolving in decreasing volumes of water.
19. Prepare 50 × 2.5 cm strips of Whatman no. 1 chromatography paper (prewashed in water by descending chromatography for 2 d).
20. Spot sample on strip.
21. Perform descending paper chromatography for 2 d in 4:4:1 by vol butanol–ethanol–water for *N*-glycans and 8:2:1 1 by vol butanol–ethanol–water for *O*-glycans.
22. Remove strip from tank and allow all traces of solvent to evaporate.
23. Cut out region of strip from −2 cm to +5 cm from application.
24. Roll up cut chromatography paper and place in a 2.5-mL nonlubricated syringe.
25. Fit a 0.45 µm PTFE filter to syringe.
26. Add 0.5 mL of water and allow to soak into paper for 15 min.
27. Fit syringe plunger and force solution through filter.
28. Wash filter with water 4×, and pass through filter.
29. Evaporate sample to dryness, dissolve in 50 µL of water, transfer to microcentrifuge tubes, and store at −20°C until required.

3.2. Glycan Labeling

Fluorescent labelling with 2-aminobenzamide was performed as described by Bigge et al. ***(20)*** using the kit provided by Ludger Ltd.(Abingdon, UK). The procedure is as follows:

1. Take an aqueous solution of glycan that should contain a minimum of 0.1 pmol and a maximum of 50 pmol of glycans. The volume should be no more than 50 µL.
2. Place in a 0.5-mL microcentrifuge tube and dry down in centrifugal evaporator.
3. Prepare labelling solvent by addition of 150 µL of glacial acetic acid to 100 µL of dimethyl sulfoxide (DMSO). Add 100 µL of the acidified dimethyl sulfoxide solvent to 2-aminobenzamide to make a 0.25 *M* solution. Mix well to dissolve the 2-AB (may require gentle warming).
4. Add all this solution to sodium cyanoborohydride to make a 1.0 *M* solution.
5. Mix well for 5 min to dissolve the reductant.
6. Add 5 µL of the labelling reagent to the dried sample.
7. Mix well and centrifuge briefly.
8. Incubate at 65°C for 1 h and mix well. Incubate for a further 2 h.
9. Cool the labelling mixture on ice.
10. Remove free label by either technique given in **Subheadings 3.2.1** and **3.2.2**.

3.2.1. Removal of Free 2-AB Label by Ascending Paper Chromatography

1. Cool the 2-AB reaction mixture in freezer.
2. Apply all 5 µL of sample to a point in centre of strip 1 cm from the bottom.
3. Allow to dry for 2 h.
4. Perform ascending chromatography for 1 h in acetonitrile.
5. Examine strip under UV to see if the spot of free dye has migrated to the top of the strip.
6. If it is not at the top continue chromatography until it is.
7. Dry the paper completely.
8. Cut out the origin on the strip.
9. Place in a 2.5-mL syringe fitted with a 0.45-µm PTFE filter.
10. Apply 0.5 mL of water and leave for 15 min.
11. Push water through the filter.
12. Wash twice with a further 0.5 mL of water.
13. Dry down labeled sample in a vacuum centrifuge.

3.2.2. Removal of 2-AB Label on Filter Disks

1. Before use wash Whatman no. 1 filter paper in 500 mL of MilliQ water. Place filter paper in a beaker and add water. Leave for 15 min at room temperature. Decant water. Repeat this 4 times.

2. Dry paper in a 65°C over for 2 h. The paper may be stored at room temperature after this step.
3. Cut 6-mm discs from washed paper.
4. Place discs in a Bio-Rad disposable column. For a sample of < 10 µg of glycoprotein use two discs; for more use five discs).
5. Add 2 mL of water and leave for 5 min with columns capped.
6. Uncap columns and wash with another 4 × 2 mL of water (*see* **Note 11**).
7. Wash with a further 5 × 2 mL of 30% acetic in water (*see* **Note 11**).
8. Cap column and add 2 mL of acetonitrile.
9. Leave for 5 min and uncap the column.
10. Wash with a further 2 mL of acetonitrile just before applying sample; cap column.
11. Remove incubation vial and put in freezer for 5 min to cool down.
12. Centrifuge the tube and spot all the sample onto the disc.
13. Leave for 15 min and rinse tube with 100 µL of acetonitrile and add to disc. Leave for 5 min.
14. Add 2 mL of acetonitrile—uncap column and discard wash.
15. Wash with a further 4 × 2 mL of acetonitrile.
16. Place syringes (2.5-mL Fortuna) fitted with a 0.45-µm filter and stoppers, under the filter.
17. Elute glycans with 4 × 0.25 mL of water (*see* **Note 11**).
18. Dry sample down for analysis.

Note: *A kit employing a proprietary separation membrane for separation of free 2-AB from glycans (LudgerCleanTM EB Cartridges) is now available from Ludger Ltd (Abingdon, UK)*

3.3. Normal Phase Chromatography

The following conditions are recommended:

1. Buffers:

Ammonium formate: 50 m*M* formic acid adjusted to pH 4.4 with ammonia solution.

Acetonitrile: HPLC grade;

2. Column: GlycoSep N™ column (Ludger Ltd) or TokoHas TSK-amide 80.
3. Gradient:
4. Sample loading:

a. The sample should be loaded in 80% acetonitrile–20% water (v/v). In practice take 20 µL of the sample in water and add 80 µL of acetonitrile.
b. Inject 95 µL of the sample.
c. A standard dextran should be included with all sample runs.
d. **Fig. 2** shows a typical separation of human serum IgG with dextran ladder calibration.

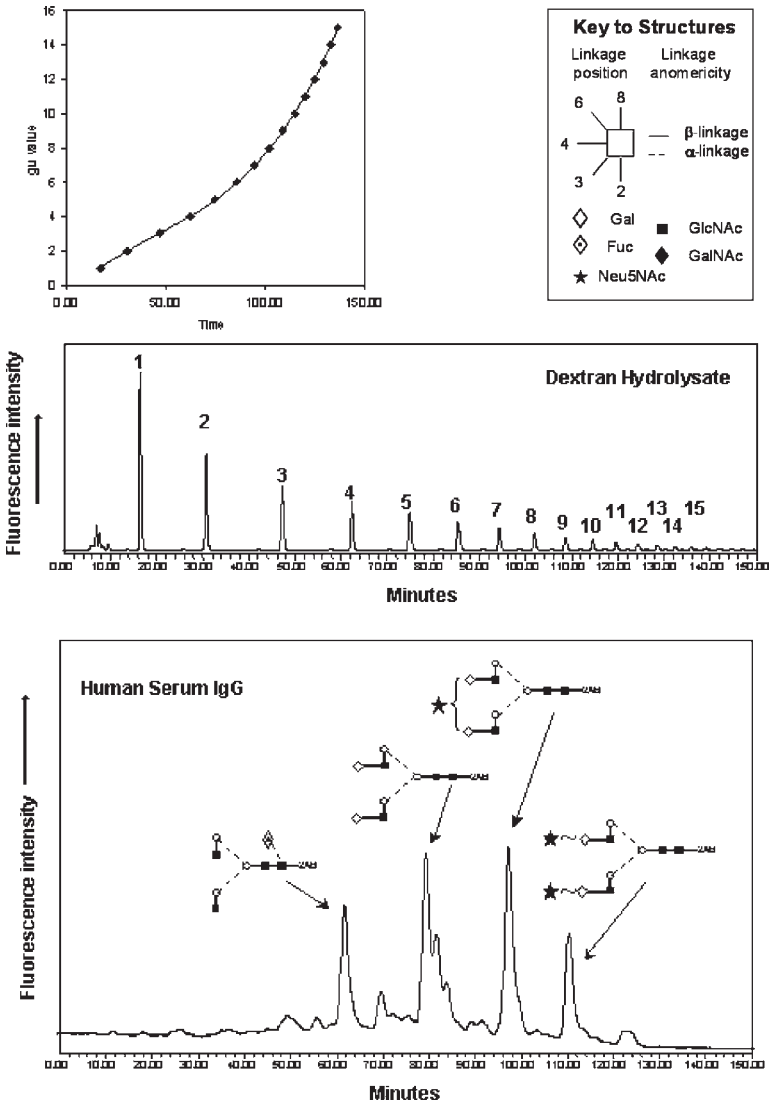

Fig. 2. Analysis of IgG N-glycans released by hydrazinolysis on normal phase HPLC. The top panel shows the calibration curve for conversion of retention time into glucose units based on a third order polynomial. The *middle panel* shows the separations of glucose oligomers from the dextran ladder. The *lower panel* shows the separation of the fluorescently labeled glycans from IgG with structures corresponding to the major peaks indicated. Software (GlycoBase) for this purpose is now available on the Internet as part of the EuroCarbDB project (http://www.eurocarbdb.org/) (*see* **Note 3**).

a. Startup method run time, 30 min.				b. Separating method run time, 180 min			
Time (min)	Flow (ml/min)	A (%)	B (%)	Time (min)	Flow (ml/min)	A (%)	B (%)
0	0	20	80	0	0.4	20	80
04	1.4	20	80	152	0.4	058	42
08	1.4	95	05	155	0.4	100	00
13	1.4	95	05	157	10.	100	00
16	1.4	20	80	162	10.	100	00
25	1.4	20	80	163	10.	020	80
26	0.4	20	80	177	10.	020	80
60	0.4	20	80	178	0.4	020	80
61	0	20	80	260	0	2200	80

5. Data analysis:
a. The elution times of all peaks in the dextran ladder should be recorded.
b. To assign glucose unit values a polynomial fit should be applied to the data to generate a standard curve. A third-order polynomial will generally give a good fit (*see* **Fig. 2**).
c. The glucose unit values of sample peaks may then be calculated (*see also* **Note 3**).
d. Published values of glucose unit values for a wide series of glycans may be used to give an indication of possible structures present. These are now available on the Internet as part of the GlycoBase software developed by NIBRT, Dublin (http://glycobase.ucd.ie/cgi-bin/public/glycobase.cgi) for the EUROCarbDB project (http://www.eurocarbdb.org/)

3.4. Reverse-Phase Chromatography

1. Buffers:
a. ammonium formate–triethylamine 50 m*M* formic acid adjusted to pH 5.0 with triethylamine.
b. Acetonitrile: HPLC grade; *see* **Subheading 2.2.**
2. Column: Reverse-phase column GlycoSep™ R—Ludger Ltd (Abingdon, UK) or equivalent.
3. Sample loading:

a. Startup method run time, 30 min				b. Separating method run time, 180 min				
Time	Flow	A	B	Time	Flow	A	B	
00	0.05	05	95	000	0.5	95	05	
05	100.	05	95	030	0.5	95	05	
10	100.	05	95	160	0.5	85	15	
20	100.	05	95	165	0.5	76	24	
21	100.	95	05	166	1.5	05	95	
28	100.	95	05	172	1.5	05	95	
29	0.50	95	05	173	1.5	95	05	
90	0.50	95	05	178	1.5	95	05	
91	00.0	95	05	179	0.5	95	05	
				220	0.5	95	05	
				221		0	95	5

a. The sample should be loaded as a aqueous solution. A volume of 95 µL of sample should be loaded.
b. A standard of an arabinose oligomers (available from Dextra Labs, Reading) should be included with all sample runs.

4. Data analysis:

a. The data may be analyzed in a similar way to that of normal phase but using the values for the arabinose ladder.
b. Typical values for the AU units for a number of structures are available *(37)*.
c. It can often be helpful to compare normal and reverse-phase profiles for the same glycans as shown in **Fig. 3**. The different principles for separation are illustrated by the differences in separation on the two systems. By combining both types of analysis all four structures can readily be identified, for example, the separation of A2G2F and A2G2FB.

3.5. Weak Anion-Exchange Chromatography (WAX)

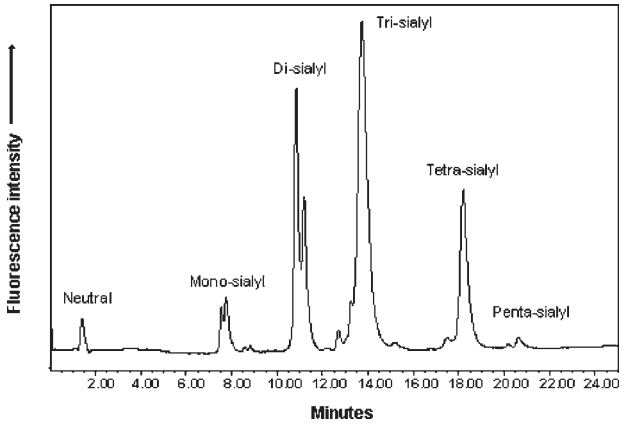

Fig. 3. Analysis of fetuin on Weak Anion Exchange Chromatography. The separation of glycans possessing from 1 to 5 sialic acids is shown.

1. Buffers:
a. 500 m*M* Formic acid adjusted to pH 9.0 with ammonia solution.
b. Methanol water: 10:90 (v/v).
2. Gradient
3. Sample loading
a. The sample should be loaded as an aqueous solution. A volume of 95 µL of sample should be loaded.

a.Startup method run time, 30 min. Separating method run time, 180 min

Time	Flow	A	B	Time	Flow	A	B
000	0	0	0	0	1	00	100
05	10.	05	95	12	1	005	095
20	10.	05	95	50	1	080	020
21	10.	95	05	55	1	100	000
28	10.	95	05	65	1	100	000
29	0.5	95	05	66	2	000	100
90	0.5	95	05	77	2	000	100
91	00.	95	05	78	1	000	100

b. No suitable standards are currently available although it is useful to run a well characterized glycoprotein such as bovine serum fetuin (Sigma).
c. The glycans generally elute on the basis of charge although the size of the glycan also contributes to the position of elution.
d. A typical separation of charged *N*-glycans from bovine serum fetuin is shown in **Fig. 3**.

3.6. Exoglycosidase Digestion of N-Glycans

Digestions are generally performed on the pool of glycans by the application of exoglycosidases under the incubation conditions shown in Table 1 in a series of enzyme arrays of increasing complexity as shown in Table 2.

1. The amount required for each digestion can be judged from the previous profiling run, but in general 100 fmol of glycan is detectable. In practice more may

Table 2
Typical Arrays for N-Glycan Sequencing

Array	Vol enzyme	Vol buffer	Water
ABS	1	2	7
ABS BTG	1 2	2	5
ABS BTG BKF	1 2 1	2	4
ABS BTG BKF AMF	1 2 1 1	2	3
ABS BTG BKF AMF JBH	1 2 1 1 2	2	1
JBM (high)	10		
JBM (low)	0.8		9.2

be used with the enzyme concentrations given below if sufficient material is available.

2. Pipette no more than 50 µL of solution into a 0.5-mL microcentrifuge tube.
3. Evaporate glycan solutions to dryness in a vacuum centrifuge.
4. Add 2–5 µL of enzyme solution and 2 µL of incubation buffer.
5. Make the total volume up to 10 µL with water.
6. Incubate for 16–24 h at 37°C.
7. Cool and load the digestion mixture onto a protein binding filter (Microspin 45).
8. Leave for 15 min at room temperature.

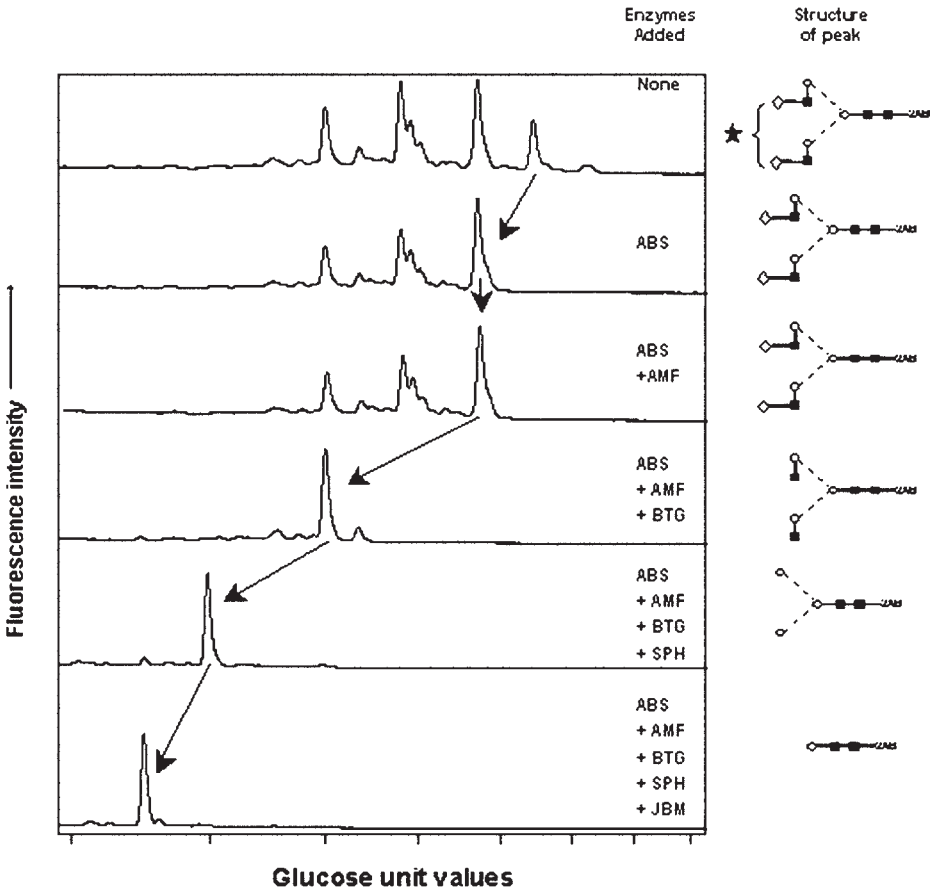

Fig. 4. Exoglycosidase digestion of IgG glycans monitored on normal phase column normal phase HPLC. Exoglycosidase abbreviations ABS – α 2,6 + α 2,3 specific sialidase (Arthrobacter Ureafaciens), BTG 1,2 (+ α 1–4) specific galactosidase (Bovine Testes), AMF- α 2,3 specific fucosidase (Almond Meal) SPH- β1,3 (4,6) specific hexosaminidase (Streptococcus Pneumonae) JBM-α-mannosidase (Jack Bean).

9. Centrifuge for 15 min at 5000*g*.
10. Wash tube with 10 µL of freshly prepared 5% acetonitrile in water and load onto filter.
11. Leave for 15 min at room temperature.
12. Centrifuge for 15 min at 5000*g*.
13. Repeat **steps 10–12**.
14. Twenty microliters of sample may be directly analyzed by HPLC if sufficient material is available; if not, then dry down sample and redissolve in 20 µL of water.
15. Example of digestion of *N*-glycans from IgG is shown in **Fig. 4**.

3.7. Exoglycosidase Digestion of O-Glycans

Digestions are generally performed on the pool of glycans; however, the strategy differs from that for *N*-glycans. Digestions should be performed by the following mixtures of glycans where the choice of glycosidases is dictated by the outcome of previous digestions. Since several *O*-glycans may co elute on any matrix the analysis on both normal and reverse phase is recommended. Incubation conditions recommended for common exoglycosidases are shown in Table 1. A detailed description of the procedure and reference values for digestion products may be found at the following web site; http://glycobase.ucd.ie/

1. The samples are prepared for digestion as described in steps 1–3 (*see* **Subheading 3.6**).
2. First perform ABS digestion to detect presence of sialic acid (in any linkage).
3. Perform ABS + BTG digestion to show the presence of galactose.
4. Perform ABS + BKF digestion to show the presence of fucose.
5. Perform ABS + JBH digestion to show presence of *N*-acetylglucosamine or *N*-acetylgalac-tosamine.
6. In each case digestion will be apparent from a shift in peaks. If the digests are analyzed by normal phase and reverse phase then possible identities of structures may be found from the GU and AU values.
7. If digestion with ABS occurs then also digest pool with NDVS to determine if the sialic acid linkage is 2,3.
8. If digestion with ABS + BTG occurs then digest with ABS + SPG to determine if linkage of galactose is 1,4.
9. If digestion occurs with ABS + BKF then digest with ABS + AMF to determine if fucose linkage is 1,3 or 1,4.
10. If digestion with ABS + JBH occurs then digest with ABS + SPH to determine if *N*-acetylglucosamine or *N*-acetylgalactosamine is present.
11. Note that the complete characterization may require repeated digestions as there is no common core sequence as found for *N*-glycans.
12. Example of *O*-glycan sequencing is shown **Fig. 5**.

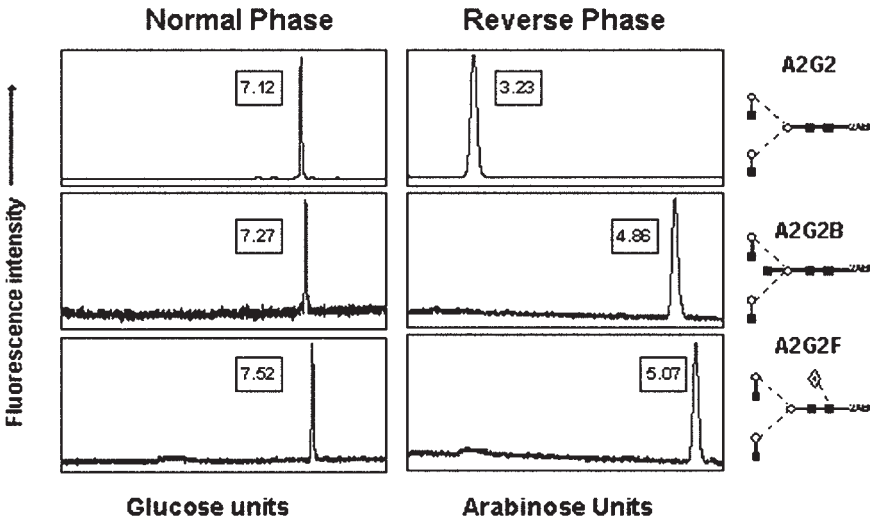

Fig. 5. Analysis of bi-anennary, fucosylated, bisected glycans by reverse phase HPLC – comparison with normal phase HPLC showing complimentarily of separation techniques.

3.7.1. Data Analysis (software for this analysis is now available as pert of the open access EUROCarbDB project (http://www.eurocarbdb.org/).

1. The movement of a peak in an exoglycosidase incubation indicates that it contains the monosaccharides in the linkages removed by that enzyme.
2. A shift in the position of peaks will be seen with decreasing complexity of the chromatogram with increase in the number of enzymes applied.
3. Reference to the last chromatogram in a series will allow identification of the basic core *N*-glycan structure as shown in **Fig. 4**.
4. The last digest in a series will indicate the core glycans present.
5. Working back through the digests, the structures from which a glycan has been removed are identified.

a. In the example the presence of terminal *N*-acetylglucosamine in the structure is shown comparing digest 5 to 4.
b. The presence of terminal galactose is shown by comparing digest 3 to 4.
c. The presence of sialic acid is shown by comparing digest 3 to 1.
d. In this way the structure shown can be assigned to peak A.

6. The presence of other peaks indicates that monosaccharides not covered by the array are present (such as oligomannose) or that residues are substituted by groups such as sulfate or phosphate.
7. An examples of *O*-glycan sequencing is shown in **Fig. 6** with sequential application of glycosidases.

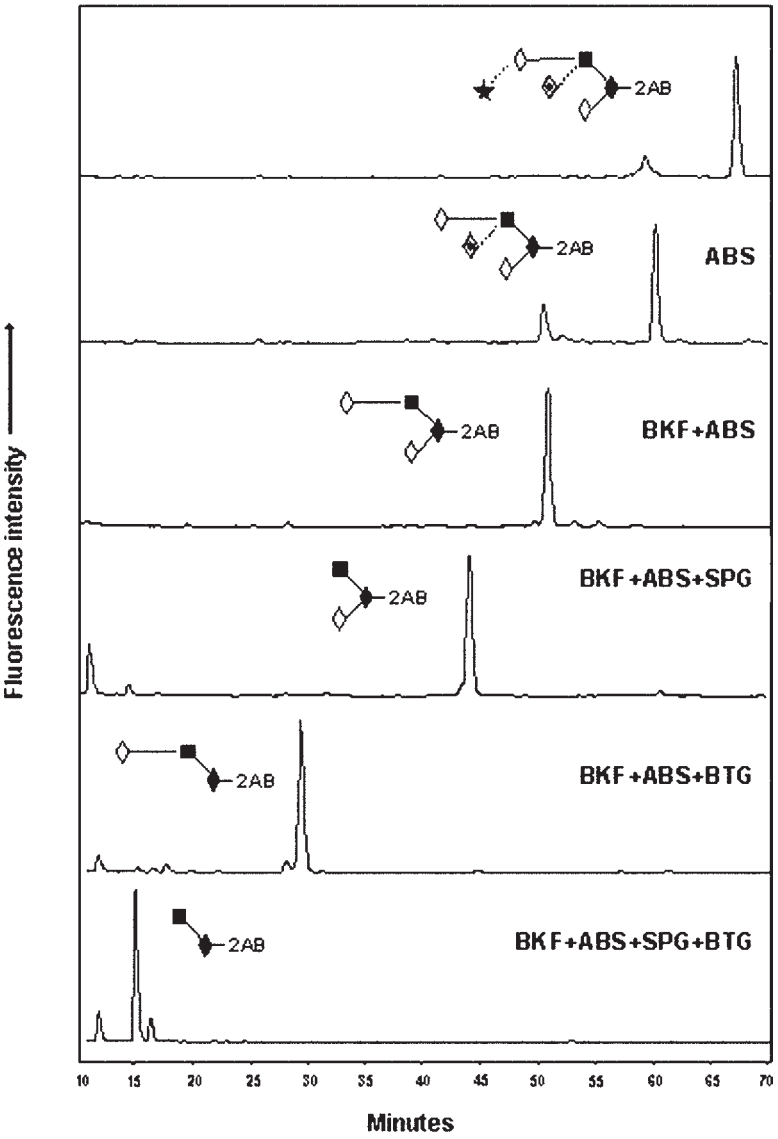

Fig. 6. Example of exoglycosidase sequencing an *O*-glycan on normal phase HPLC. SPG -β1,4 specific galactosidase (*Streptococcus pneumoniae*), other exoglycosidse abbreviations as in **Fig. 4**.

3.8. Mass Spectrometry

Samples may be further analyzed by mass spectrometry (MALDI-TOF or ESI/ MS/MS) for confirmation of structures but generally require further desalting although online systems are now available and are particularly suitable for this kind of analysis. A recent International Study by HUPO (Human Disease Glycolic/Proteome Initiative) compared various techniques for HPLC analysis and showed that the combination of HPLC and Mass Spectrometry allowed sensitive and accurate analysis of N-glycans *(38)*. This study is now being extended to O-glycans. The tools developed by the EuroCarbDB are particularly recommended

1. It is often useful to perform the MS analysis on the glycan pool alongside the HPLC analysis but approx 10× more material is generally required.
2. As all solvents used are volatile, fractions containing peaks from the HPLC run may be collected and dried in a vacuum centrifuge but cleanup may be required (*see* **Note 12**).

4. Notes

1. Waters System is recommended. Hewlett-Packard is also suitable. System with similar specification from other manufacturers may be suitable but must be capable of high-pressure mixing of acetonitrile and aqueous solvents.
2. Jasco or Waters is recommended but other detectors of similar specificity may be suitable.
3. Glycobase is a list of GU values and associated software for analysis of exoglycosidase digestion of glycans that was originally developed at the Oxford Glycobiology Institute and subsequently at NIBRT, Dublin, as part of the EuroCarbDB project. It will form one of the databases available at www.eurocarbdb.org/.
4. Great care should be taking in the handling of hydrazine. Dry hydrazine of suitable quality may be obtained from Ludger Ltd. (Abingdon, UK).
5. Available from Ludger Ltd. (Abingdon, UK).
6. Suitable glycoproteins include ribonuclease B, bovine serum fetuin, and human serum haptoglobulin.
7. The change in position of a band on SDS-PAGE indicates *N*-glycosylation. In some cases incomplete digestion may lead to the production of a series of bands corresponding to partially deglycosylated glycoprotein. Complete release is indicated by conversion to a single band at the lowest molecular weight.
8. The presence of most salts, dyes, or detergents will interfere with hydrazinolysis. The sample must also be completely anhydrous.
9. All glassware used should be soaked in 4 *M* nitric acid for 4 h and thoroughly washed in water before use.

10. The use of cryogenic drying by placing under high vacuum connected to a trap of charcoal submerged in liquid nitrogen for a period of 72 h as described by Ashford et al. ***(34)*** is recommended.
11. It may be necessary to apply slight pressure to the top of the column or to use a suitable vacuum apparatus.
12. Double-distilled (sub boiling point) water should be used for mass spectrometric analysis. Suitable techniques for post-HPLC cleanup and for mass spectrometry by electrospray ***(8)*** and by MALDI ***(9)*** have been described recently.

Acknowledgments

Professor Sviatlana Astrautsova is at the Department of Microbiology, Medical University of Grodno, Belarus. The advice and help of the former members of the Glycoimmunology group at the Oxford Glycobiology Institute, Director Professor R. A. Dwek and Group Leader Prof. Pauline Rudd (now at NIBRT, Dublin), is gratefully acknowledged. In particular, I would like to thank Dr. Louise Royle (now at Ludger Ltd Abingdon, UK) and Dr Catherine Radcliffe for their valued help and comments. Thanks also to Dr Max Crispin (STRUBI, Oxford) for data in **Fig. 4** and for his helpful comments on the manuscript.

The techniques described here are the result of many years of development by previous members of the Oxford Glycobiology Institute, and in particular Dr David Harvey for his mass spectrometry expertise, Dr. Geoffrey Guile for his HPLC expertise and Dr. Taj Mattu who were all involved in the development of the protocols described in this chapter.

Although the group no longer exists at the Glycobiology Institute in Oxford Prof Rudd is continuing development and in particular training all the procedures detailed here at the NIBRT Dublin and the EuroGlycosciences Forum (www.glycosciences.eu) is promoting training in this area.

Glycoprofiling Purified Glycoproteins Using Surface Plasmon Resonance

Angeliki Fotinopoulou and Graham A. Turner

1. Introduction

1.1. Glycosylation and Its Investigation

The carbohydrate part of glycoproteins can define several of their biological properties, including the clearance rate, immunogenicity, thermal stability, solubility, the specific activity, and conformation ***(1)***. Often, small differences in the composition of the sugar side chains of a glycoprotein can affect the biological properties ***(2)***. Characterization of oligosaccharide structures on glycoproteins is essential for glycoprotein therapeutic products, because inflammatory and systemic responses may arise if glycosylation of the product is different from that of the native substance.

Determination of the precise oligosaccharide profile of a glycoprotein, however, cannot yet be considered as a routine laboratory task. Methods for glycosylation analysis can be generally divided in two major categories, direct methods and methods using lectins. This chapter describes a recently developed method that measures the binding of lectins to glycoproteins using surface plasmon resonance (SPR). Lectins are a class of proteins that bind to carbohydrates in a noncovalent reversible way that does not chemically modify the sugar molecule ***(3)***. The lectin specificity is not absolute, but usually there is one carbohydrate grouping to which a lectin binds with much higher affinity than to other carbohydrate structures. This property makes them ideal for recognizing oligosaccharide structures. Although lectin methods are indirect, they can be used when comparisons are needed. They provide many advantages compared to other methods for investigating carbohydrate structures. There are a large number of lectins available with different and distinct specificities. Lectin methods are also quick and simple ***(4)***.

1.2. Surface Plasmon Resonance and Lectins

SPR is an optical sensing phenomenon that allows one to monitor biomolecule interactions in real time (**Fig. 1**). The sensor device is composed of a sensor chip consisting of three layers (glass, a thin gold film, and a carboxymethylated dextran matrix); a prism placed on the glass surface of the chip; and a microfluidic cartridge, which controls the delivery of liquid to the sensor chip surface ***(5).*** When light illuminates the thin gold film, energy is transferred to the electrons in the metal surface causing the reflected light to have reduced intensity at a specific incident angle. This angle of nonreflectance changes as the refractive index in the vicinity of the metal surface changes. The refractive index depends upon the mass on the surface of the gold film. A response of 1000 resonance units (RUs) corresponds to a shift of 0.1° in the resonance angle and represents a change in the surface protein concentration of about 1 ng/mm^2 ***(6).***

Because all proteins, independent of sequence, contribute the same refractive index, SPR can be used as a mass detector. A glycoprotein, therefore, can be immobilized onto a sensor chip surface and then be probed by a panel of lectins. The binding or nonbinding of the lectins provides information about the oligosaccharide structures found on the carbohydrate chains. For example, if a glycoprotein has a trimannose core on its *N*-linked chains, it will bind to the lectin concanavalin A (Con A), or if it has terminal α2–3 or α2–6 *N*-acetylneuraminic acid (Neu5NAc) on its oligosaccharide chains it will bind to the Neu5NAc specific lectins *Maackia amurensis* agglutinin (MAA) or *Sambucus nigra* agglutinin (SNA), respectively.

Lectin binding can also be performed after treatment with glycosidases to gain more information about the oligosaccharide structures present. By sequentially treating the immobilized glycoprotein with glycosidases and measuring

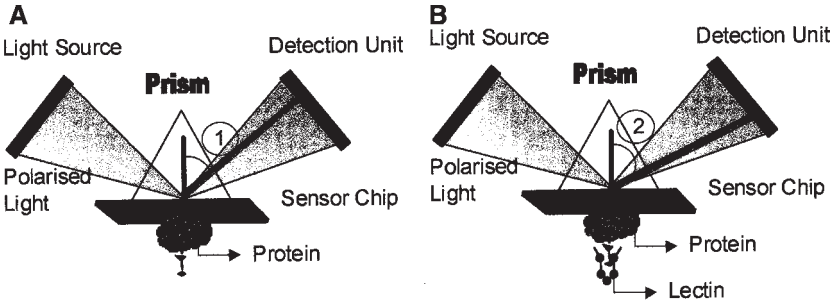

Fig. 1. SPR detects changes in the angle of nonreflectance. This angle changes if the refractive index of the chip surface changes, for example, when a protein is immobilized on the chip. **(A)** A glycoprotein is immobilized resulting in *angle 1*; **(B)** a lectin is bound to the immobilized glycoprotein resulting in *angle 2*.

the binding of a panel of lectins after every treatment it is possible to gain information on the oligosaccharide sequence.

Some lectins will bind to the immobilized glycoprotein only if they are pretreated with sialidase to remove the terminal Neu5NAc. An example of this is peanut agglutinin (PNA), which binds to Galactose β1–3 *N*-acetylgalactosamine groupings on *O*-linked chains after the removal of Neu5NAc.

SPR has been used for investigating the kinetics of the interaction between oligosaccharides and lectins ***(7–9),*** for characterization of fetuin glycosylation ***(10),*** for the determination of agalactoIgG in rheumatoid arthritis patients ***(11),*** and recently, we have developed a method for investigating the glycosylation of recombinant glycoproteins ***(12).***

2. Materials

2.1. Reagents

1. 0.05 *M N*-Hydroxysuccinimide (NHS).
2. 0.2 *M N*-ethyl-*N*' (dimethylaminopropyl)-carbodiimide (EDC).
3. 1 *M* Ethanolamine hydrochloride, pH 8.5.
4. 0.1 *M* HCl.
5. Running buffer (HBS): 10 m*M* 2-[4-(2-hydroxyethyl)-1-piperazinyl] ethanesulfonic acid (HEPES), pH 7.4, 150 m*M* NaCl, 3.4 m*M* ethylenediaminetetraacetic acid (EDTA), 0.0005% Surfactant P20.
6. 10 m*M* Sodium acetate, pH 4.0.
7. 10 m*M* Sodium acetate, pH 4.5.
8. 10 m*M* Sodium acetate, pH 5.0.
9. 10 m*M* Sodium acetate, pH 5.5.
10. Lectin buffer: 10 m*M* sodium acetate, pH 5.0 with cations 2 m*M* $MgCl_2$, $MnCl_2$, $ZnCl_2$, $CaCl_2$.
11. Lectins used: *MAA, SNA, Datura stramonium Agglutinin (DSA), ConA, PNA, aleuria aurantia Agglutinin (AAA).*

2.2. Equipment

BIAcore 1000 apparatus (Biacore AB, Uppsala) is fully automated and controlled by the manufacturer's software. During the operation of the equipment the output from the chip is displayed on VDU as resonance units (RUs) vs time.

3. Method

The procedure used for lectin/SPR can be divided into four steps. The first three are essential for any SPR experiments and the last one is optional.

1. "Preconcentration" step.
2. Ligand immobilization step.
3. Lectin binding.
4. Enzyme treatment.

3.1. Preconcentration

Before immobilizing a ligand to the chip surface a procedure called "preconcentration" needs to be performed. The latter step is important for efficient chemical immobilization of the ligand. It is accomplished by passing the ligand over the chip surface and utilizing the electrostatic attraction between the negative charges on the surface matrix (carboxymethyl dextran on a CM chip) and positive charges on the ligand at pH values below the ligand pI. Preconcentration is performed at 25°C. The ligand is injected at different pHs and the pH that provides the steepest curve is used (*see* **Note 1**). The detailed sequence of steps is as follows:

1. A continuous flow of HBS buffer is applied at flow rate of 10 mL/min.
2. A 2-min pulse of ligand in 10 m*M* sodium acetate, pH 4.0, is applied.
3. A 2-min pulse of ligand in 10 m*M* sodium acetate, pH 4.5, follows.
4. A 2-min pulse of ligand in 10 m*M* sodium acetate, pH 5.0, follows.
5. A 2-min pulse of ligand in 10 m*M* sodium acetate, pH 5.5, follows.
6. Two 2-min washes with 0.1 *M* HCl follow for regeneration.

3.2. Glycoprotein Immobilization

Choosing the correct matrix for immobilization depends on properties of the glycoprotein to be used and the functional groups on the chip surface. There are various types of chips available, which utilize different immobilization chemistries. Amine coupling is used for neutral and basic proteins ***(13).*** This introduces *N*-hydroxysuccinimide esters into the surface matrix by modifying the carboxymethyl groups of the matrix with a mixture of NHS and EDC. These esters react with the amines and other nucleophilic groups on the ligand to form covalent links.

Optimization of the amount of immobilized ligand is an important factor in SPR measurements and different buffers, ligand concentrations and injection times must be investigated. This procedure is performed at 25°C (**Fig. 2**).

1. A continuous flow of HBS buffer is applied at flow rate of 5 µL/min.
2. The sensor chip surface is activated with a 7-min pulse of NHS and EDC.
3. Immobilization of ligand is performed by a 7-min pulse of the ligand solution (*see* **Notes 2** and **3**).
4. Deactivation of excess reactive groups on the surface and removal of noncovalently bound material is performed by a 7-min pulse of ethanolamine.
5. Two 4-min pulses with HCl perform regeneration (complete removal of nonbound material).

3.3. Lectin Binding

Lectin binding is performed at 37°C. A continuous liquid flow is applied to the chip and the lectin is injected as a short pulse. If the lectin recognizes a carbohydrate grouping on the glycoprotein then it will bind resulting in an increasing

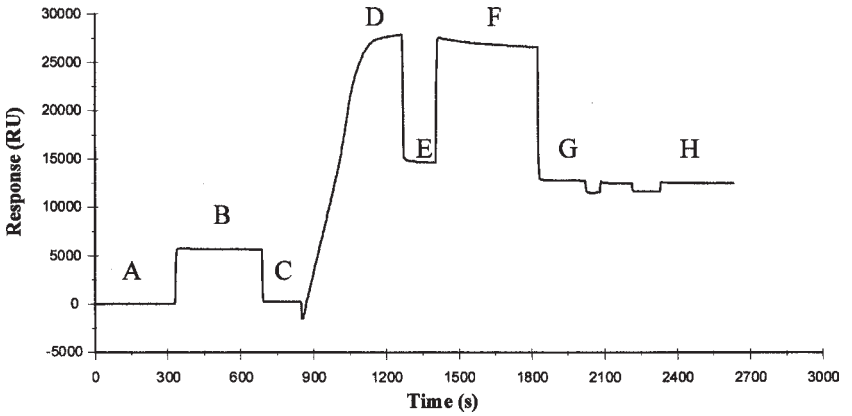

Fig. 2. **(A)** Baseline during continuous buffer flow; **(B)** injection of NHS/EDC to activate the surface; **(C)** baseline after activation; **(D)** injection of ligand; **(E)** immobilized ligand before deactivation; **(F)** deactivation of chip surface using ethanolamine; **(G)** immobilized ligand after deactivation; **(H)** final immobilization level after two HCl washes.

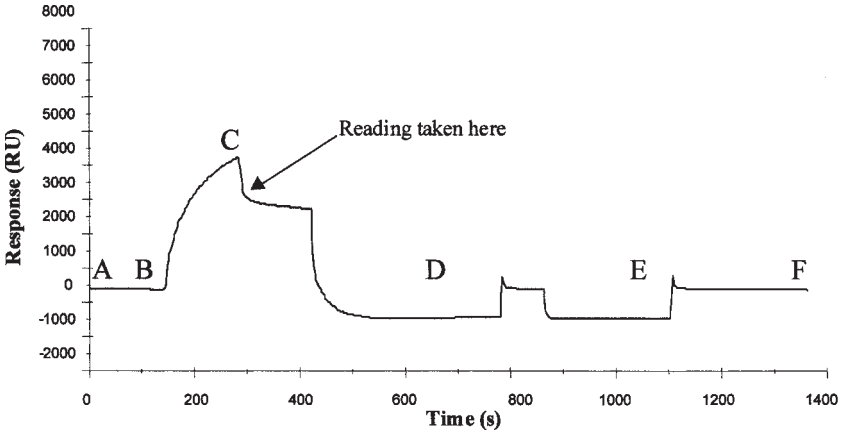

Fig. 3. Typical sensogram of ConA binding. AB, baseline; B, sample injection; BC, association; CD, dissociation; D, E, HCl injections; F, baseline.

RU value. A RU reading is taken approx 15 s after dissociation starts. Bound lectin is removed by passing HCl over the chip and then the binding of another lectin is investigated (**Fig. 3**).

1. A continuous flow of HBS buffer is applied at flow rate of 5 µL/min.
2. Lectin is injected by a 7-min pulse (*see* **Note 4**).
3. A reading is taken 15 s after dissociation starts (*see* **Note 5**).

4. Lectin is removed by two 4-min pulses with HCl (*see* **Note 6**).
5. **Steps 1–4** are repeated for each lectin and buffer solution.

3.4. Enzyme Treatment

The specificity of lectin binding measured by SPR can be confirmed by enzyme treatment at 37°C with glycosidases. These are usually very specific for one carbohydrate structure. After enzyme treatment lectin binding should not be detected if the interaction was specific. **Figure 4** shows the binding of MAA before and after treatment with neuraminidase. Immobilized glycoproteins can be treated with other enzymes such as galactosidase and PGNase F (*see* **Note 7**).

1. Neuraminidase treatment is performed by a 7-min injection of the enzyme followed by a stop in the flow for 6 h.
2. The flow rate restored back to 5 µL/mL.
3. Regeneration (removal of neuraminidase) is performed by two 4-min pulses with HCl.
4. Lectin injection, reading, and regeneration as in **steps 1–5** of **Subheading 3.3.**
5. The same procedure as described in **steps 1–4** can be repeated for other enzymes until all residues on a sugar chain are chopped off.

4. Notes

1. A preliminary choice of pH for immobilization can be made if the pI of the ligand is known according to the following rule of thumb: for pI > 7, use pH 6, for pI 5.5–7 use 1 unit pH below pI, for pI 3.5–5.5, use 0.5 pH units below pI. For pH range of 4–5.5 10 m*M* acetate buffer is recommended.

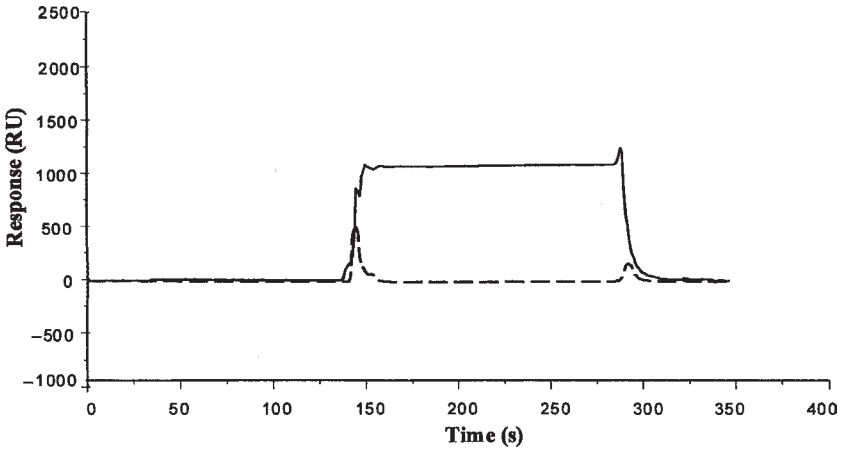

Fig. 4. MAA binding before (*solid line*) and after (*dotted line*) neuraminidase treatment (buffer plot subtracted from both sensograms).

Table 1
Typical Results for Different Glycoproteins with Different Lectins

	ConA	SNA[b]	SNA[a]	MAA[b]	MAA[a]	PNA[b]	PNA[a]	DSA	AAA
IgG	1680	344	50	25	26	24	23	33	71
Fetuin	776	1230	78	624	5	5	80	230	32
Rec1	2768	22	20	10	25	26	30	11	22
Rec2	1203	10	25	325	22	4	297	42	15

[a,b]Before and after neuraminidase treatment. IgG and fetuin were commercial products, while rec1 and rec2 are recombinant glycoproteins. Buffer readings gave values of 20–35 RU. *See* **Note 8.**

2. The time of activation may be modified to regulate the amount of ligand immobilized.
3. For a given pH the ideal ligand concentration is the lowest value that gives maximum preconcentration. Usually, a suitable concentration will be in the range 10–200 µg/mL. A target response is a level of immobilization that gives about 0.07 pmol ligand/mm^2. That corresponds to mol wt/15 RU.
4. Analyte concentration can be chosen between 5 µg/mL and 500 µg/mL.
5. A reading value above 30–40 RU is considered as real binding.
6. After regeneration the baseline should be at the same level as before lectin binding. A drift in the baseline may appear after repeated regeneration, which may be due to loss of Neu5Ac.
7. Different enzyme incubation times may apply depending on the enzyme properties.
8. **Table 1** gives typical results for different glycoproteins with different lectins. The following conclusions can be drawn from these results: IgG has *N*-linked chains (ConA), α2–6 Neu5NAc (SNA) and fucose (AAA) and it does not have any *O*-linked chains (PNA) or any α2–3 Neu5NAc (MAA); Fetuin has *N*- and *O*-linked chains, α2–6 Neu5NAc and α2–3 Neu5NAc, galactose β1–4 *N*-acetylglucosamine (DSA) and no fucose; Rec1 has *N*-linked chains and no fucose, no Neu5NAc, no *O*-linked chains; Rec2 has *N*- and *O*-linked chains, α2–6 Neu5NAc, no α2–3 Neu5NAc and no fucose.

Sequencing Heparan Sulfate Saccharides

Jeremy E. Turnbull

1. Introduction

The functions of the heparan sulfates (HSs) are determined by specific saccharide motifs within HS chains. These sequences confer selective protein binding properties and the ability to modulate protein activities ***(1,2)***. HS chains consist of an alternating disaccharide repeat of glucosamine (GlcN; *N*-acetylated or *N*-sulfated) and uronic acid (glucuronic [GlcA] or iduronic acid [IdoA]). The initial biosynthetic product containing N-acetylglucosamine (GlcNAc) and GlcA is modified by *N*-sulfation of the GlcN, ester (*O*)-sulfation (at positions 3 and 6 on the GlcN and position 2 on the uronic acids) and by epimerization of GlcA to IdoA. The extent of these modifications is incomplete and their degree and distribution varies in HS between different cell types. In HS chains *N*- and *O*-sulfated sugars are predominantly clustered in sequences of up to eight disaccharide units separated by *N*-acetyl-rich regions with relatively low sulfate content ***(3)***.

Sequence analysis of HS saccharides is a difficult analytical problem and until recently sequence information had been obtained for only relatively short saccharides from HS and heparin. Gel chromatography and high-performance liquid chromatography (HPLC) methods have been used to obtain information on disaccharide composition ***(3,4)***. Other methods such as nuclear magnetic resonance (NMR) spectroscopy and mass spectroscopy ***(5–9)*** have provided direct sequence information, but are difficult for even moderately sized oligosaccharides and in the case of NMR requires large amounts of material (micromoles). This situation has changed rapidly in the last few years with the availability of recombinant exolytic lysosomal enzymes. These exoglycosidases and exosulfatases remove specific sulfate groups or monosaccharide residues from the nonreducing end (NRE) of saccharides ***(10)***. They can be employed in combination with polyacrylamide gel electrophoresis (PAGE) separations to

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

derive direct information (based on band shifts) on the structures present at the nonreducing end of GAG saccharides (***11***; *see* **Fig. 1** for an example).

Integral glycan sequencing (IGS), a PAGE-based method using the exoenzymes, was developed as the first strategy for rapid and direct sequencing of HS and heparin saccharides ***(11)***. Its introduction has been quickly followed by a variety of similar approaches using other separation methods including HPLC and matrix-assisted laser desorption (MALDI) mass spectrometry ***(12–14)***. An outline of the IGS sequencing strategy is given in **Fig. 2**. An HS (or heparin) saccharide (previously obtained from the polysaccharide by partial chemical or enzymatic degradation and purification) is labeled at its reducing terminus with a fluorescent tag. It is then subjected to partial nitrous acid treatment to give a ladder of evenly numbered oligosaccharides (di-, tetra-, hexa-, etc.) each having a fluorescent tag at their reducing end. Portions of this material are then treated

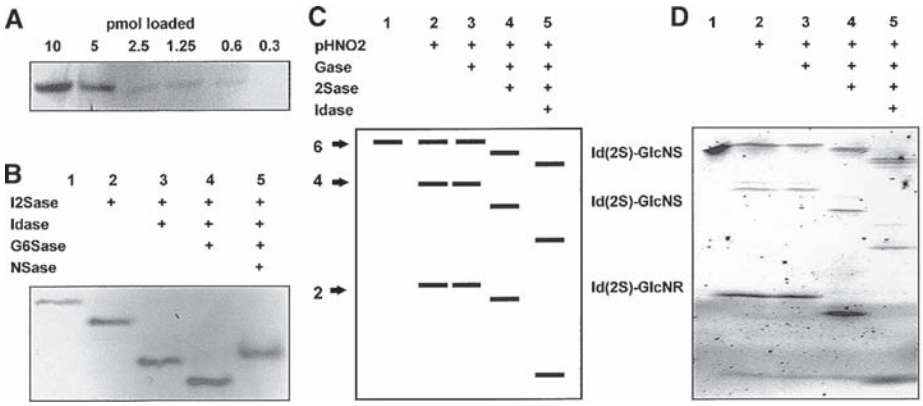

Fig. 1. Basic principles of integral glycan sequencing. (A) Fluorescence detection of different amounts of a 2-AA-tagged heparin tetrasaccharide run on a 33% minigel. (B) Exosequencing of a 2-AA-tagged heparin tetrasaccharide with lysosomal enzymes and separation of the products on a 33% minigel (15 pmol per track). Band shifts following the exoenzyme treatments shown reveal the structure of the nonreducing end disaccharide unit (*track 1*, untreated). I2Sase, iduronate-2-sulfatase; Idase, iduronidase; G6Sase, glucosamine-6-sulfatase; Nsase, sulfamidase. (C) Schematic representation of IGS of a hexasaccharide (pHNO2, partial nitrous acid treatment). (D) Actual example of IGS performed on a purified heparin hexasaccharide, corresponding to the scheme in C, using the combinations of pHNO2 and exoenzyme treatments indicated (*track 1*, untreated, 25 pmol; other tracks correspond to approx 200 pmol per track of starting sample for pHNO2 digest). The hexasaccharide (purified from bovine lung heparin) has the putative structure IdoA(2S)-GlcNSO$_3$(6S)-IdoA(2S)-GlcNSO$_3$(6S)-IdoA(2S)-AMannR(6S). Electrophoresis was performed on a 16-cm 35% gel (from ref. 11, Copyright 1999 National Academy of Sciences, USA).

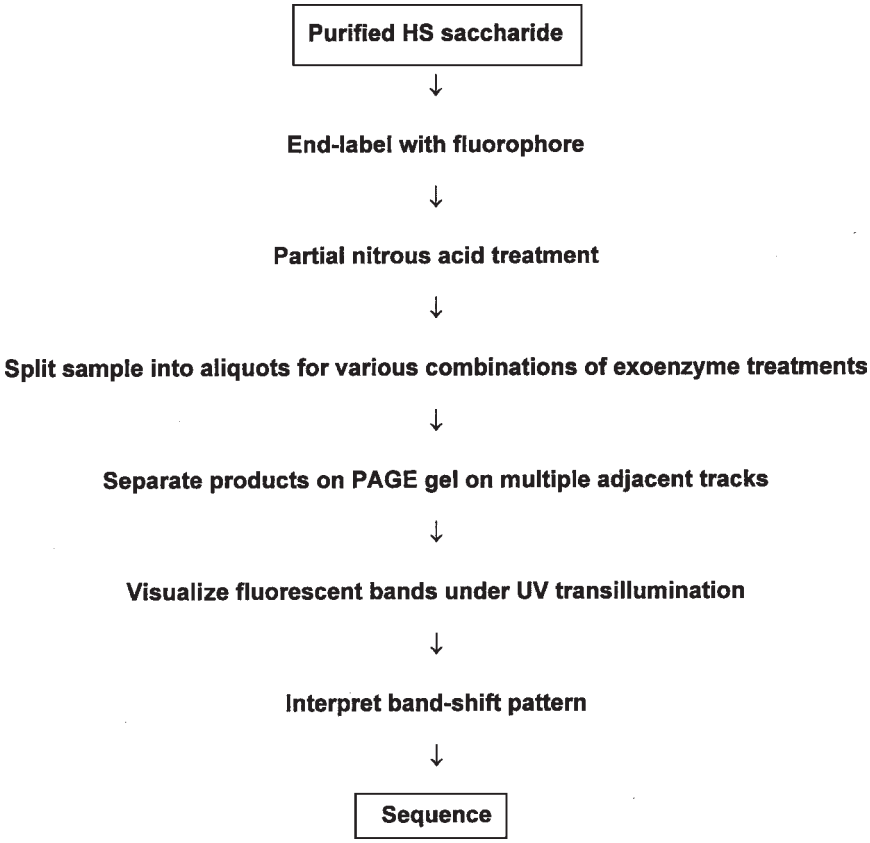

Fig. 2. The IGS sequencing strategy.

with a variety of highly specific exolytic lysosomal enzymes (exosulfatases and exoglycosidases) that act at the nonreducing end of each saccharide (if it is a suitable substrate). The various digests are then separated on a high-density polyacrylamide gel and the positions of the fragments detected by excitation of the fluorescent tag with a UV transilluminator. Band shifts resulting from the different treatments permit the sequence to be read directly from the banding pattern (*see* **Fig. 1** for an example). This novel strategy allows direct read-out sequencing of a saccharide in a single set of adjacent gel tracks in a manner analogous to DNA sequencing. IGS provides a rapid approach for sequencing HS saccharides, and has proved very useful in recent structure–function studies ***(15)***. It should be noted that this methodology is designed for sequencing purified saccharides, not whole HS preparations. An important factor in all sequencing methods is the availability of sufficiently pure saccharide starting material.

HS and heparin saccharides can be prepared following selective scission by enzymic (or chemical) reagents and isolation by methods such as affinity chromatography ***(4)***. Final purification usually requires the use of strong anion-exchange HPLC ***(11,15)***.

2. Materials

1. 2-Aminobenzoic acid (2-AA; Fluka Chemicals).
2. 7-Aminonaphthalene-1,3-disulfonic acid monopotassium salt (ANDSA; Fluka Chemicals).
3. Formamide.
4. Sodium cyanoborohydride (>98% purity).
5. Sodium triacetoxyborohydride (Aldrich).
6. Distilled water.
7. Oven or heating block at 37°C.
8. Desalting column (Sephadex G-25; e.g., HiTrap™ desalting columns, Pharmacia).
9. Centrifugal evaporator.
10. 200 m*M* HCl.
11. 20 m*M* Sodium nitrite (1.38 mg/mL in distilled water; prepare fresh).
12. 200 m*M* Sodium acetate, pH 6.0:27.2 g/L of sodium acetate trihydrate; adjust pH to 6.0 using acetic acid.
13. Enzyme buffer: 0.2 *M* Na acetate, pH 4.5. Make 0.2 *M* sodium acetate (27.2 g/L of sodium acetate trihydrate) and 0.2 *M* acetic acid (11.6 mL/L) and mix in a ratio of 45 mL to 55 mL, respectively.
14. Enzyme stock solutions (typically at concentrations of 500 mU/mL, where 1 U = 1 µmol substrate hydrolyzed per minute). Available from Glyko, Novato, CA.
15. Vortex tube mixer.
16. Microcentrifuge.
17. Acrylamide stock solution (T50%–C5%). **Caution: Acrylamide is neurotoxic.** Wear gloves (and a face mask when handling powdered forms). It is convenient to use premixed *bis*-acrylamide such as Sigma A-2917. Add 43 mL of distilled water to the 100-mL bottle containing the premixed chemicals and dissolve using a small stirrer bar (approx 2 h). The final volume should be approx 80 mL. Store the stock solution at 4°C. Note that it is usually necessary to warm gently to redissolve the acrylamide after storage.
18. Resolving gel buffer stock solutions: 2 *M* Tris-HCl, pH 8.8 (242.2 g/L of Tris base; adjust pH to 8.8 with HCl).
19. Stacking gel buffer stock solution: 1 *M* Tris-HCl, pH 6.8 (121.1 g/L of Tris base; adjust pH to 6.8 with HCl).
20. Electrophoresis buffer: 25 m*M* Tris, 192 m*M* glycine, pH 8.3.3 g/L of Tris base, 14.4 g/L of glycine; adjust pH to 8.3 if necessary with HCl.
21. 10% Ammonium persulfate in water (made fresh or stored at −20°C in aliquots).
22. *N*,*N*,*N* ,*N* -Tetramethylethylenediamine (TEMED).
23. Vertical slab gel electrophoresis system (minigel or standard size).
24. D.C. Power supply unit (to supply up to 500–1000 V and 200 mA).

25. UV transilluminator (312 nm maximum emission wavelength).
26. Glass UV bandpass filter larger than gel size (type UG-11, or M-UG2).
27. Charge coupled device (CCD) imaging camera fitted with a 450-nm (blue) bandpass filter.

3. Methods

3.1. Tagging Saccharides with a Fluorophore

HS (and heparin) saccharides can be endlabeled by reaction of their reducing aldehyde functional group with a primary amino group of a fluorophore (reductive amination). For sulfated saccharides anthranilic acid (2-AA; ***11***) has been found to be effective for the IGS methodology. 2-AA conjugates display an excitation maxima in the range 300–320 nm, which is ideal for visualization with a commonly available 312-nm UV source (e.g., transilluminators used for visualizing ethidium bromide stained DNA). Emission maxima are typically in the range 410–420 nm (bright violet fluorescence). It has also been found that approx 10-fold more sensitive detection is possible using an alternative fluorophore ANDSA, and this has been demonstrated to be effective for HS sequencing ***(16)***. ANDSA has an excitation maxima of 350 nm and emission maxima of 450 nm. Both approaches described in **Subheadings 3.1.1.** and **3.1.2.** allow rapid labeling and purification of tagged saccharide from free tagging reagent, and give quantitative recoveries and products free of salts that might interfere with subsequent enzymic conditions. For saccharides in the size range hexa to dodecasaccharides, approx 2–3 nmol (approx 2–10 µg) of purified starting material is the minimum required using the 2-AA label and approx 5- to 10-fold less for ANDSA labeling. It should be noted that recently a novel label, BODIPY hydrazide, has been developed for highly sensitive detection of saccharides including those from HS (***17***). This label couples more efficiently to saccharides, has an excitation maxima at 503nm (making it ideal for detection using common 488nm lasers) and an extinction co-efficient of 71,000; this permits very sensitive detection of labelled saccharides (~100fmol on a standard HPLC fluorimeter). In the future it may prove possible to apply this label to highly sensitive IGS sequencing on gels using fluorescent gel scanners or alternatively HPLC or capillary electrophoresis separations with in-line fluorescence detection.

3.1.1. Labeling Saccharides with 2-AA

1. Dry down the purified saccharide (typically 2–10 nmol) in a microcentrifuge tube by centrifugal evaporation.
2. Dissolve directly in 10–25 µL of formamide containing freshly prepared 400 m*M* 2-AA (54.8 mg/mL) and 200 m*M* reductant (sodium cyanoborohydride; 12.6 mg/mL) and incubate at 37°C for 16–24 h in a heating block or oven. **(Caution: The reductant is toxic and should be handled with care.)** The volume used should be sufficient to provide a 500–1000-fold molar excess of 2-AA over saccharide (*see* **Note 1**).

3. Remove free 2-AA, reductant, and formamide from the labeled saccharides by gel filtration chromatography (Sephadex G-25 Superfine). Dilute the sample (maximum 250 µL of reaction mixture) to a total of 1 mL with distilled water (*see* **Note 2**).
4. Load sample onto two 5-mL HiTrap™ Desalting columns (Pharmacia Ltd.) connected in series. Alternatively it is possible to use self-packed columns of other dimensions.
5. Elute with distilled water at a flow rate of 1 mL/min and collect fractions of 0.5 mL. Saccharides consisting of four or more monosaccharide units typically elute in the void volume (approx fractions 7–12). Note that the HiTrap™ columns can be eluted by hand with a syringe without need for a pump.
6. Pool and concentrate these fractions by centrifugal evaporation or freeze drying.

3.1.2. Labeling Saccharides with ANDSA

1. Dry down the purified saccharide (typically 2–10 nmol) in a microcentrifuge tube by centrifugal evaporation.
2. Dissolve directly in 10 µL of formamide.
3. Mix with 15 µL of formamide containing ANDSA at a concentration of 80 mg/mL (approaching saturation) and incubate at 25°C for 16 h.
4. Mix with 10 µL of formamide containing 1 mg of the reductant sodium triacetoxyborohydride (*see* **Note 1**) and incubate for 2 h at 25°C.
5. Remove free ANDSA by gel filtration as described in **Subheading 3.1.1.** for 2-AA.

3.2. Nitrous Acid Treatment of Saccharides

Low pH nitrous acid cleaves HS only at linkages between *N*-sulfated glucosamine and adjacent hexuronic acid residues ***(18,19)***. Under mild controlled conditions nitrous acid cleavage creates a ladder of bands corresponding to the positions of internal *N*-sulfated glucosamine residues in the original intact saccharide ***(11)***. A series of different reaction stop points are pooled, resulting in a partial digest with a range of different fragment sizes.

1. Dry down 1–2 nmol of labeled saccharide by centrifugal evaporation.
2. Redissolve in 80 µL of distilled water and chill on ice.
3. Add 10 µL of 200 m*M* HCl and 10 µL of 20 m*M* sodium nitrite (both prechilled on ice) and incubate on ice.
4. At a series of individual time points (typically 15, 30, 60, 120, and 180 min), remove an aliquot and stop the reaction by raising the pH to approx 5.0 by the addition of 1/5 volume of 200 m*M* sodium acetate buffer, pH 6.0 (*see* **Note 3**).
5. Pool the set of aliquots and either use directly for enzyme digests or desalt as described in

3.3. Exoenzyme Treatment of Saccharides

The approach for treatment of HS samples with exoenzymes is described below. Details of the specificities of the exoenzymes is given in **Table 1**. These enzymes have differing optimal pH and buffer conditions, but in general they

Table 1
Exoenzymes for Sequencing Heparan Sulfate and Heparin

Enzyme*a*	Substrate specificity*b*
Sulfatases	
Iduronate-2-sulfatase	IdoA(2*S*)
Glucosamine-6-sulfatase	GlcNAc(6*S*), GlcNSO3(6*S*)
Sulphamidase (glucosamine *N*-sulfatase)	GlcNSO3
Glucuronate-2-sulfatase	GlcA(2*S*)
Glucosamine-3-sulfatase	GlcNSO3(3*S*)
Glycosidases	
Iduronidase	IdoA
Glucuronidase	GlcA
α-*N*-Acetylglucosaminidase	GlcNAc
Bacterial exoenzymes	
Δ4,5-Glycuronate-2-sulfatase	ΔUA(2*S*)
Δ4,5-Glycuronidase	ΔUA

[a]Enzyme availability: Glucuronidase is widely available commercially as purified or recombinant enzyme. Recombinant iduronate-2-sulfatase, iduronidase, glucosamine-6-sulfatase, sulfamidase, and α-*N*-acetylglucosaminidase were purchased from from the Glyko product range, now supplied by Prozyme (San Leandro, CA; www.prozyme.com). Glucuronate-2-sulfatase and glucosamine-3-sulfatase have only been purified from cell and tissue sources to date. The bacterial exoenzymes are available from Grampian Enzymes, Nisthouse, Harray, Orkney, Scotland; e-mail, grampenz@aol.com.

[b] The specificities are shown as the nonreducing terminal group recognized by the enzymes.

can be used under the single set of conditions given here, which simplifies the multiple enzyme treatments required (*see* **Note 4**).

Sulfatases remove only the sulfate group, whereas the glycosidases cleave the whole nonsulfated monosaccharide.

1. Dissolve the sample (typically 10–200 pmol of saccharide) in 10 µL of H_2O in a microcentrifuge tube.
2. Add 5 µL of exoenzyme buffer (100 m*M* sodium acetate buffer, pH 4.5), 1 µL of 0.5 mg/mL bovine serum albumin, 2 µL of appropriate exoenzyme [0.2–0.5 mU], and distilled water to bring the final volume to 20 µL.
3. Mix the contents well on a vortex mixer, and centrifuge briefly to ensure that the reactants are at the tip of the tube.
4. Incubate the samples at 37°C for 16 h in a heating block or oven.

3.4. Separation of Saccharides by PAGE

PAGE is a high-resolution technique for the separation of HS and heparin saccharides of variable sulfate content and disposition. Its resolution is generally superior to gel filtration or anion-exchange HPLC ***(20,21)***. Improved resolution can be obtained using gradient gels, although these are more difficult to prepare

and use routinely. In most cases sufficient resolution can be obtained with isocratic gels (*see* **Note 5**). PAGE provides a simple but powerful approach for separating the saccharide products generated in the sequencing process.

3.4.1. Preparing the PAGE Gel

1. Assemble the gel unit (consisting of glass plates and spacers, etc).
2. Prepare and degas the resolving gel acrylamide solution without ammonium persulfate or TEMED. To make a 30% acrylamide gel solution for a 16 cm • 12 cm • 0.75 mm gel, 16 mL is required. Mix 9.6 mL of T50%–C5% acrylamide stock with 3 mL of 2 *M* Tris, pH 8.8, and 3.4 mL of distilled water.
3. Add 10% ammonium persulfate (30 µL) and TEMED (10 µL) to the gel solution, mix well, and immediately pour into the gel unit.
4. Overlay the unpolymerized gel with resolving gel buffer (375 m*M* Tris-HCl, pH 8.8, diluted from the 2 *M* stock solution) or water-saturated butanol. Polymerization should occur within approx 30–60 min. The gel can then be used immediately or stored at 4°C for 1–2 wk.

3.4.2. Electrophoresis

1. Immediately before electrophoresis, rinse the resolving gel surface with stacking gel buffer (0.125 *M* Tris-HC1 buffer, pH 6.8, diluted from the 1 *M* stock solution).
2. Prepare and degas the stacking gel solution (for 5 mL, mix 0.5 mL of T50%–C5% acrylamide stock with 0.6 mL of 1 *M* Tris, pH 6.8, and 3.9 mL of distilled water).
3. Add 10% ammonium persulfate (10 µL) and TEMED (5 µL). Immediately pour onto the top of the resolving gel and insert the well-forming comb.
4. After polymerization (approx 15 min) remove the comb and rinse the wells thoroughly with electrophoresis buffer.
5. Place the gel unit into the electrophoresis tank and fill the buffer chambers with electrophoresis buffer.
6. Load the oligosaccharide samples (5–20 µL dependent on well capacity, containing approx 10% [v/v] glycerol or sucrose in 125 m*M* Tris-HCl, pH 6.8) carefully into the wells with a microsyringe. Marker samples containing bromophenol blue and phenol red should also be loaded into separate tracks.
7. Run the samples into the stacking gel at 150–200 V (typically 20–30 mA) for 30–60 min, followed by electrophoresis at 300–400 V (typically 20–30 mA and decreasing during run) for approx 5–8 h (for a 16-cm gel). Heat generated during the run should be dissipated using a heat exchanger with circulating tap water, or by running the gel in a cold room or in a refrigerator.
8. Electrophoresis should be terminated before the phenol red marker dye is about 5 cm from the bottom of the gel. (At this point, disaccharides should be 3–4 cm from the bottom of the gel.)

3.5. Gel Imaging

The most effective approach for gel imaging requires a CCD camera that can detect faint fluorescent banding patterns by capturing multiple frames. Systems

commonly used for detection of ethidium bromide stained DNA can usually be adapted with appropriate filters as described below (*see* **Note 6**).

1. Place a UV filter (UG-1, UG-11, or MUG-2) onto the transilluminator, and fit a 450-nm blue filter onto the camera lens.
2. Remove the gel carefully from the glass plates after completion of the run and place on the UV transilluminator surface wetted with electrophoresis buffer. Wet the upper surface of the gel to reduce gel drying and curling.
3. Switch on the transilluminator and capture the image using the CCD camera. Exposure times are typically 1–5 s depending on the amount of labeled saccharide (*see* **Note 7**).

3.6. Data Interpretation

The sequence of saccharides can be read directly from the banding pattern by interpreting the band shifts due to removal of specific sulfate or sugar moieties.

Fig. 1 shows an actual example and a schematic representation. First, bands generated by the partial nitrous acid treatment indicate the positions of *N*-sulfated glucosamine residues in the original saccharide (**Fig. 1C**, *track 2*). A "missing" band in the ladder at a particular position indicates the presence of an *N*-acetylated glucosamine residue in the original saccharide at that position (an example of this is shown in **Fig. 3**). Such saccharides can be sequenced by the additional use of the exoenzyme *N*-acetylglucosaminidase, which removes this residue and allows further sequencing of an otherwise "blocked" fragment. Following the nitrous acid treatment, the "ladder" of bands is then subjected to various exoenzyme digestions. The presence of specific sulfate or sugar residues can be deduced from the band shifts that occur (**Fig. 1C**, *tracks 3–5*). **Figure 4** shows an example of a decasaccharide from HS that has been purified by SAX-HPLC and sequenced using IGS ***(11)***.

Although the band shifts are usually downwards (because of to the lower molecular mass and thus higher mobility of the product) it should be noted that occasionally upward shifts occur, probably due to subtle differences in charge/mass ratio (for examples, *see* **Figs. 1B**, **3B**, and **4C**). Note also that minor "ghost" bands sometimes appear after the nitrous acid treatment. They are probably due to loss of an *N*-sulfate group, and normally these do not affect interpretation of the shifts in the major bands ***(11)***.

If the saccharide being sequenced was derived by bacterial lyase treatment, it will have a Δ4,5-unsaturated uronate residue at its nonreducing terminus. If this residue has a 2-*O*-sulfate attached, this can be detected by susceptibility to I2Sase (*see* **Fig. 3B**), but the sugar residue itself is resistant to both Idase and Gase. Its removal is required to confirm whether there is a 6-*O*-sulfate on the adjacent nonreducing end glucosamine (*see* **Figs. 3B** and **4C** for examples). Bacterial enzymes that specifically remove the Δ4,5-unsaturated uronate residues (and the 2-*O*-sulfate groups that may be present on them) are now available

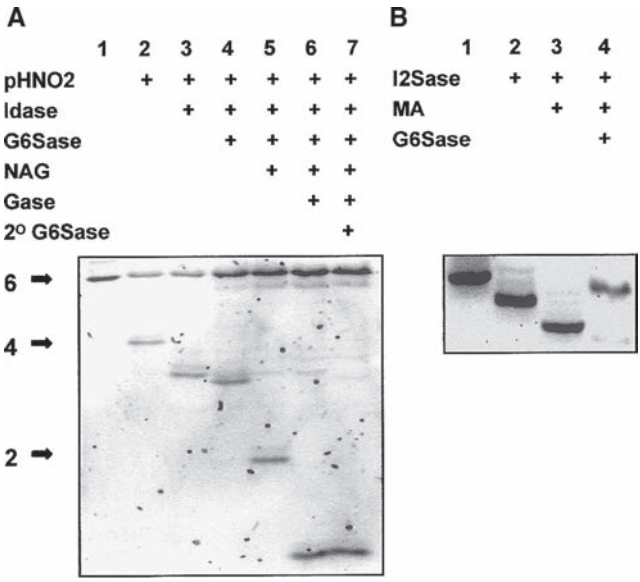

Fig. 3. IGS of a heparin hexasaccharide. A heparin hexasaccharide with the structure ΔHexA(2S)-GlcNSO3(6S)-IdoA-GlcNAc(6S)-GlcA-GlcNSO3(6S) was 2-AA-tagged and subjected to sequencing on a 16-cm 33% gel. (**A**) IGS of hexasaccharide using the combinations of $pHNO_2$ and exoenzyme treatments indicated (*track 1*, untreated, 20 pmol; other tracks correspond to approx 90 pmol per track of starting sample for $pHNO_2$ digest). NAG, *N*-acetylglucosaminidase. (**B**) Determining the sequence of the nonreducing disaccharide unit of the hexasaccharide using the I2Sase, G6Sase, and mercuric acetate (MA) treatments shown (approx 20 pmol per track; *track 1*, untreated). (From ref. 11, Copyright 1999 National Academy of Sciences, USA.)

commercially (*see* **Table 1**). Alternatively, they can be removed chemically with mercuric acetate (***22***; *see* **Figs. 3B** and **4C**).

In addition to the basic sequencing experiment, it is wise to confirm agreement of the data with an independent analysis of the disaccharide composition of the saccharide ***(11)***. It can sometimes be difficult to sequence the reducing terminal monosaccharide owing to it being a poor substrate for the exoenzymes. In these cases it has proved more effective to analyze the terminal 2AA-labeled disaccharide unit in comparison to 2AA-labeled disaccharide standards ***(11)***. In the future it is anticipated that methods using HPLC or capillary electrophoresis separations and the fluorophore BODIPY hydrazide (***17***) will permit ultra-high sensitivity IGS sequencing of HS saccharides, superceding the standard electrophoretic methods described in this chapter.

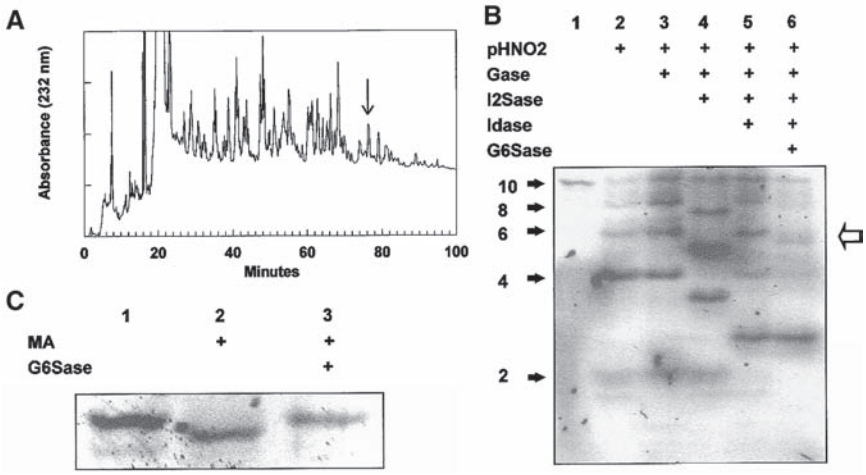

Fig. 4. HPLC purification and IGS of a HS decasaccharide. (**A**) SAX-HPLC of a pool of HS decasaccharides derived by heparitinase treatment of porcine mucosal HS (for details *see* **ref**. 11). The *arrowed peak* was selected for sequencing. (**B**) IGS of the purified HS decasaccharide on a 16-cm 33% gel using the combinations of $pHNO_2$ and exoenzyme treatments indicated (*track 1*, untreated, 20 pmol; other tracks correspond to approx 400 pmol per track of starting sample for $pHNO_2$ digest). (**C**) Determining the sequence of the nonreducing disaccharide unit of the HS decasaccharide using the mercuric acetate (MA) and G6Sase treatments shown (approx 40 pmol per track; *track 1*, untreated). (From ref. 11, Copyright 1999 National Academy of Sciences, USA.)

4. Notes

1. Using large excesses of reagent as described, saccharides derived from HS and heparin by bacterial lyase scission generally couple with 2-AA with efficiencies in the range of 60–70%. Note that saccharides derived from HS and heparin by low pH nitrous acid scissioning (i.e., having an anhydromannose residue at their reducing ends) label more efficiently (approx 70–80% coupling efficiency). Labeling with ANDSA achieves similar coupling efficiencies, and the alternative reducing agent, sodium triacetoxyborohydride, is less toxic than sodium cyanoborohydride.
2. Unwanted reactants and solvent can also be removed from labeled saccharides by methods such as dialysis but the rapid gel filtration chromatography step described above using the HiTrap desalting columns is convenient and usually allows good recoveries of loaded sample (typically 70–80%).
3. It is best to perform some trial incubations to test for optimal time points needed to generate a balanced mix of all fragments in the partial nitrous

acid digestion. With longer saccharides (octasaccharides and larger) it is observed that the largest products are generated quickly and thus a bias toward shorter incubation times is required as saccharide length increases ***(16)***.

4. The enzyme conditions described should provide for complete digestion of all susceptible residues. This is important to the sequencing process, as incomplete digestion would create a more complex banding pattern and would give a false indication of sequence heterogeneity. It is useful to run parallel controls with standard saccharides to enable monitoring of reaction conditions. Where combinations of exoenzymes are required, these can be incubated simultaneously with the sample. If required, the activity of one enzyme can be destroyed prior to a secondary digestion with a different enzyme by heating the sample at 100°C for 2–5 min.
5. Adequate separations, particularly over limited size ranges of saccharides, can be obtained using single concentration gels, typically in the range 25–35% acrylamide. Improvements in resolution can be made by using longer gel sizes. Different voltage conditions (usually in the range 200–600 V) and running times are required for different gel formats, and should be established by trial and error with the particular samples being analyzed. Gels up to 24 cm in length can usually be run in 5–8 h using high voltages, whereas for longer gels it is often convenient to use lower voltage conditions and overnight runs. Minigels can also be used effectively for separation of small HS–heparin saccharides up to octasaccharides in size (*see* **Fig. 1**). Note that it is also possible to run Tris-acetate gels with a Tris-MES electrophoresis buffer (*see* **Fig. 1**; ***11***).
6. Because the emission wavelength of 2-AA tagged saccharides is 410–420 nm, there is a need to filter out background visible wavelength light from the UV lamps. This can be done effectively with special glass filters that permit transmission of UV light but do not allow light of wavelengths >400 nm to pass. A blue bandpass filter on the camera also improves sensitivity. Suitable filters are available from HV Skan (Stratford Road, Solihull, UK; Tel: 0121 733 3003) or UVItec Ltd. (St. John's Innovation Centre, Cowley Road, Cambridge, UK; www.uvitec.demon.co.uk).
7. Required exposure times are strongly dependent on sample loading and the level of detection required. Over-long exposures will result in excessive background signal. Note that negative images are usually better for band identification (*see* figures). Under the conditions described the limit of sensitivity is approx 10–20 pmol per band of original starting material for 2-AA (*see* **Fig. 1**) and 2–5 pmol per band for ANDSA.

Analysis of Glycoprotein Heterogeneity by Capillary Electrophoresis and Mass Spectrometry

Andrew D. Hooker and David C. James

1. Introduction

The drive toward protein-based therapeutic agents requires both product quality and consistency to be maintained throughout the development and implementation of a production process. Differences in host cell type, the physio-logical status of the cell, and protein structural constraints are known to result in variations in posttranslational modifications that can affect the bioactivity, receptor binding, susceptibility to proteolysis, immunogenicity, and clearance rate of a therapeutic recombinant protein in vivo ***(1)***. Glycosylation is the most extensive source of protein heterogeneity, and many recent developments in analytical biotechnology have enhanced our ability to monitor and structurally define changes in oligosaccharides associated with recombinant proteins.

Variable occupancy of potential glycosylation sites may result in extensive glycosylation macroheterogeneity in addition to the considerable diversity of carbohydrate structures that can occur at individual glycosylation sites, often referred to as glycosylation microheterogeneity. Variation within a heterogeneous population of glycoforms may lead to functional consequences for the glycoprotein product. Therefore, regulatory authorities such as the US Food and Drug Administration (FDA) and the Committee for Proprietary Medical Productions demand increasingly sophisticated analysis for biologics produced by the biotechnology and pharmaceutical industries ***(2)***. The FDA has described a "well-characterized biologic" as "a chemical entity whose identity, purity, impurities, potency and quantity can be determined and controlled."

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

The glycosylation of a recombinant protein product can be examined by:

1. Analysis of glycans released by chemical or enzymatic means.
2. Site-specific analysis of glycans associated with glycopeptide fragments following proteolysis of the intact glycoprotein.
3. Direct analysis of the whole glycoprotein.

A number of techniques are currently available to provide rapid and detailed analysis of glycan heterogeneity:

1. High-pH anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD).
2. Enzymatic analysis methods such as the reagent array analysis method (RAAM; ***3,4***).
3. High-performance capillary electrophoresis (HPCE).
4. Matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS).
5. Electrospray ionization mass spectrometry (ESI-MS).

In particular, novel mass spectrometric strategies continue to rapidly advance the frontiers of biomolecular analysis, with technical innovations and methodologies yielding improvements in sensitivity, mass accuracy, and resolution.

1.1. High-Performance Capillary Electrophoresis

Capillary electrophoresis has been employed in various modes in the high-resolution separation and detection of glycoprotein glycoforms, glycoconjugates, glycopeptides, and oligosaccharides, even though carbohydrate molecules do not absorb or fluorese and are not readily ionized ***(5–8)***. A number of approaches have been employed to render carbohydrates more amenable to analysis which include *in situ* complex formation with ions such as borate and metal cations ***(9)*** and the addition of ultraviolet (UV)-absorbing or fluorescent tags to functional groups ***(10)***.

1.2. MALDI-MS

MALDI-MS has been extensively used to determine the mass of proteins and polypeptides, confirm protein primary structure, and to characterize posttranslational modifications. MALDI-MS generally employs simple time-of-flight analysis of biopolymers that are co-crystallized with a molar excess of a low molecular weight, strongly UV absorbing matrix, such as 2,5-dihydroxybenzoic acid, on a metal sample disk. Both the biopolymer and matrix ions are desorbed by pulses of a UV laser. Following a linear flight path the molecular ions are detected, the time between the initial laser pulse and ion detection being directly proportional to the square root of the molecular ion mass/charge (*m/z*) ratio. For maximum mass accuracy, internal and external protein or peptide calibrants of known molecular mass are required. In addition to this “linear” mode, many instruments offer a “reflectron” mode that effectively lengthens the flight path

by redirecting the ions toward an additional ion detector that may enhance resolution, at the expense of decreased sensitivity. MALDI-MS is tolerant to low (micromolar) salt concentrations, can determine the molecular weight of biomolecules in excess of 200 kDa with a mass accuracy of ±0.1%, and is capable of analyzing heterogeneous samples with picomole to femtomole sensitivity. These properties combined with its rapid analysis time and ease of use for the nonspecialist have made it an attractive technique for the analysis of glycoproteins, glycopeptides, and oligosaccharides.

1.3. Electrospray Ionization Mass Spectrometry

ESI-MS is another mild ionization method, where the covalent bonding of the biopolymer is maintained and is typically used in combination with a single or triple quadrupole. This technique is capable of determining the molecular weight of biopolymers up to 100 kDa with a greater mass accuracy (±0.01%) and resolution (±2000) than MALDI-MS. Multiply charged molecular ions are generated by the ionization of biopolymers in volatile solvents, the resulting spectrum being convoluted to produce noncharged peaks.

ESI-MS has been extensively used for the direct mass analysis of glycopeptides and glycoproteins and is often interfaced with liquid chromatography ***(11–13)***, but has found limited application for the direct analysis of oligosaccharides ***(14)***. ESI-MS is better suited to the analysis of whole glycoprotein populations than MALDI-MS, its superior resolution permitting the identification of individual glycoforms ***(15, 16)***.

3. Methods

This chapter describes some of the recent technological advances in the analysis of posttranslational modifications made to recombinant proteins and focuses on the application of HPCE, MALDI-MS, and ESI-MS to the monitoring of glycosylation heterogeneity. These techniques are illustrated by describing their application to the analysis of recombinant human γ-interferon (IFN-γ), a well-characterized model glycoprotein that has *N*-linked glycans at Asn_{25} and at the variably occupied site, Asn_{97} ***(17)***.

3.1. Glycosylation Analysis by HPCE

Micellar electrokinetic capillary chromatography (MECC) can be used to rapidly "fingerprint" glycoforms of recombinant human IFN-γ produced by Chinese Hamster Ovary (CHO) cells ***(8)*** and to quantitate variable-site occupancy (macroheterogeneity; *see* **Fig. 1**). This approach allows glycoforms to be rapidly resolved and quantified without the need for oligosaccharide release, derivatization or labeling.

1. Separations are performed with a P/ACE 2100 capillary electrophoresis system using a capillary cartridge containing a 50 mm internal diameter (i.d.) × 57 cm length of underivatized fused silica capillary.
2. Buffer solutions are prepared from phosphoric and boric acids using NaOH to adjust the pH.
3. Capillaries are prepared for use by rinsing with 0.1 *M* NaOH for 10 min, water for 5 min, 0.1 *M* borate, pH 8.5, for 1 h, then 0.1 *M* NaOH and water for 10 min,

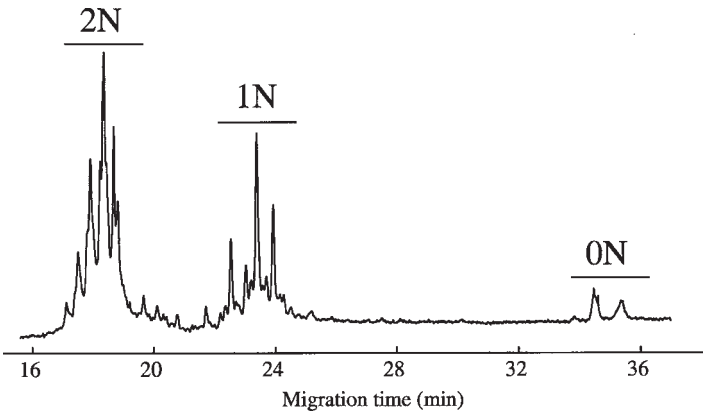

Fig. 1. Whole recombinant human IFN-γ analyzed by capillary electrophoresis. Recombinant human IFN-γ glycoforms were "fingerprinted" by micellar electrokinetic capillary chromatography. Peak groups represent IFN-γ variants with both Asn sites occupied (2N), one site occupied (1N), or no sites occupied (0N).

respectively. Prior to use, capillaries are equilibrated with electrophoresis buffer (400 m*M* borate + 100 m*M* sodium dodecyl sulfate [SDS], pH 8.5) for 1 h.

4. Voltages are applied over a 0.2-min linear ramping period at a detection wavelength of 200 nm and operating temperature of 25°C. Recombinant human IFN-γ (1 mg/mL in 50 m*M* borate, 50 m*M* SDS, pH 8.5) is injected for 5 s prior to electrophoresis at 22 kV. Between each separation, the capillary is rinsed with 0.1 *M* NaOH, water, and electrophoresis buffer for 5 min, respectively (*see* **Note 1**).

3.2. Glycosylation Analysis by MALDI-MS

There are only a few reports of the analysis of whole glycoproteins due to the limited resolution of this technique ***(18)***. As a result, analysis of intact glycoproteins is generally limited to those proteins that contain one glycosylation site and are < 15–20 kDa ***(15)***.

MALDI-MS has proved more useful for the identification and characterization of glycopeptides following their separation and purification by reverse-phase HPLC ***(19)***. The advantage of this approach over other methods is that site-specific glycosylation data can be obtained (***20,21***; *see* **Note 2**). This approach has been successfully used to determine the differences in *N*-linked glycosylation for the Asn_{25} and Asn_{97} sites of recombinant human IFN-γ when produced in different expression systems ***(22)***, to monitor changes during batch culture ***(23)***, and to monitor intracellular populations (***24***; *see* **Fig. 2**).

1. Purified IFN-γ samples are digested with trypsin (1.5 μγ; 50 μg) for 24 h at 30°C.
2. The glycopeptides containing the *N*-glycan populations are isolated following their separation by reverse-phase HPLC. Samples are applied in 0.06% (v/v) trifluoroacetic acid (TFA) and the peptides separated with a linear gradient (0–70%) of 80% (v/v) aqueous CH_3CN with 0.052% TFA over 100 min at a flow rate of 0.1 ml/min. Peptide peaks are detected at a wavelength of 210 nm and collected individually.
3. The glycopeptides are reduced to the aqueous phase in a Speed Vac concentrator, lyophilized overnight, and stored at −20°C.
4. A 0.5-μL aliquot of the digest samples is mixed with 0.5 μL of a saturated solution of α-cyano-4-hydroxy cinnaminic acid in 60% (v/v) aqueous CH_3CN and allowed to co-crystallize on stainless steel sample discs.
5. MALDI-MS is performed with a N_2 laser at 337 nm. Desorbed positive ions are detected after a linear flight path by a microchannel plate detector and the digitalized output signal adjusted to obtain an optimum output signal-to-noise ratio from 20 averaged laser pulses. Mass spectra are calibrated with an external standard, vasoactive intestinal peptide with an average molecular mass of 1425.5.
6. Digestion of glycopeptides with peptide-*N*-glycosidase F (PNGaseF) prior to analysis by mass spectrometry confirms the mass of the core peptide. For this determination, 0.5 μL of sample and 0.5 μL of PNGaseF are incubated at 30°C for 24 h and 0.5-μL aliquots are removed for MALDI-MS analysis.
7. Simultaneous digestion of purified glycopeptides with linkage-specific exoglycosidase arrays for the sequential removal of oligosaccharides permit the sequen-cing of

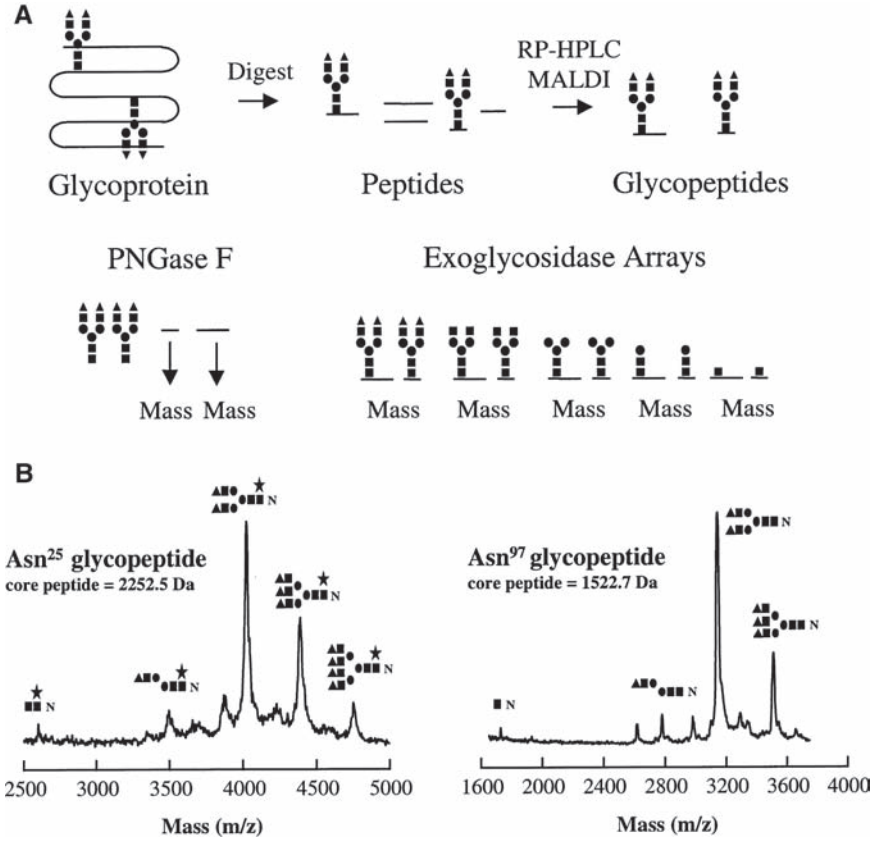

Fig. 2. Site-specific *N*-glycosylation of recombinant human IFN-γ examined by MALDI-MS analyses of glycopeptides. **(A)** The complete analytical protocol. The masses of individual *N*-glycans at a single glycosylation site were calculated by subtracting the known mass of the core peptide moiety from each component in a glycopeptide spectrum. **(B)** An *N*-glycan structure was then tentatively assigned, based on mass criteria alone. As ionization is entirely dependent on the core peptide moiety after desialylation, individual *N*-glycan structures can be quantified. Monosaccharide structures are schematically represented as: (▲), galactose (162.14); (■), *N*-acetylglucosamine (203.20 Da); (●), mannose (162.14 Da); and (★), fucose (146.14 Da).

N-glycans at individual glycosylation sites by MALDI-MS ***(21–24)***. Sample (0.5 µL) and glycosidase (0.5 µL), or a combination of glycosidases, are incubated at 30°C for 24 h and 0.5-µL aliquots are removed for MALDI-MS analysis (*see* **Note 3**).

3.3. Glycosylation Analysis by ESI-MS

ESI-MS has been used to aid the analysis of glycosylation macro- and micro-heterogeneity and proteolytic cleavage of the C-terminal in conjunction with information obtained by HPLC and MALDI-MS of released oligosaccharides (***25***; *see* **Note 4**).

1. Spectra are obtained with a VG Quattro II triple quadrupole mass spectrometer having a mass range for singly charged ions of 4000 Da (**Fig. 3**).
2. Lyophilized proteins are dissolved in 50% aqueous acetonitrile, 0.2% formic acid to a concentration of 0.1 µg/µL and introduced into the electrospray source at 4 µL/min. The mass-to-charge (*m/z*) range of 600–1800 Da are scanned at 10 s/scan and data are summed for 3–10 min, depending on the intensity and complexity of the spectra.

Fig. 3. Heterogeneous glycoprotein populations directly analyzed by ESI-MS. This technique provides highly resolved mass analyses with a mass accuracy of 0.01% (1 Dalton/10 kDa). In this example, individual transgenic mouse derived recombinant human IFN-γ components were assigned a C-terminal polypeptide cleavage site and an overall monosaccharide composition.

During each scan, the sample orifice-to-skimmer potential (cone voltage) are scanned from 30 V at *m/z* 600 to 75 V at *m/z* 1800. The capillary voltage is set to 3.5 kV.

3. Mass scale calibration employ the multiply charged ion series from a separate introduction of horse heart myoglobin (average molecular mass of 16,951.49). Molecular weights are based on the following atomic weights of the elements: C = 12.011, H = 1.00794, N = 14.00674, O = 15.9994, and S = 32.066 (*see* **Note 5**).
4. Background subtracted *m/z* data are processed by software employing a maximum-entropy (MaxEnt) based analysis to produce zero-charge protein molecular weight information with optimum signal-to-noise ratio, resolution, and mass accuracy.

4. Notes

1. Attempts to separate IFN-γ with borate alone, as used by Landers et al. ***(26)*** for the separation of ovalbumin glycoforms ***(26)***, were unsuccessful, because SDS is required to disrupt the hydrogen-bonded dimers. Application of this technique to ribonuclease B and fetuin met with variable success. The glycoprotein microheterogeneity of a monoclonal antibody with a single glycosylation site has been mapped using a borate buffer at high pH; the glycans were enzymatically or chemically cleaved and the resulting profile used for testing batch-to-batch consistency in conjunction with MALDI-MS analysis ***(27)***.
2. MALDI-MS of free *N*-linked oligosaccharides, following chemical release with hydrazinolysis or enzymatic release with an endoglycosidase such as PNGaseF, is also popular as it requires no prior structural knowledge of the glycoprotein of interest and is ideal for the analysis of underivatized populations of oligosaccharides. However, there is a loss of glycosylation site-specific data. Enzymatic release of oligosaccharides is preferred where an intact deglycosylated protein product is required, as *N*-glycan release by hydrazinolysis may result in peptide bond cleavage and the oligosaccharide product requires reacetylation. A drawback to the enzymatic release of oligosaccharides is that the presence of SDS is often required to denature the glycoprotein and has to be removed prior to MALDI-MS analysis. MALDI-MS has also been used for the analysis of IFN-γ glycoforms separated by SDS-polyacrylamide gel electrophoresis (PAGE) ***(28)***.
3. Until recently, only desialylated oligosaccharides could be analyzed successfully by MALDI-MS using 2,5-dihydroxybenzoic acid as matrix, as negatively charged sialic acids interfere with the efficiency of ionization using this procedure ***(29,30)***. However, advances in matrix mixtures and sample preparation schemes now promise to further improve analytical protocols. For example, sialylated oligosaccharides have recently been shown to ionize effectively, with picomole to femtomole sensitivity, as deprotonated molecular ions using 2,4,6-trihydroxyacetophenone as matrix in the presence of ammonium citrate ***(31)***. Further improvements in sensitivity and resolution may be obtained by derivatization of oligosaccharides with

fluorophores such as 2-aminoacridome (AMAC) or 2-aminobenzamidine (AB; **Fig. 4**). Integration of MALDI-MS peak areas obtained on analysis of sialylated glycans from IFN-γ provided quantitative information that compared favorably with analysis of the derivatized sialylated glycans by ion-exchange HPLC.

Fig. 4. Sialylated *N*-glycans associated with recombinant human IFN-γ released with PNGaseF, labeled with 2-aminobenzamide, and analyzed by MALDI-MS using 2,4,6-trihydroxyacetophenone as matrix (**A**). The masses of individual *N*-glycans are used to assign an overall monosaccharide composition, including degree of sialylation (**B**). H, hexose; N, *N*-acetylhexosamine; D, deoxyhexose; and S, *N*-acetylneuraminic acid.

4. Glycopeptides may be directly analyzed by ESI-MS ***(32,33)***, and the oligosaccharides sequenced following digestion with combinations of exoglycosidases ***(34)*** or glycoforms separated by liquid chromatography prior to analysis ***(35)***. Possibly the most powerful application of this technique has resulted from its interfacing with liquid chromatography which permits the separation and on-line identification of glycoproteins from protein digests ***(36)***. Although ESI-MS may be interfaced with capillary electrophoresis, the separation of glycoproteins and glycopeptides under acidic conditions makes the analysis of sialylated oligosaccharides unsuitable.
5. ESI-MS is not ideally suited for the analysis of neutral and anionic oligosaccharides that have been chemically or enzymatically released from a glycoprotein of interest as they do not readily form multiply charged ions. However, the characterization of methylated derivatives of oligosaccharides from recombinant erythropoietin by ESI-MS has been reported ***(37)***.

Affinity Chromatography of Oligosaccharides and Glycopeptides with Immobilized Lectins

Kazuo Yamamoto

1. Introduction

Sugar moieties on the cell surface play one of the most important roles in cellular recognition. In order to elucidate the molecular mechanisms of these cellular phenomena, assessment of the structure of sugar chains is indispensable. However, it is difficult to elucidate the structures of cell-surface oligosaccharides because of two technical problems. The first is the difficulty in fractionating various oligosaccharides that are heterogeneous in the number, type, and substitution patterns of the outer sugar branches. The second problem is that only very limited amounts of material may be available, making it difficult to perform detailed structural studies.

Lectins are proteins with sugar-binding activity. Each lectin binds to a specific sugar sequence in oligosaccharides and glycopeptides. Therefore, lectins are very useful tools for overcoming the problems described above. Recently, many attempts have been made to fractionate oligosaccharides and glycopeptides on immobilized-lectin columns. The use of a series of immobilized-lectin columns, with sugar-binding specificities that have been precisely elucidated, has enabled us to fractionate very small amounts (~10 ng) of oligosaccharides or glycopeptides into structurally distinct groups. Here, we summarize our serial lectin-Sepharose affinity-chromatographic techniques for the rapid, sensitive, and specific fractionation and analysis of asparagine-linked oligosaccharides of glycoproteins.

The structures of asparagine-linked oligosaccharides fall into three main categories, termed high mannose-type, complex-type, and hybrid-type oligosaccharides ***(1)***. They share the common core structure, Manα1-3(Manα1-6)

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

Manβ1-4GlcNAcβ1-4GlcNAc-Asn, but differ in their outer branches **(Fig. 1).** High mannose-type oligosaccharides have two to six α-mannose residues added to the core structure. Typical complex-type oligosaccharides contain two to four outer branches with a sialyllactosamine sequence. Hybrid-type structures have the features of both high mannose-type and complex-type oligosaccharides and most contain a bisecting *N*-acetylglucosamine, which has a β1-4 linkage to the β-linked mannose residue of the core structure. A novel type of carbohydrate chain, called the poly-*N*-acetyllactosamine-type oligosaccharide, also has been described ***(2–5).*** Its outer branches have a characteristic structure composed of *N*-acetyllactosamine repeating units. Although it may be classified as a complex-type oligosaccharide, it is antigenically and functionally distinct from standard complex-type sugar chains ***(4).*** Some poly-*N*-acetyllactosamine-type oligosaccharides have branched sequences containing Galβ1-4GlcNAcβ1-3(Galβ1-4GlcNAcβ1-6)Gal units ***(2, 3),*** which is the determinant of the I-antigen. Another novel complex-type sugar chain, having GalNAcβ1-4GlcNAc groups in its outer chain moieties, has been found ***(6, 7)*** and GalNAc residues are sometimes sulfated

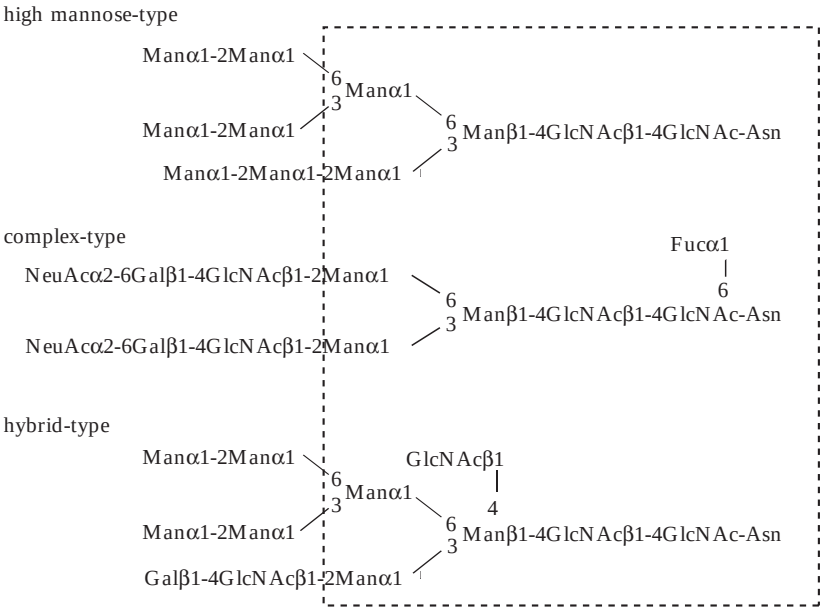

Fig. 1. Structures of major types of asparagine-linked oligosaccharides. The boxed area encloses the core structure common to all asparagine-linked oligosaccharides.

at the C-4 position or sialylated at the C-6 position. Complex-type sugar chains with non-reducing Galα1-3(4)Gal structures have also been reported ***(8).***

Glycopeptides or oligosaccharides can be prepared from glycoproteins by enzymatic digestions or chemical methods, as discussed in subsequent chapters in this book. The most widely used means for preparing glycopeptides is to completely digest the material with pronase. Oligosaccharides can be prepared from glycoproteins or glycopeptides by treating samples with anhydrous hydrazine ***(9)*** or endoglycosidases. Since the released oligosaccharides retain their reducing termini, they can be radiolabeled by reduction with NaB^3H_4 ***(10)*** or fluorescently labeled by 2-aminopyridine ***(11).*** Primary amino groups of the peptide backbone of glycopeptides are labeled by acetylation with [^{3}H]- or [^{14}C]-acetic anhydride (12). Before employing columns of immobilized lectins for analyses, oligosaccharides or glycopeptides should be separated on a column of QAE- or DEAE-cellulose, based on the anionic charge derived from sialic acid, phosphate, or sulfate residues. Separated acidic oligosaccharides should be converted to neutral oligosaccharides to simplify the subsequent separations. For simplicity, the oligosaccharides discussed here do not contain sialic acid, phosphate, or sulfate residues, although these acidic residues, especially sialic acid residues, are found in many oligosaccharides. In most cases, the influence of these residues on the interaction of oligosaccharides with immobilized lectins is weak, but where documentation of the effects of these residues is available, it will be mentioned in the appropriate sections. Here we describe the general procedure for serial lectin affinity chromatography of glycopeptides and oligosaccharides using several well-defined immobilized lectins.

2. Materials

1. Mono Q HR5/50 GL, DEAE-Sepharose, Sephadex G-25 (GE Healthcare Bio-Sciences AB, Uppsala, Sweden).
2. High performance liquid chromatograph, two pumps, with detector capable of monitoring ultraviolet absorbance at 220 nm.
3. Neuraminidase: 1 unit/ml of neuraminidase from *Streptococcus sp*. (Seikagaku Kogyo, Tokyo, Japan) in 50 m*M* acetate buffer, pH 6.5.
4. Dowex 50W-X8 (50–100 mesh, H^+ form).
5. Bio-Gel P-4 minus 400 mesh (Bio-Rad, Richmond, CA).
6. HPLC mobile phase for Mono Q: A, 2 m*M* Tris-HCl, pH 7.4; B, 2 m*M* Tris-HCl, pH 7.4, 0.5 *M* NaCl.
7. HPLC mobile phase for Bio-Gel P-4: distilled water.
8. HPLC standard for Bio-Gel P-4: partial hydrolysate of chitin, prepared according to Rupley (13); 10 µg mixed with 50 µl distilled water. Store frozen.
9. Concanavalin A, *Ricinus communis* lectin, wheat germ lectin, *Datura stramonium* lectin, *Maackia amurensis* leukoagglutinin, *Wistaria floribunda* lectin, *Allomyrina dichotoma* lectin, *Amaranthus caudatus* lectin, *Griffonia (Bandeiraea) simplicifolia*

isolectin B_4 (EY Laboratories, San Mateo, CA), *Phaseolus vulgaris* erythroagglutinin, *P. vulgaris* leukoagglutinin (Seikagaku Kogyo). Immobilized lectins are prepared at a concentration of 1–5 mg lectin/ml of gel (*see* **Notes 1** and **2**). The following may be obtained commercially as immobilized lectins: *Galanthus nivalis* lectin, *Lens culinaris* lectin, *Pisum sativum* lectin, *Vicia fava* lectin, pokeweed mitogen, *Sambucus nigra L.* lectin (e.g., GE Healthcare Bio-Sciences AB, EY Laboratories, Bio-Rad, Seikagaku Kogyo).

10. ^{3}H-NaB^{3}H$_4$: 3.7×10^9 Bq of ^{3}H-NaBH$_4$ (sp. $1.9–5.6 \times 10^{11}$ Bq/mmol; PerkinElmer, Boston, MA) mixed with 2 ml 10 m*M* NaOH; store at −80°C.
11. Tris-buffered saline (TBS): 10 m*M* Tris-HCl, pH 7.4, 0.15 *M* NaCl.
12. Lectin column buffer: 10 m*M* Tris-HCl, pH 7.4, 0.15 *M* NaCl, 1 m*M* $CaCl_2$, 1 m*M* $MnCl_2$ (*see* **Note 3**).
13. *N*-acetylgalactosamine (Sigma, St Louis, MO): 100 m*M* in lectin column buffer; store refrigerated.
14. Methyl-α-mannoside (Sigma): 100 m*M* in TBS; store refrigerated.
15. Methyl-α-glucoside (Sigma): 10 m*M* in TBS; store refrigerated.
16. Lactose (Sigma): 50 m*M* in TBS; store refrigerated.
17. *N*-acetylglucosamine (Sigma): 200 m*M* in TBS; store refrigerated.

3. Methods

3.1. Separation of Acidic Sugar Chains on Mono Q or DEAE-Sepharose and Removal of Sialic Acids.

3.1.1. Ion Exchange Chromatography

1. Equilibrate the Mono Q or DEAE-Sepharose column with 2 m*M* Tris-HCl, pH 7.4, at a flow rate of 1 ml/min at room temperature.
2. Dissolve the oligosaccharides or glycopeptides in 0.1 ml of 2 m*M* Tris-HCl, pH 7.4, and apply to the column.
3. Elute with 2 m*M* Tris-HCl, pH 7.4, for 10 min, followed by a linear gradient (0-20%) of 2 m*M* Tris-HCl, pH 7.4, 0.5 *M* NaCl for 60 min, at a flow rate of 1 ml/min.
4. Neutral oligosaccharides are recovered in the pass-through fraction. Acidic monosialo-, disialo-, trisialo-, and tetrasialooligosaccharides are eluted successively by the linear gradient of NaCl.

3.1.2. Removal of Sialic Acid Residues

1. To 10–100 µg oligosaccharides, free of buffers and salts, add 100 µl of neuraminidase buffer and 100 µl of neuraminidase and incubate at 37°C for 18 h.
2. Heat-inactivate the neuraminidase by immersion in a boiling-water bath for 3 min.
3. Apply to the Dowex 50W-X8 column (0.6 cm id × 2.5 cm), wash the column with 1 ml of distilled water, and concentrate the eluate under vacuum.

Alternatively, add 500 µl of 0.1 *M* HCl to 10–100 µg oligosaccharides, heat at 80°C for 30 min, and dry the sample using an evaporator.

3.2. Separation of Poly-*N*-Acetyllactosamine-Type Sugar Chains from Other Types of Sugar Chains

Poly-*N*-acetyllactosamine-type sugar chains vary as to the number of *N*-acetyllactosamine repeating units and their branching modes. Thus, the structural characterization of poly-*N*-acetyllactosamine-type sugar chains has been quite difficult ***(14).*** This type of sugar chain has a higher molecular weight than high mannose-type, complex-type, or hybrid-type chains. Poly-*N*-acetyllactosamine-type sugar chains with molecular masses of more than 4,000 are excluded in the Bio-Gel P4 column chromatography ***(2, 15, 16)*** and thus are easily separated from other types.

1. Equilibrate two coupled Bio-Gel P-4 columns (0.8 cm id × 50 cm) in water at 55°C using a water jacket.
2. Elute the oligosaccharides at a flow rate of 0.3 ml/min and collect 0.5 ml fractions. Monitor absorbance at 220 nm.
3. Collect poly-*N*-acetyllactosamine-type oligosaccharides that elute in the void volume of the column. Other types of oligosaccharides are subjected to subsequent separations **(Subheadings 3.3–3.6),** as illustrated in **Fig. 2.** The specificities of the lectins are summarized in **Fig. 3** and **Table 1.**

3.3. Separation of Complex-Type Sugar Chains Containing GalNAc 1-4GlcNAc Groups from Other Sugar Chains

Novel complex-type oligosaccharides and glycopeptides with GalNAcβ1-4GlcNAcβ1–2 outer chains bind to a *W. floribunda* lectin (WFA)-Sepharose column ***(7).***

1. Equilibrate the WFA-Sepharose column (0.6 cm id × 5.0 cm) in lectin column buffer.
2. Dissolve oligosaccharides or glycopeptides in 0.5 ml of lectin column buffer and apply to the column.
3. Elute 1.0-ml fractions with three column-volumes of lectin column buffer and then with three column-volumes of 100 mM *N*-acetylgalactosamine, at a flow rate of 2.5 ml/h at room temperature.
4. Collect other types of sugar chains, which pass through the column.
5. Collect complex-type sugar chains with GalNAcβ1-4GlcNAc outer chains, which elute after the addition of *N*-acetylgalactosamine.

3.4. Separation of High Mannose Type Sugar Chains from Complex Type and Hybrid Type Sugar Chains

3.4.1. Affinity Chromatography on Immobilized RCA

After the separation of high-molecular-weight poly-*N*-acetyllactosamine-type oligosaccharides, a mixture of the other three types of sugar chains can

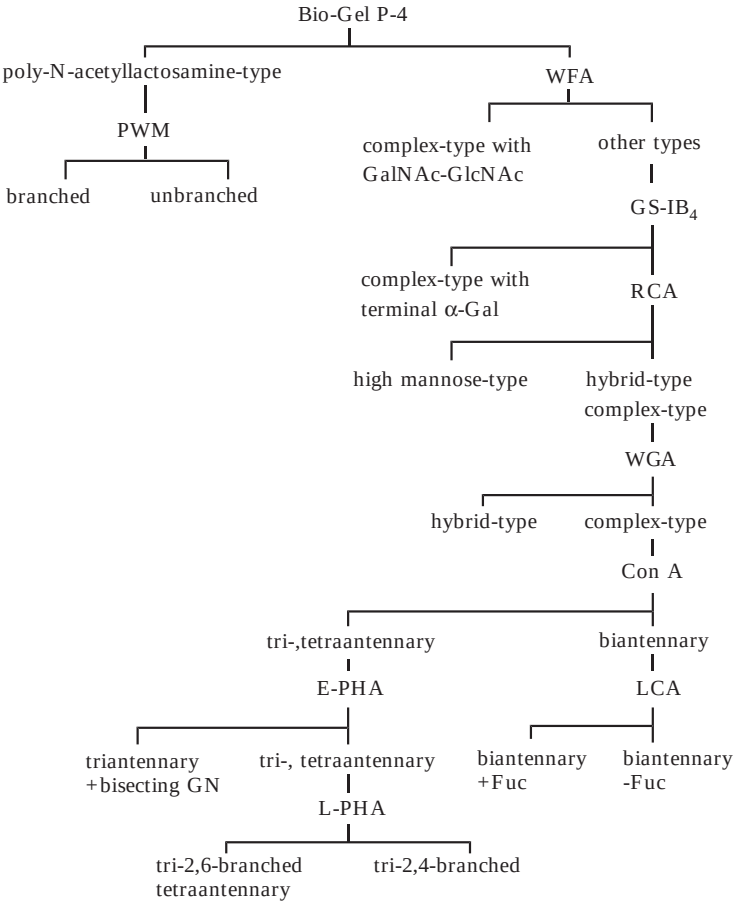

Fig. 2. Fractionation scheme for asparagine-linked sugar chains by affinity chromatography with immobilized lectins

be separated on a column of *R. communis* lectin (RCA), which recognizes the Galβ1-4GlcNAc sequence ***(17, 18).***

1. Equilibrate the RCA-Sepharose column (0.6 cm id × 5.0 cm) in TBS.
2. Dissolve oligosaccharides or glycopeptides in 0.5 ml TBS and apply to the column.
3. Elute 1.0-ml fractions with three column-volumes of TBS, and then with three column-volumes of 50 mM lactose, at a flow rate of 2.5 ml/h at room temperature.
4. Bind both complex-type and hybrid-type sugar chains to the RCA-Sepharose column (*see* **Note 4**).
5. Collect high mannose-type oligosaccharides, which pass through the column.

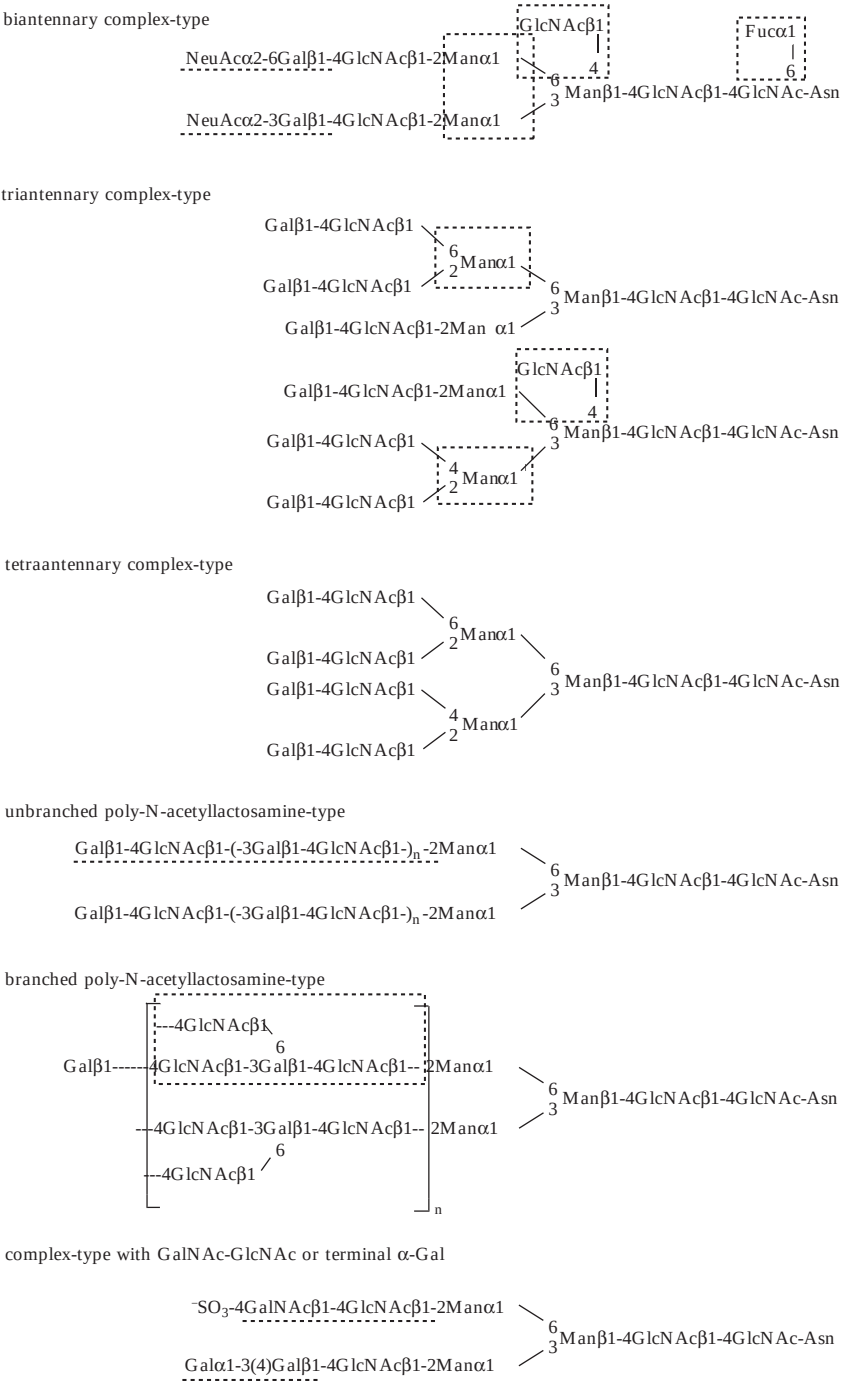

Fig. 3. Structures of several complex-type oligosaccharides. The boxed areas indicate the characteristic structures that are recognized by immobilized lectins.

6. Purify the oligosaccharides or glycopeptides from salts and haptenic sugar by gel filtration on a Sephadex G-25 column (1.2 cm id × 50 cm) equilibrated with distilled water.

3.4.2. Affinity Chromatography on Immobilized Snowdrop Lectin

High mannose-type glycopeptides, which carry Manα1-3Man units are specifically retarded on immobilized snowdrop (*G. nivalis*) lectin (GNA) ***(19).***

1. Equilibrate the GNA-Sepharose column (0.6 cm id × 5.0 cm) in TBS.
2. Dissolve oligosaccharides or glycopeptides in 0.5 ml TBS and apply to the column.
3. Elute 0.5-ml fractions with five column-volumes of TBS to collect sugar chains lacking Manα1-3Man units or hybrid-type sugar chains, which are not retarded.
4. Elute with three column-volumes of 100 mM methyl-α-mannoside at a flow rate of 2.5 ml/h at room temperature to obtain the specifically retarded high mannose-type glycopeptides that carry Manα1-3Man units.

3.5. Separation of Hybrid Type Sugar Chains from Complex Type Sugar Chains

3.5.1. Affinity Chromatography on Immobilized WGA

Wheat germ lectin (WGA)-Sepharose has a high affinity for hybrid-type sugar chains. It has been demonstrated that the GlcNAcβ1-4Manβ1-4GlcNAcβ1-4GlcNAc-Asn structure is essential for tight binding of glycopeptides to a WGA-Sepharose column ***(20).***

1. Equilibrate the WGA-Sepharose column (0.6 cm id × 5.0 cm) in TBS.
2. Dissolve glycopeptides in 0.5 ml TBS and apply to the column.
3. Elute 0.5-ml fractions with five column-volumes of TBS.
4. Collect the typical complex-type (and also high mannose-type) sugar chains eluted in the void volume of the column.
5. Collect hybrid-type glycopeptides with a bisecting *N*-acetylglucosamine residue, which are retarded on the WGA column.

3.6. Separation of Complex Type Biantennary Sugar Chains

3.6.1. Affinity Chromatography on Immobilized Concanavalin A (Con A)

Oligosaccharides and glycopeptides with tri- and tetraantennary complex-type sugar chains pass through Con A-Sepharose, whereas biantennary complex-type, hybrid-type, and high mannose-type sugar chains bind to Con A and can be differentially eluted from the column ***(21, 22).***

1. Equilibrate the Con A-Sepharose column (0.6 cm id × 5.0 cm) in lectin column buffer.
2. Pass the oligosaccharide mixture of complex-type chains from the WGA column through the Con A-Sepharose column.
3. Elute 1-ml fractions with three column-volumes of lectin column buffer.

4. Collect oligosaccharides with tri- and tetraantennary complex-type sugar chains, which pass through the column. Complex-type biantennary glycopeptides or oligosaccharides having bisecting GlcNAc also pass through the column.
5. Elute 1-ml fractions with three column-volumes of 10 mM methyl-α-glucoside and then with three column-volumes of 100 mM methyl-α-mannoside.
6. Collect complex-type biantennary sugar chains, which elute after the addition of methyl-α-glucoside.
7. Collect high mannose-type and hybrid-type oligosaccharides or glycopeptides eluted after the addition of methyl-α-mannoside.

3.6.2. Affinity Chromatography on Immobilized LCA, PSA, or VFA

The biantennary complex-type sugar chains bound to the Con A-Sepharose column and eluted with 10 mM methyl-α-glucoside include two types of oligosaccharides, which can be separated on a column of lentil (*L. culinaris*) lectin (LCA), pea (*P. sativum*) lectin (PSA), or fava (*V. fava*) lectin (VFA) ***(23–25)*** (*see* **Note 5**).

1. Equilibrate the LCA-, PSA-, or VFA-Sepharose column (0.6 cm id × 5.0 cm) in lectin column buffer.
2. Pass the biantennary complex-type sugar chains from the Con A column through the LCA-, PSA-, or VFA-Sepharose column.
3. Elute 1.0-ml fractions with three column-volumes of lectin column buffer, followed by three column-volumes of 100 mM methyl-α-mannoside, at a flow rate of 2.5 ml/h at room temperature.
4. Collect biantennary complex-type sugar chains without fucose, which pass through the column.
5. Elute bound biantennary complex-type sugar chains having a fucose residue attached to the innermost *N*-acetylglucosamine.

3.6.3. Affinity Chromatography on Immobilized E-PHA

Complex-type biantennary sugar chains having outer galactose residues and bisecting *N*-acetylglucosamine are retarded by *P. vulgaris* erythroagglutinin (E-PHA)-Sepharose ***(18, 26).***

1. Equilibrate the E-PHA-Sepharose column (0.6 cm id × 5.0 cm) in lectin column buffer.
2. Apply the pass-through fraction from the Con A column to the E-PHA-Sepharose column.
3. Elute 0.5-ml fractions with five column-volumes of lectin column buffer at a flow rate of 2.5 ml/h at room temperature.
4. Collect biantennary complex-type sugar chains having a bisecting *N*-acetylglucosamine residue, which were retarded on the E-PHA column (*see* **Note 6**). When the column is eluted at 4°C, biantennary complex-type oligosaccharides without a bisecting *N*-acetylglucosamine are also retarded by the E-PHA-Sepharose column.

3.7. Separation of Complex Type Triantennary and Tetraantennary Sugar Chains

3.7.1. Affinity Chromatography on Immobilized E-PHA

E-PHA-Sepharose interacts with high affinity with triantennary (having 2,4-branched mannose) oligosaccharides or glycopeptides containing both outer galactose residues and a bisecting *N*-acetylglucosamine residue **(26).**

1. Equilibrate the E-PHA-Sepharose column (0.6 cm id × 5.0 cm) in lectin column buffer.
2. Apply the pass-through fraction from the Con A column to the E-PHA-Sepharose column.
3. Elute 0.5-ml fractions with five column-volumes of lectin column buffer at a flow rate of 2.5 ml/h at room temperature.
4. Collect retarded triantennary (having 2,4-branched mannose) oligosaccharides or glycopeptides containing both outer galactose and bisecting *N*-acetylglucosamine. Other tri- and tetraantennary oligosaccharides pass through the column (*see* **Note 7**).

3.7.2. Affinity Chromatography on Immobilized L-PHA

P. vulgaris leukoagglutinin (L-PHA), which is an isolectin of E-PHA, interacts with triantennary and tetraantennary complex-type glycopeptides having an α-linked mannose residue substituted at positions C-2 and C-6 with Galβ1-4GlcNAc (27).

1. Equilibrate the L-PHA-Sepharose column (0.6 cm id × 5.0 cm) in lectin column buffer.
2. Apply the pass-through fraction from the Con A column to the L-PHA-Sepharose column.
3. Elute 0.5-ml fractions) with five column-volumes of lectin column buffer at a flow rate of 2.5 ml/h at room temperature.4. Collect retarded triantennary and tetraantennary complex-type glycopeptides having both 2,6-branched α-mannose and outer galactose (*see* **Note 8**). Other tri- and tetraantennary oligosaccharides pass through the column.

3.7.3. Affinity Chromatography on Immobilized DSA

D. stramonium lectin (DSA) has high affinity for tri- and tetraantennary complex-type oligosaccharides. Triantennary complex-type oligosaccharides containing 2,4-substituted α-mannose are retarded by the DSA-Sepharose column. Triantennary and tetraantennary complex-type oligosaccharides having an α-mannosyl residue substituted at the C-2 and C-6 positions bind to the column and are eluted by GlcNAc oligomers ***(28, 29).***

1. Equilibrate the DSA-Sepharose column (0.6 cm id × 5.0 cm) in TBS.
2. Apply the pass-through fraction from the Con A column to the DSA-Sepharose column.

3. Elute 0.5-ml fractions with three column-volumes of TBS at a flow rate of 2.5 ml/h at room temperature to obtain the retarded triantennary complex-type sugar chains having 2,4-branched α-mannose.
4. Elute with three column-volumes of 5 mg/ml *N*-acetylglucosamine oligomer at a flow rate of 2.5 ml/h at room temperature to obtain bound triantennary and tetraantennary complex-type oligosaccharides having an α-mannose residue substituted at the C-2 and C-6 positions.

3.8. Separation of Poly-*N*-Acetyllactosamine Type Sugar Chains

High-molecular-weight poly-*N*-acetyllactosamine-type oligosaccharides are classified into two groups: branched poly-*N*-acetyllactosaminoglycan containing a Galβ1-4GlcNAcβ1-3(Galβ1-4GlcNAcβ1-6)Gal unit and a linear poly-*N*-acetyllactosamine structure that lacks galactose substitutions at the C-3 and C-6 positions.

3.8.1. Affinity Chromatography on Immobilized PWM

Branched poly-*N*-acetyllactosamine-type oligosaccharides can be separated using a pokeweed mitogen (PWM)-Sepharose column ***(30).*** Since the sugar sequence Galββ1-4GlcNAcβ1-6Gal firmly binds to the PWM-Sepharose column, the branched poly-*N*-acetyllactosamine chains can be retained and the unbranched chains recovered without any retardation ***(31)*** (*see* **Note 9**).

1. Equilibrate the PWM-Sepharose column (0.6 cm id × 5.0 cm) in TBS.
2. Apply the poly-*N*-acetyllactosamine-type sugar chains separated on Bio-Gel P-4 (*see* **Subheading 3.2**) to the PWM-Sepharose column.
3. Elute 1.0-ml fractions with three column-volumes of TBS, followed by three column-volumes of 0.1 M NaOH, at a flow rate of 2.5 ml/h at room temperature.
4. Collect the unbranched poly-*N*-acetyllactosamine-type sugar chains, which pass through the column.
5. Collect the bound branched poly-*N*-acetyllactosamine-type sugar chains.

3.8.2. Affinity Chromatography on Immobilized DSA

Immobilized DSA lectin interacts with high affinity with sugar chains having a linear, unbranched poly-*N*-acetyllactosamine sequence. For binding to DSA-Sepharose, more than two intact *N*-acetyllactosamine repeating units may be essential ***(29).***

1. Equilibrate the DSA-Sepharose column (0.6 cm id × 5.0 cm) in TBS.
2. Apply the poly-*N*-acetyllactosamine-type sugar chains separated on Bio-Gel P-4 (*see* **Subheading 3.2**) to the DSA-Sepharose column.
3. Elute 1.0-ml fractions with three column-volumes of TBS, followed by three column-volumes of 5 mg/ml GlcNAc oligomer, at a flow rate of 2.5 ml/h at room temperature.
4. Collect branched poly-*N*-acetyllactosamine-type sugar chains, which pass through the column and are separated from unbranched poly-*N*-acetyllactosamine-type sugar chains, which bind to the column.

3.9. Separation of Terminally Sialylated or β-galactosylated sugar chains

The basic Galβ1-4GlcNAc sequence present in complex-type sugar chains usually contains sialic acids in α2,6 or α2,3 linkages in the outer galactose residues.

3.9.1. Affinity chromatography on immobilized MAL

M. amurensis leukoagglutinin (MAL) ***(32, 33)*** interacts with high affinity with complex-type tri- and tetraantennary glycopeptides containing an outer sialic acid residue linked α2,3 to the penultimate galactose. Glycopeptides containing sialic acid linked only α2,6 to galactose do not interact detectably with the immobilized MAL (*see* **Note 10**).

1. Equilibrate the MAL-Sepharose column (0.6 cm id × 5.0 cm) in lectin column buffer.
2. Apply the acidic oligosaccharides or glycopeptides separated on Mono Q or DEAE-Sepharose (*see* **Subheading 3.1.1**, step 1) to the MAL-Sepharose column.
3. Elute 0.5-ml fractions with five column-volumes of lectin column buffer at a flow rate of 2.5 ml/h at room temperature.
4. Collect glycopeptides or oligosaccharides containing α2,6-linked sialic acid(s), which pass through the column.
5. Collect retarded glycopeptides or oligosaccharides containing α2,3-linked sialic acid(s).

3.9.2. Affinity Chromatography on Immobilized Allo A

A. dichotoma lectin (allo A) (34, 35) recognizes the other isomer of sialyllactosamine. Mono-, di-, and triantennary complex-type oligosaccharides containing terminal sialic acid(s) in α2,6 linkages bind to allo A-Sepharose, whereas complex-type sugar chains having isomeric α2,3-linked sialic acid(s) do not bind to immobilized allo A.

1. Equilibrate the allo A-Sepharose column (0.6 cm id × 5.0 cm) in TBS.
2. Apply the acidic oligosaccharides or glycopeptides separated on Mono Q or DEAE-Sepharose (*see* **Subheading 3.1.1,** step 1) to the allo A-Sepharose column.
3. Elute 0.5-ml fractions with three column volumes of TBS and then with three column-volumes of 50 mM lactose at a flow rate of 2.5 ml/h at room temperature.
4. Collect glycopeptides or oligosaccharides containing α2,3-linked sialic acid(s), which pass through the column.
5. Elute bound glycopeptides or oligosaccharides having α2,6-linked sialic acid(s) (*see* **Note 11**).

3.9.3. Affinity Chromatography on Immobilized SNA

Elderberry (*S. nigra L.*) bark lectin (SNA) ***(36, 37)*** has the same sugar-binding specificity as allo A. All types of oligosaccharides with at least one NeuAcα2-6Gal unit bind firmly to SNA-Sepharose.

1. Equilibrate the SNA-Sepharose column (0.6 cm id × 5.0 cm) in TBS.
2. Apply the acidic oligosaccharides or glycopeptides separated on Mono Q or DEAE-Sepharose (*see* **Subheading 3.1.1,** step 1) to the SNA-Sepharose column.
3. Elute 0.5-ml fractions with three column-volumes of TBS, followed by three column-volumes of 50 mM lactose, at a flow rate of 2.5 ml/h at room temperature.
4. Collect glycopeptides or oligosaccharides containing α2,3-linked sialic acid(s), which pass through the column.
5. Bound glycopeptides or oligosaccharides having α2,6-linked sialic acid(s) elute in the 50 m*M* lactose.

3.9.4. Affinity Chromatography on Immobilized GS-IB$_4$

Griffonia (Bandeiraea) simplicifolia isolectin B_4 (GS-IB_4) binds specifically and with high affinity to complex-type sugar chains containing terminal Galα1-3Gal or Galα1-4Gal sequences ***(8, 38).*** Although *G. simplicifolia* isolectin A_4 (GS-IA_4) and GS-IB_4 bind α-galactosyl groups with equal affinity, B_4 has a K_a for α-*N*-acetylgalactosaminyl groups that is three orders of magnitude smaller than that of A_4.

1. Equilibrate the GS-IB_4-Sepharose column (0.6 cm id × 5.0 cm) in TBS.
2. Apply the neutral oligosaccharides or glycopeptides onto the GS-IB_4-Sepharose column.
3. Elute 0.5-ml fractions with three column-volumes of TBS, followed by three column volumes of 100 mM methyl α-galactoside, at a flow rate of 2.5 ml/h at room temperature.
4. Collect glycopeptides or oligosaccharides without the Galα1-3(4)Gal sequence, which pass through the column.
5. Retarded or bound glycopeptides or oligosaccharides having α-galactosyl residue(s) elute in the 100 m*M* methyl α-galactoside eluant.

4. Notes

1. During the coupling reactions, sugar-binding sites of lectins must be protected by the addition of the specific haptenic sugars.
2. Immobilized lectin is stored at 4°C. In most cases, immobilized lectin is stable for several years.
3. Some lectins, especially leguminous lectins, need Ca^{2+} and Mn^{2+} ions for sugar binding. Therefore, the buffers used for affinity chromatography on the lectin column should contain 1 mM $CaCl_2$ and 1 mM $MnCl_2$.
4. Complex-type and hybrid-type oligosaccharides are retarded on, rather than tightly bound to, a RCA-Sepharose column when their sugar sequences are masked by sialic acids or α-galactosyl residues.
5. Intact *N*-acetylglucosamine and asparagine residues at the reducing end are required for tight binding of complex-type oligosaccharides to LCA-, PSA-, or VFA-Sepharose columns.

6. High-affinity interaction with E-PHA-Sepharose is prevented if both outer galactose residues on a bisected sugar chain are substituted at position C-6 by sialic acid.
7. Biantennary and triantennary complex-type sugar chains having bisecting GlcNAc can be separated on a Bio-Gel P-4 column.
8. L-PHA-Sepharose does not retard the elution of sugar chains lacking outer galactose residues.
9. WGA can be used instead of PWM.
10. *M. amurensis* hemagglutinin (MAH), which is an isolectin of MAL, binds strongly to sialylated Ser/Thr-linked Galβ1-3GalNAc, but not to sialylated Asn-linked sugar chains ***(38).***
11. Mono-, di-, tri-, and tetraantennary complex-type oligosaccharides without sialic acid(s) are retarded by the allo A lectin column.
12. More detailed reviews on the separation of oligosaccharides and glycopeptides by means of affinity chromatography on immobilized lectin columns have been published ***(39, 40).***

In-Gel Enzymatic Release of *N*-Glycans

David J. Harvey

1. Introduction

Analysis of *N*-linked glycans, those attached to Asn in an Asn-Xxx-Ser(Thr) motif, where Xxx is any amino acid except proline, requires determination of which consensus sequence is occupied, the extent of occupancy and the structures of the glycans that are attached to each site. Structural analysis of the glycans is most commonly performed following their removal, either chemically ***(1,2)*** or enzymatically, and this chapter describes an enzymatic method for glycan removal using protein *N*-glycosidase F (PNGase F) ***(3)*** from within the SDS-PAGE gels commonly used to separate and purify the glycoproteins. The method is a modification of that described by Küster *et al*. ***(4)*** in 1997. It can be used for mammalian glycans but not for those that are substituted at the 3-position of the reducing terminal GlcNAc residue, commonly found in plants and insects. These glycans are resistant to PNGase F but can be released with PNGase A after trypsinolysis of the protein. Released glycans can then be examined directly by mass spectrometry, usually with MALDI or electrospray ionization, or they can be labeled at their reducing terminus for analysis by chromatographic or electrophoretic techniques.

2. Materials

2.1. Apparatus

2.1.1. Electrophoresis and Glycan Release

1. BioRad Mini-Protean II apparatus with 80 × 80 × 0.75 mm plates, or similar.
2. 500 µL Eppendorf tubes.
3. Temperature-controlled heating block.
4. BioRad Spin column or equivalent.
5. Plastic hypodermic-type syringe (1 mL).
6. Millipore 0.5 µm FH-type filters.

2. Reference glycoprotein (e.g., ovalbumin. ribonuclease B)
3. Aluminium foil.
4. Protein *N*-glycosidase F e.g. 1000 U/mL recombinant glycerol-free lyophilisate (Roche Life Sciences) (*see* **Note 1**).
5. Dowex AG50Wx12 Resin (H^+ form; 100 to 200 mesh; Bio-Rad).
6. pH Test paper (to check for neutrality).

2.2.2. Optional Glycan Purification

1. Dowex AG3x4 resin
2. C-18 resin (*see* **Note 2**).
3. Dimethylsulfoxide (DMSO).
4. Methyl iodide.
5. Sodium hydroxide.

2.2.3. Solutions

1. 17.5% Resolving gel for proteins in the range 10–70 kDa (*see* **Note 3**): 87.5 mL of 30% acrylamide, 5.5 mL of 2% bis-acrylamide 50.5 mL of 1 M Tris buffer (pH 8.8, acetic acid), 0.75 mL of 20% SDS and add water to give a total volume of 150 mL.
2. 12.5% Resolving gel for proteins in the range 70–200 kDa: 62.5 mL of 30% acrylamide, 15.5 mL of 2% bis-acrylamide 56.0 mL of 1 *M* Tris buffer (pH 8.8, acetic acid), 0.75 mL of 20% SDS and add water to give a total volume of 150 mL.
3. Resolving gel polymerization mixture: 18 µL TEMED and 33 µL of 10% APS.
4. Stacking gel: 20.0 mL of 30% acrylamide, 7.8 mL of 2% bis-acrylamide 15.0 mL of 1 *M* Tris buffer (pH 8.8, acetic acid), 0.6 mL of 20% SDS and add water to give a total volume of 120 mL.
5. Stacking gel polymerization mixture: 12 µL TEMED and 25 µL of 10% APS.
6. Loading buffer: 5 mL 2 *M* ammonium formate, pH 4.4; 50 mL Milli-Q-purified water, Adjust pH to 8.6, Add 0.4 g SDS and water to a final volume of 100 mL.
7. Electrophoresis running buffer: 25 m*M* Tris, 190 m*M* glycine, 0.5% SDS.
8. Destain solution: 5% methanol/7% acetic acid.
9. Incubation buffer: 20 m*M* $NaHCO_3$, pH 7.0; 336 mg $NaHCO_3$ in 200 mL Milli-Q water, adjust to pH 7.0 with acetic acid.
10. 45 mM DTT solution: 6.9 mg of DDT in 1mL of $NaHCO_3$ buffer.
11. Iodoacetamide solution: 18.5 mg of iodoacetamide in 1 mL of $NaHCO_3$ buffer (*see* **Note 4**).

12. PNGase-F solution: 50 Units of PNGase F powder in 0.25 mL Milli-Q water (200 Units/mL and dialyse into 20 m*M* $NaHCO_3$ buffer (*see* **Note 5**). Add 50 µL distilled water to give a final concentration of 100 Units/mL.

3. Methods

3.1. Gel Electrophoresis

3.1.1. Preparation of Gel

1. Mix 5 mL of the resolving gel mixture with the polymerization mixture and pour to 1 cm below the top of the electrophoresis cell.
2. Overlay with about 2 mm of *iso*-butanol/water and leave the gel to set for about 30 min.
3. Wash off *iso*-butanol/water and remove excess water.
4. Mix 5 mL of the stacking gel mixture with the polymerization mixture and pour onto the resolving gel to fill the cell.
5. Insert the comb into the stacking gel, avoiding air bubbles, and allow the mixture to set for 30 mins.

3.1.2. Preparation of Sample

1. Mix the sample, which should contain about 50–100 pmol of glycoprotein with twice its volume of loading buffer and bromophenol blue.
2. Boil for 5 mins in a hot block (in an uncapped tube), cool and spin in a microcentrifuge.

3.1.3. Running of Gel

1. Clip the cell containing the gel into its frame and place into the electrophoresis tank.
2. Add running buffer to the tank and remove any air bubbles.
3. Remove the comb from the stacking gel and wash the wells with Milli-Q water.
4. Fill the spaces with running buffer.
5. Add bromophenol blue dye to the outer lanes.
6. Add 3 µL of molecular weight markers to the next lanes.
7. Add a reference glycoprotein (e.g. ovalbumin 10 µL, 100 pmol, 4.5 mg) + dye to one lane.
8. Load the samples (10 µL) into the remaining lanes (*see* **Note 6**).
9. Fill empty lanes with running buffer.
10. Connect to the power supply (200 V).
11. Switch on and set the current to about 50 mA.
12. Allow to run until the dye runs out at the bottom of the gel (*see* **Note 7**).

3.1.4. Gel Staining

1. Empty the tank, remove the gel in its cell and wash with tap water.
2. Remove the spacers, lever apart the glass plates and remove the stacking gel.
3. Mark the top of the gel by cutting off a corner.
4. Wash the gel from the remaining glass plate with a stream of water into a plastic box.

5. Cover the gel with Coomassie blue solution, cover and shake for 10–15 mins
6. Pour away the dye solution.

3.1.5. Gel Destaining

1. Wash the gel with tap water.
2. Cover the gel with the destain solution (*see* **Note 8**) and shake for 10 min
3. Change the destain solution and shake for a further 10 mins.
4. Repeat step 3.
5. Cut out the bands from the gel that contains the target glycoproteins. (*see* **Note 9**) and place into the Eppendorf tube with a small amount of destain solution.
6. Place the tube in a shaker overnight at room temperature.
7. Wash gel pieces with 300 µL of incubation buffer, vortex, centrifuge briefly, and soak for 30 min at room temperature. Discard the wash.
8. Repeat step 7.
9. Wash the gel pieces for 60 min in 300 µL of 1:1 acetonitrile: 20 mM $NaHCO_3$ to remove residual SDS.
10. Dry gel pieces in a vacuum centrifuge.

3.2. Glycan Removal

3.2.1. Reduction of Glycoprotein

1. Add 300 µL of incubation buffer (to cover gel bits).
2. Add 20 µL of the DTT solution.
3. Cap, spin and heat in a shaker at 60°C for 30 mins.

3.2.2. Alkylation of Glycoprotein

1. Add 20 µL of the iodoacetamide solution to the gel-containing tube.
2. Wrap the tube in aluminium foil and shake for 30 min at room temperature.
3. Remove the buffer and iodoacetamide.
4. Add about 0.5 mL of $NaHCO_3$ buffer and 0.5 mL of acetonitrile and shake at room temperature for 1 hour.
5. Remove the buffer and acetonitrile.
6. For each sample, cut the gel piece into small bits and place the gel bits into a 500 µL Eppendorf tube that has holes pierced in the lid.
7. Place the tubes in a SpeedVac (continuous rotor) until they are dry (crisp).

3.2.3. Removal of Sugars with PNGase-F

1. Add 30 µL of the PNGase solution to each sample (the solution should just cover the gel bits).
2. Leave at room temperature until all liquid has been taken up by the gel (20–30 mins.)
3. Add 150 µL of $NaHCO_3$ buffer.
4. Incubate at 37°C overnight.

3.2.4 *Extraction of* N*-Glycans from the Gel*

1. Prepare AG50 (30 µL/sample) by adding the AG50 resin (*see* **Note 10**) to a BioRad BioSpin column, running approx. 10 col. volumes of HCl (1:1, v:v dilution of concentrated HCl) through the AG50 and then washing with Milli-Q water until the washings are neutral (about pH 5 as tested by pH paper).
2. Add 100 µL of distilled water to each sample and sonicate for 30 mins.
3. Remove the solution and add to a small screw-cap tube containing the AG50 resin.
4. Repeat steps 2 and 3 twice, adding the solution to the tube containing the resin.
5. Add 200–300 µL of acetonitrile to each sample and sonicate for 30 mins. (*see* **Note 11**).
6. Remove the acetonitrile and add to the tube containing the resin.
7. Shake the resin-containing tube and spin in a microcentrifuge.
8. Filter through a 0.5 µm FH-type Millipore filter attached to a 1 mL plastic syringe.
9. Wash the resin, filter the washings and add to the first filtrate
10. Dry the sample in a SpeedVac.
11. Add 20 µL 1% formic acid and allow to stand at room temperature for 40 mins (*see* **Note 12**).
12. Dry in a SpeedVac.

3.2.5. *Removal of Contaminants from the Glycans*

The samples will still be contaminated with, possibly, peptides, salts, SDS etc. that must be removed before analysis by mass spectrometry or HPLC. Several methods are available. We prefer the Nafion membrane procedure ***(5)*** that is described in the chapter on the analysis of *N*-glycans by mass spectrometry. However, a second stage of preliminary cleaning may be required. For neutral glycans (*see* **Note 13**), this can be achieved as follows:

1. Fill a GelLoader tip with ethanol.
2. Add a few µL of G3 × 4 resin, followed by washed AG50 resin and C-18 resin to the GelLoader tip to form three layers.
3. With nitrogen from a cylinder, force ethanol through column until just to the top of the resin (*see* **Note 14**).
4. Add 100 µL of Milli-Q water to the top of the resin "sandwich" and force the water through the resins with the nitrogen.
5. Repeat the washing procedure twice.
6. Add the aqueous sample solution to the resin column.
7. Force the solution through the resins with nitrogen and collect into a small Eppendorf (PCR) tube.
8. Add 50 µL Milli-Q water to the resins, blow through and add to the glycan solution.
9. Dry the glycans in a Speedvac.

3.2.6. Sialylated Glycans

Sialylated glycans will be removed by the AG3 resin in the above procedure. However they can be neutralized (and stabilized for analysis by MALDI mass spectrometry) by formation of methyl esters prior to clean-up by the three-bed resin procedure.

1. Place about 100 µL AG5OW × 12 resin in a short column.
2. Wash with 1 mL of 1 M sodium hydroxide solution followed by water until the washings are approximately neutral.
3. Dissolve the glycan sample (100–500 pmole) in about 5–20 µL water and apply to the column.
4. Wash through with 5–100 µL of water and collect the washings in a small Eppendorf tube.
5. Dry in a rotary evaporator.
6. Dissolved the glycans in about 1 µL of dry DMSO and add 1 µL of methyl iodide (*see* **Note 15**).
7. Mix well and allow to stand for 2 h at room temperature.
8. Add about 10 mL of DMSO and evaporate the methyl iodide with a stream of nitrogen.
9. Evaporate to dryness (*see* **Note 16**).

4. Notes

1. Preparations containing glycerol should be avoided.
2. C18 resin can be obtained from a C18 SepPak cartridge
3. Higher bis-acrylamide concentrations lead to increased cross-linking and reduced glycan yield.
4. Iodoacetamide is light sensitive and solutions should be kept in the dark.
5. It is best not to use nonammonium-containing buffers at this stage. PNGase F releases the glycans as the glycosylamine that need to be converted into the free sugars before further analysis. Ammonium-containing buffers promote glycosylamine retention ***(6)***.
6. It is a good idea to load the samples asymmetrically so that it is possible to determine the left and right sides of gel.
7. The current normally drops to about 10 mA.
8. A low concentration of acetic acid is used to minimizes loss of sialic acid from the glycans.
9. The gel pieces should be small but wide enough to retain minor glycoforms.
10. The resin, which should be stored in water, can be handled with a Gilson pipette fitted with a blue or yellow tip that has been cut to widen the end.
11. The acetonitrile causes the gel to shrink, expelling the remaining water.
12. Because the glycans are released as glycosylamines, a considerable amount of the sample may be in this form at this stage. The glycosylamines can

be detected by mass spectrometry by their mass being one unit less than that of the native glycan. If labelling of the reducing terminus is attempted at this stage, the glycosylamines will not react, resulting in a poor yield of labeled material. Furthermore, the rate and extent of glycosylamine hydrolysis to the glycan depends on whether or not there is a fucose residue at the reducing terminus. Consequently, samples must be fully converted into their native glycan (OH) form before analysis is attempted. Conversion can be achieved by leaving the glycans to stand in water or, better, in dilute formic acid. However, care must be taken to avoid hydrolysis of sensitive bonds such as those linking the sialic acids.

13. The AG3 resin is included in this clean-up procedure mainly to remove any residual SDS. However, it will also remove acidic (sialylated, sulfated glycans). To prevent sialic acid removal, the sialic acids can be converted into methyl esters as described by Powell and Harvey *(7)* and in Subheading 3.2.6 before the 3-resin method is applied. However, sulfates cannot be methylated by this method.
14. In this and subsequent steps, release the nitrogen pressure when the top surface of the liquid reaches the top of the resins in order to avoid introducing air bubbles to the resin.
15. Methyl iodide is toxic; consequently, this procedure should be performed in a fume hood.
16. DMSO is not very volatile, consequently, evaporation is slow.

Acknowledgments

The author would like to thank Professor Bernhard Küster who originally developed the in-gel method and the Oxford Glycobiology endowment fund for financial support.

Analysis of *N*-Linked Glycans by Mass Spectrometry

David J. Harvey

1. Introduction

Analysis of *N*-linked glycans, those attached to Asn in an Asn-Xxx-Ser(Thr) motif, where Xxx is any amino acid except proline, involves determination of which consensus sequence is in fact occupied by glycans, the extent of occupancy and the structures of the glycans that are attached. This chapter deals only with a small set of these procedures, namely the structural analysis of the carbohydrates using mass spectrometry as the main analytical technique. It is assumed that the glycans have been released from the glycoprotein or derived glycopeptide by techniques such as hydrazinolysis ***(1,2)*** or enzymolysis with an endoglycosidase such as protein-*N*-glycosidase F (PNGase F) ***(3,4)*** and that the released glycans are available in aqueous solution. Traditionally, such mixtures of glycans would be labeled with a chromophore or fluorophore such as 2-aminobenzamide ***(5)*** and profiled by gel-filtration or high-performance liquid chromatography (HPLC) with structures being deduced by subsequent profiling of the products of sequential exoglycosidase digestion with a library of exoglycosidases. Knowledge of the enzyme specificity and the number of constituent monosaccharide residues removed at each stage of the procedure allows the structure of the glycan(s) to be deduced. The method, although valuable to the mass spectroscopist for providing information on the nature of the constituent monosaccharides, is limited by the range, availability and purity of the available exoglycosidases which does not include enzymes appropriate for all structural features.

Mass spectrometry, although capable of rapidly supplying much of the information that is difficult to obtain by the exoglycosidase technique, still relies on

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

it for confirmation of the identity of the constituent monosaccharides. However, because of the very conserved nature of the *N*-glycan biosynthetic pathway and because much work on the analysis of *N*-glycans is performed with species with well characterized enzymology, mass measurements are often sufficient to provide the structural information that is required. This information relates to questions such as what type of glycan (high-mannose, hybrid, complex) is present and the branching pattern and composition of the antennae. However, for rigorous work, it must be remembered that a mass measurement will only classify monosaccharide constituents into groups such as hexose, HexNAc, and so on.

The ideal mass spectrometric approach is one in which the initial spectrum produces the glycan profile, preferably quantitatively, with no fragmentation and subsequent spectra give extensive fragmentation to provide the detailed structural information required on each component. Glycan profiles are conveniently obtained by matrix-assisted laser desorption/ionization (MALDI) mass

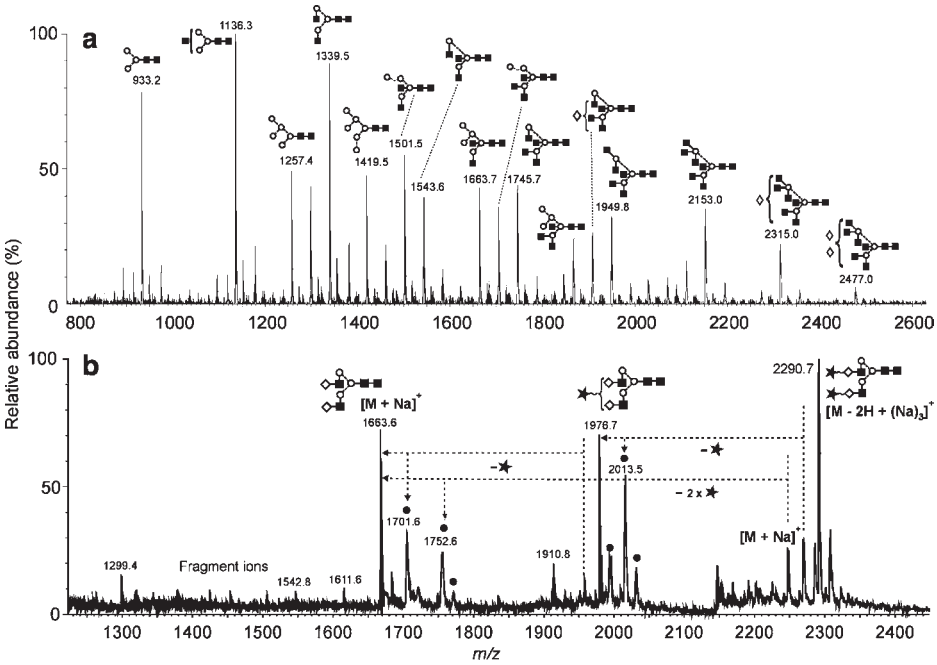

Fig. 1. **(a)** Positive ion MALDI-TOF mass spectrum of *N*-glycans released from a mixture of glycoproteins (mainly ovalbumin) from chicken egg white. **(b)** Positive ion reflectron MALDI-TOF spectrum of a disialylated biantennary glycan. Peaks annotated with a black spot are metastable (PSD) ions. Key to symbols used for the constituent monosaccharides in this scheme and subsequent Figs. ◊ = *galactose,* ▤ = *GlcNAc*, ▤ = *mannose,* ▤ = *fucose,* ▤ = *N-acetylneuraminic* (sialic) acid. Solid lines connecting the symbols are β-bonds and broken lines are α-bonds.

spectrometry ***(6–9)***, a technique that gives a quantitative response and negligible fragmentation for neutral *N*-glycans of varying structure ***(10,11)*** (**Fig. 1a**). Sialylated glycans, however, tend to fragment by loss of sialic acid (**Fig. 1b**) but can be neutralized and stabilized by methyl ester formation ***(12)***. The somewhat milder technique of electrospray ionization (ESI) is being increasingly used but tends to produce ions in different charge states that limit its usefulness as a profiling technique. It is, however, an ideal method for introducing glycans into a mass spectrometer for fragmentation analysis. Older, less sensitive techniques such as fast-atom bombardment (FAB) mass spectrometry have also been widely used for glycan analysis ***(13,14)*** but produce extensive fragmentation, require derivatization of the glycans and are now mainly of historical interest.

The mass of the glycan provides a direct indication of the constituent monosaccharide composition in terms of sugar type (hexose, deoxy-hexose, and so on) because most *N*-glycans consist of only a limited number of mass-different monosaccharides. **Table 1** lists the residue masses for these monosaccharides. Suitable software is available on the internet at https://tmat.proteomesystems.

Table 1
Residue Masses of Common Monosaccharides Found in *N*-Glycans

Monosaccharide	Residue formula	Residue mass[a]
Pentose	$C_5H_8O_4$	132.042
		132.116
Deoxy-hexose	$C_6H_{10}O_4$	146.078
		146.143
Hexose	$C_6H_{10}O_5$	162.053
		162.142
Hexosamine	$C_6H_{11}NO_4$	161.069
		161.157
HexNAc	$C_8H_{13}NO_5$	203.079
		203.179
Hexuronic-Acid	$C_6H_8O_6$	176.032
		176.126
N-Acetyl-neuraminic acid	$C_{11}H_{17}NO_8$	291.095
		291.258
N-glycoyl-neuraminic acid	$C_{11}H_{17}NO_9$	307.090
		307.257

a) Top Fig. = monoisotopic mass (based on C = 12.000000, H = 1.007825, N = 14.003074, O = 15.994915), Lower Fig. = average mass (based on C = 12.011, H = 1.00794, N = 14.0067, O = 15.9994.
The masses of the intact glycans can be obtained by addition of the residue masses given above, plus the mass of the terminal group (H_2O for an unmodified glycan) 18.011 (monoisotopic) and 18.152 (average) and the mass of any reducing-terminal or other derivative.

com/glyco/glycosuite//glycodb (requires password) for deriving compositions from experimental masses. Once the monosaccharide composition is established, structural features can be assigned by fragmentation. Fragmentation from MALDI-generated ions produced in time-of-flight (TOF) instruments can be obtained by analysis of spontaneously produced post-source decay (PSD) ions ***(15)*** but resolution is generally poor and many commercial instruments require the spectra to be recorded in segments with consequent reduction in quantitative information. Greatly improved performance can be obtained by generating the fragments by collision in a tandem instrument such as a quadrupole/time-of flight (Q-Tof) mass spectrometer ***(16–20)***. Multiple successive fragmentations can be produced with a storage instrument such as an ion trap ***(21–23)*** and can be used to extract detailed structural information from small fragments of the glycan.

The information that can be obtained from the spectrum depends to a large extent on the type of ion that is initially formed. MALDI Produces mainly $[M+Na]^+$ ions that fragment predominantly by cleavage between the sugar rings (glycosidic cleavage) to provide sequence information but little linkage data. Linkage information is provided by cross-ring cleavage fragments that are usually present in only low relative abundance in low-energy spectra of the type produced by trap and Q-Tof-type instruments. Cross-ring fragments of higher abundance are found in the spectra recorded with instruments providing higher-energy collisions ***(24–26)***. Unfortunately, fragmentation spectra of $[M+Na]^+$ ions contain ambiguous information because fragment ions of the same mass and composition often arise from different regions of the molecule. The situation is even more difficult with the $[M+H]^+$ ions frequently encountered in ESI spectra **(Fig. 2a);** fragmentation of these ions rarely yield cross-ring cleavages and are prone to internal rearrangements ***(27–30)*** that again yield ambiguous information.

Negative ion spectra, on the other hand, are much more informative because cross-ring cleavage reactions are frequently dominant ***(31–37)*** **(Fig. 2)** and the

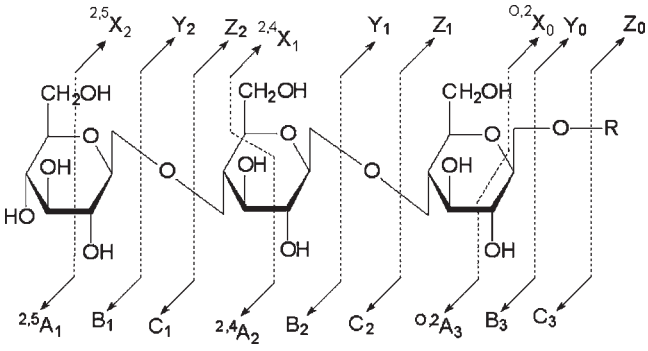

Fig. 2. Nomenclature for describing fragment ions from carbohydrates according to Domon and Costello ***(39).***

redundancy seen in the positive ion spectra is largely absent. Spectra of isomeric compounds are usually different in that they produce ions of different masses unlike positive ion spectra where the presence of isomers is often only reflected in differences in ion abundance. Consequently, the spectra contain ions that are diagnostic of specific structural features that cannot be obtained easily from the positive ion spectra or from the more classical analytical methods and form the basis of this chapter. The protocol described below is one that is used in our laboratory to provide most of the structural information necessary to analyse complex mixtures of *N*-glycans that have been released with PNGase from glycoproteins separated in SDS-PAGE gels ***(4)***.

2. Materials

2.1. Purification of Glycans

1. Nafion 117 membrane (Aldrich Chemical Co. Ltd., Poole, UK).
2. 35% Nitric acid.
3. Milli-Q water.

2.2. MALDI Mass Spectrometry

1. Matrix solution (saturated solution of dihydroxybenzoic acid (DHB) in acetonitrile (*see* **Note 1**).
2. Ethanol.

2.3. Electrospray Mass Spectrometry (Negative Ion)

1. Ammonium phosphate.
2. Nanospray capillaries (Proxeon).
3. Methanol:Milli-Q water (1:1, v:v).
4. Gel-Loader pipette tips (Eppenforf 20 µL).

3. Methods

3.1. Purification of Glycans

Most glycan solutions contain residual salt, peptides etc. whose presence will degrade the quality of the mass spectrum or completely suppress the signals from the glycans. Normally neutral glycans give much weaker signals than peptides on account of their different ionization properties (formation of $[M+Na]^+$ rather than $[M+nH]^{n+(-)}$ ions. If such contamination is expected, proceed with a clean-upstage as follows. If not, this stage can be omitted. The method is essentially as described by Börnsen *et al*. ***(38)***.

1. Condition small squares (about 3 cm square) of the Nafion 117 membrane by heating in 35% nitric acid for 4 hours at 80°C.
2. Wash each square thoroughly with Milli-Q water (*see* **Note 2**).

3. Dry a square of membrane with filter paper and float it on the surface of Milli-Q water in a small shallow container.
4. Deposit 1 µL (or similar) drops of the aqueous glycan solutions (*see* **Note 3**) onto the membrane surface and allow it to sit for about 20 mins. (*see* **Note 4**).
5. Remove the glycan solution with a pipette and either deposit directly onto the MALDI target or dilute for ESI analysis as described below.

3.2. MALDI Mass Spectrometry

1. Deposit 0.5–1 µL glycan solution onto the MALDI target.
2. Using a separate pipette tip, add 0.3 µL matrix solution and allow the mixture to dry at room temperature. Inspect the dried sample deposit. (*see* **Notes 5 and 6**).
3. If good crystals are present, redissolve the spot in the minimum amount of ethanol and allow it to recrystalize (*see* **Note 7**).
4. Introduce the target into the mass spectrometer and acquire both positive and negative ion spectra in reflectron mode (*see* **Note 8**). Keep the laser power as low as practical in order to avoid peak broadening and consequent mass errors (*see* **Note 9**) and frequently move the laser spot to different areas of the target (*see* **Note 10**) until a satisfactory signal:noise ratio is obtained (*see* **Note 11**).
5. If sialic acids are detected, they can be stabilized by forming methyl esters using the protocol described in the chapter on in-gel release of glycans and reference ***(12)*** (*see* **Note 12**).
6. If desired, recover the remaining sample from the MALDI target after MS analysis by dissolving the spot in several repetitive additions of 2 µL of 1:1 (v:v) methanol:water and removing with a pipette. The matrix can then removed from the resultant solution by drop dialysis or use of a C18 ZipTip.

3.3. Electrospray Mass Spectrometry (Negative Ion)

1. Dilute the cleaned glycan solution with about 5 µL of 1:1 (v:v) methanol:water containing a trace of ammonium phosphate (*see* **Note 13**).
2. Introduce the glycan solution into the nanospray capillary with a 20 µL pipette fitted with a GelLoader pipette tip (*see* **Note 14**).
3. Introduce the capillary into the mass spectrometer with the voltage set to zero, introduce a small pressure on the capillary and start the flow by touching the tip of the capillary on the cone. If the spray does not start immediately, scrape the tip on the cone to try and break off the end.
4. Once the flow has started, turn up the capillary voltage to about 1.1 kV (Waters-Micromass Q-Tof Ultima Global instrument. Other instruments may vary).
5. Record the MS spectrum and then the MS/MS spectra of each relevant ion (*see* **Notes 15** and **16**).

3.4. Spectral Interpretation

3.4.1. Neutral Glycans

The *N*-glycans fragment by glycosidic (between the monosaccharide rings) and cross-ring cleavages. All glycosidic cleavages are accompanied by hydrogen

migration to give the product even-electron ion and a neutral molecule. The nomenclature used to describe the fragmentation was proposed by Domon and Costello in 1988 ***(39)*** and has been universally accepted. It is outlined in **Fig. 2**. Ions retaining the charge on the reducing terminus are designated *X*, *Y*, and *Z* where *X* is a cross ring cleavage and *Y* and *Z* are glycosidic cleavages depending on which side of the linking oxygen the bond is broken. Subscript numbers designate the position along the chain where cleavage occurs. Unfortunately, for series of glycans of different chain length, this number can change for the same fragmentation such as loss of the terminal residue from the reducing terminus. In order to overcome this difficulty we have introduced a modification whereby the subscript R is used for this cleavage and R-1 etc. is proposed for cleavages further into the glycan chain. For branched structures, chains are further designated by Greek letters with the largest chain being alpha. Ions retaining the charge at the nonreducing terminus are named similarly using A, B and C in place of X, Y and Z. Cross ring cleavages are further defined by superscript numbers preceding the letter and consisting of the lowest number of the two carbon atoms of the bond cleaved or "O" if the O-1 bond is cleaved. Major ions in positive ion spectra tend to be formed by B and Y glycosidic cleavages whereas ions in the negative ion spectra are mainly products of cross-ring or C-type glycosidic cleavages.

The high information content of the negative ion fragmentation spectra arises from abstraction of protons from individual and specific hydroxyl groups which catalyses specific electron movements leading to the diagnostic fragments as illustrated in **Fig. 3** for formation of the $^{2,4}A_R$ ions representing loss from the reducing terminal GlcNAc residue. Unfortunately, acidic glycans, such as those containing sialic acid, loose the acidic protons in preference to the hydroxylic hydrogens, thus suppressing formation of the diagnostic ions. Much specificity can be restored by blocking the acidic group by formation of methyl esters but the resulting fragmentation spectra are complicated by many additional ions formed by losses of methanol.

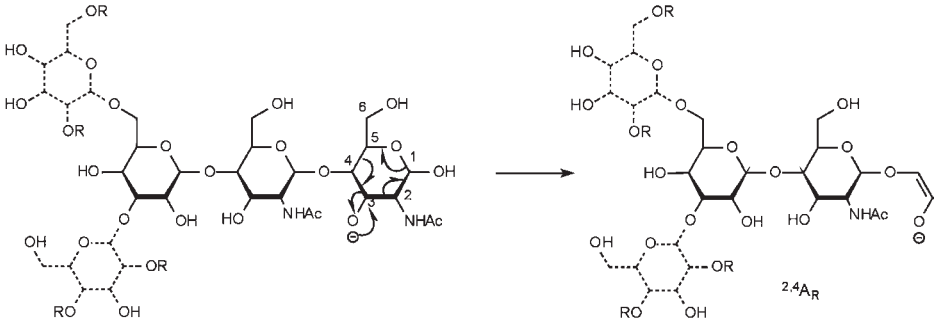

Fig. 3. Proposed mechanism for the formation of the $^{2,4}A_R$ ion from *N*-linked glycans.

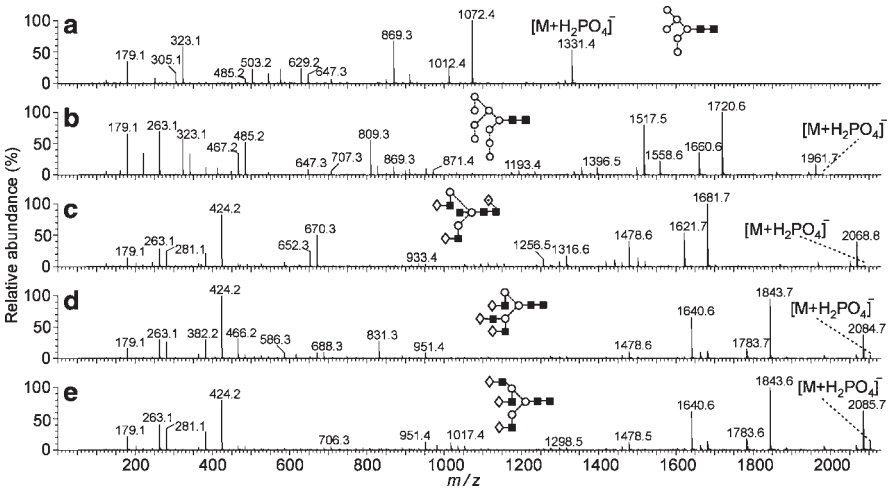

Fig. 4. Negative ion CID fragmentation spectra of (**a**) the high-mannose glycan $Man_5GlcNAc_2$ (**b**) the high-mannose glycan $Man_9GlcNAc_2$ (**c**) a fucosylated, bisected complex glycan (**d**) a 3-branched triantennary glycan (**e**) a 6-branched triantennary glycan.

A suggested spectral interpretation protocol could be as follows: typical spectra are shown in **Fig. 4**.

1. Determine the constituent monosaccharide composition of the glycans producing each peak using the information in **Table 1**. The mass of the glycans recorded by nano-electrospray as phosphate adducts will be 98 mass units higher than this calculated mass (mass of glycan + $H_2PO_4^-$) and those in the MALDI-TOF spectra will be 23 mass units higher ($[M+Na]^+$ ion).
2. From the negative ion MS/MS spectrum, verify that the adduct is phosphate. This can be done by locating the $^{2,4}A_R$, B_R and $^{2,4}A_{R-1}$ triplet at 259, 319 and 462 mass units below the mass of the molecular ion (**Fig. 4b**) or at 405, 465 and 608 mass units below if the glycan contains a fucose residue attached to the reducing terminal GlcNAc residue (**Fig. 4c**). There is a possibility of other modifications and this must also be taken into account but most common *N*-linked glycans will fit this pattern. The most likely alternative adduct is chlorine which will add 35 and 37 mass units to the mass of the glycan and whose ions can often be identified by the characteristic chlorine isotope pattern.
3. Use the information in **Table 2** and the four publications ***(40–43)*** to deduce the structure of the glycan. Some of the more important diagnostic ions are outlined below:
4. The masses of the $^{2,4}A_R$, B_R and $^{2,4}A_{R-1}$ ions can be used to determine the presence of fucose at the 6-position of the reducing terminal GlcNAc residue; fucose at the 3-position will result in the absence of the $^{2,4}A_R$ ion because its formation involves abstraction of the hydrogen from this position in the initial loss of the adduct.

5. The D-type ions in **Table 2** (*m/z* 647 in **Fig. 4a**, 971 in **Fig. 4b**, 688 in **Fig. 4d**, and 1053 in **Fig. 4e**) consist of the β-linked core mannose residue together with the mannose attached to the 6-position together with its attached residues. Thus, they can be used to determine the composition of the 6-antenna and classify the glycan into complex or high-mannose/hybrid. The ion is accompanied by a second ion 18 mass units lower of comparable abundance. If a bisecting GlcNAc is present **(Fig. 4c)**, the D ion is absent because the bisecting GlcNAc residue is readily expelled (221 mass units) to give a very abundant ion at the same mass as the D-18 ion from the un-bisected glycans.
6. Antenna composition is revealed by a ^{1,3}A cleavage of the mannose residue in that antenna to produce what is normally a very abundant ion termed an F-type ion (e.g., antennae containing Gal-GlcNAc residues produce this ion at *m/z* 424 (Gal-GlcNAc + 59 mass units, *m/z* 424 in **Figs. 4c**, **4d**, and **4e**). If fucose is present on this antenna, the ion shifts to *m/z* 570. Shifts produced by other substituents are listed in **Table 2**.
7. An ^{0,4}A-cleavage of the antennae mannose residues from an unbranched antenna of composition Gal-GlcNAc gives an ion at *m/z* 466, an ion termed E. If the 3-antenna is branched **(Fig. 4d)**, an abundant E-type ion is present at *m/z* 831 (*m/z* 466 + the mass of Gal-GlcNAc). Branching of the 6-antenna **(Fig. 4e)** does not produce this shift because the 6-position, the substitution position of the second branch in the 6-antenna is not present in the E-ion. Thus, identification of the branching pattern of triantennary glycans is very simple ***(44)***.
8. The residues at the nonreducing termini of the antennae are revealed by the C_1 ion: *m/z* 179 when hexose is present or *m/z* 220 when chains terminate in GlcNAc.
9. Other diagnostic ions and masses are listed in **Table 2**.

Table 2
Ions Defining Structural Features in the Negative Ion Spectra of *N*-Linked Glycans

Structural feature	Ion	Ionic composition	*m/z*
Composition	Molecular	$[M+X]^-$	-
Antenna sequence	C	Gal, Man, Glc	179
		GlcNAc, GalNAc	220
		[Fuc]Gal	325
		Gal-[Fuc]GlcNAc	528
		αGal-Gal, Man-Man	341
		Man-[Man]Man	503
		GalNAc-GlcNAc	423
Antenna composition	F	Man	221
		GlcNAc	262
		Gal-GlcNAc	424
		Gal-[Fuc]GlcNAc	570
		αGal-Gal	586
		GalNAc-GlcNAc	465
		$(Gal\text{-}GlcNAc)_2$	789

(continued)

Table 2 (continued)

Structural feature	Ion	Ionic composition	*m/z*
		$(Gal\text{-}GlcNAc)_2Fuc$	935
		$(Gal\text{-}GlcNAc)_3$	1154
Fucose at 6-position of reducing terminus	$^{2,4}A_R$	$[M\text{-}HCl\text{-}307]^-$	$[M\text{-}343]^-$
		$[M\text{-}HNO_3\text{-}307]^-$	$[M\text{-}370]^-$
		$[M\text{-}H_3PO_4\text{-}307]^-$	$[M\text{-}405]^-$
Absence of fucose at 6-position of reducing terminus	$^{2,4}A_R$	$[M\text{-}HCl\text{-}161]^-$	$[M\text{-}197]^-$
		$[M\text{-}HNO_3\text{-}161]^-$	$[M\text{-}224]^-$
		$[M\text{-}H_3PO_4\text{-}161]^-$	$[M\text{-}259]^-$
Composition of 6-antenna	D and $[D\text{-}18]^-$ ($[D\text{-}36]^-$)	GlcNAc	526, 508
		Gal-GlcNAc	688, 670
		Gal-[Fuc]GlcNAc	834, 816
		$(Gal\text{-}GlcNAc)_2$	1053, 1035 (1017)

		Man_3	647, 629
		Man_4	809, 791
		Man_5	971, 953
	$^{0,3}A_{R\text{-}2}$ and $^{0,4}A_{R\text{-}2}$	GlcNAc	292, 262[1]
		GalGlcNAc	454, 424
		Gal-[Fuc]GlcNAc	600, 570
		$(Gal\text{-}GlcNAc)_2$	819, 789
		$(Gal\text{-}GlcNAc)_2Fuc$	965, 935
		Man_3	251, 221
		Man_4	413, 383
		Man_5	575, 545
Composition of 3-antenna	$^{0,4}A_{R\text{-}3}$ (E) ion	Gal-GlcNAc	466
		$GlcNAc_2$	507
		$Gal\text{-}GlcNAc_2$	669
		$(Gal\text{-}GlcNAc)_2$	831
		$(Gal\text{-}GlcNAc)_2\text{-}Fuc$	977
Presence of bisect	Abundant $[D\text{-}221]^-$ ion. Ion at $[M\text{-}221\text{-}18]^-$ Missing Ion D	GlcNAc	508
		Gal-GlcNAc	670
		$(Gal\text{-}GlcNAc)_2\text{-}Fuc$	816
		$(Gal\text{-}GlcNAc)_2$	1035
		$(Gal\text{-}GlcNAc)_2Fuc$	1181
		Man_3	629
		Man_4	791
		Man_5	953
Presence of sialic acid	B_1	Neu5Ac	290
		Neu5Gc	306
Presence of α2→ 6-linked sialic acid	$^{0,4}A_2\text{-}CO_2$	Neu5Ac	306
		Neu5Gc	322

1, These ions are normally of relatively low abundance. An abundant ion at the mass of the $^{0,4}A$ ion is more likely to be an F-type ion.

4. Notes

1. Several other matrices are available (see ***[ref. 7]***) that claim to produce advantages for certain types of carbohydrate.
2. The conditioned membranes can be stored in water for several months without noticeable loss of activity. Once used, they can be regenerated by repeating the nitric acid treatment.
3. Solutions containing organic solvents should be avoided.
4. The drops should remain at the same volume but often they increase slightly as water is drawn through the membrane. If the samples contains glycerol (found in some PNGase F preparations), considerable amounts of water can be drawn into the sample and the analysis usually fails. PNGase preparations containing glycerol should, consequently, be avoided.
5. The dried sample usually has long needle-shaped crystals projecting from the periphery of the spot towards the center. If the deposit is sticky, then either the sample is much too concentrated or it contains a high concentration of detergent or glycerol. Such deposits are unlikely to yield good spectra and the sample should be purified further.
6. Some investigators prefer to premix the matrix and sample solutions prior to application to the MALDI target. In the author's hands, this method does not appear to offer any particular advantages.
7. Only ~0.2 μL ethanol is necessary, and care must be taken to prevent spreading the sample over a larger area. This procedure is used to produce a more homogeneous target than can be achieved when water is present.
8. Sialylated glycans frequently give abundant peaks in positive ion mode due to loss of sialic acid when their spectra are recorded with reflectron-TOF instruments. Consequently, their spectra are often recorded in linear mode in order to minimize observed sialic acid loss. However, it must be borne in mind that this technique only removes PSD ions and not those fragment ions produced within the ion source. Minimizing the in-source delay is the best method for reducing the abundance of these ions. Also, it must be borne in mind that the resulting mass measurement may well be of average rather than a monoisotopic mass because of the lower resolution.
9. This effect is less pronounced with delayed-extraction instruments, but increased laser power can still lead to reduced resolution.
10. The laser spot should be moved to different areas of the target during acquisition, because not all areas of the target will yield a signal. It is frequently found with DHB that an active spot will only give a signal for a few laser shots due either to depletion of the sample/matrix mixture or vertical inhomogeneities within the crystal. Recent work ***(45)*** has suggested

that carbohydrates reside predominantly on the outside of the crystals, accounting for this phenomenon.

11. Usuaully 60–70 laser shots will be sufficient but more will be required for weak signals.
12. The mass spectrometer should be calibrated. Suitable calibration compounds are a mixture of dextran oligomers (e.g. dextran from *Leuconostoc ssp*. from Fluka,) for positive ion mode (*m/z* 203.05, 365.11, 527.16, 689.21, 851.26, 1013.32, 1175.37, 1337.42, 1499.48, 1661.53, 1823.58, 1985.63, 2147.69, 2309.74, 2471.79, 2633.85, 2795.90, 2957.95, 3120.00, 3282.06, 3444.11, 3606.16, 3768.22, 3930.27, 4092.32; and the same compounds derivatized with 2-aminobenzoic acid for calibrating negative ion spectra (*m/z* 300.11, 462.16, 624.21, 786.27, 948.32, 1110.37, 1272.43, 1434.48, 1596.53, 1758.58, 1920.64, 2082.69, 2244.74, 2406.80, 2568.85, 2730.90, 2892.95, 3055.01, 3217.06, 3379.11, 3541.17, 3703.22, 3865.27, 4027.32).
13. Formation of methyl esters allows all compounds to be examined as neutral molecules in positive ion mode. Without methylation, as well as laser-induced decomposition of sialylated glycans, these compounds will form both positive and negative ions, thus splitting the signal and the sialic acids will give additional ions by formation of sodium and potassium salts.
14. Although negative ion spectra are usually associated with the formation of $[M\text{-}H]^-$ ions, these tend to be unstable and fragment in the mass spectrometer ion source. Addition of an inorganic salt such as ammonium chloride, nitrate or phosphate produces $[M+anion]^-$ ions that are much more stable and do not fragment until they reach the collision cell of the mass spectrometer. Phosphate is used because it has been found that phosphate adducts are the major species observed from glycans released from gel-separated samples. Fragmentation of adducts with different anions is virtually identical because the first loss is that of the adduct together with a proton to give what is effectively the $[M\text{-}H]^-$ ion. Larger anions such as bromide and iodide should be avoided because these produce very few fragment ions.
15. The tip should be long enough to reach to the end of the capillary.
16. MS/MS spectra of major components can be obtained in a few seconds but those of weaker components can be accumulated for many minutes in order to achieve a satisfactory signal:noise ratio. The spray should last on average from 1–3 hours.
17. It is assumed that the mass spectrometer has been set up and is operated according to the manufacturer's instructions. Suitable calibration compounds for negative ion work are the 2-AA-derivatized glycans listed above or underivatized glycans released from bovine fetuin.

Acknowledgments

The author thanks the Biotechnology and Biological Sciences Research Council and the Wellcome Trust for equipment grants to purchase the two mass spectrometers used in this work and further funding from the Oxford Glycobiology endowment.

MS Analysis of Protein Glycosylation

Nobuaki Takemori, Naoka Komori, and Hiroyuki Matsumoto

1. Introduction

Post-translational modifications (PTM) are important molecular events because they generate functional diversities of proteins. A large number of proteins undergo multiple PTM *in vivo* and over 300 types of PTM have been identified to date ***(1)***. Among various PTM, phosphorylation and glycosylation have been intensely studied because of their physiological significance. Phosphorylation plays key regulatory roles in cellular signaling processes ***(2)***, and glycosylation mediates crucial cellular mechanisms such as protein folding and trafficking ***(3, 4)***. To confirm the presence of these modifications *in vivo*, the conventional analytical procedures require large quantities of samples and laborious biochemical steps. For this reason, small-scale analysis of PTM remains among the most challenging areas of biological science.

This chapter describes our recent proteomic methodology using the combination of two-dimensional gel electrophoresis (2-DGE) and MALDI quadrupole ion trap time-of-flight mass spectrometer (MALDI-QIT-TOF MS), which enables a highly sensitive analysis of post-translational modifications (PTM). Two-DGE has been used extensively as a powerful tool to separate proteins from a limited amount of biological samples ***(5–8)***. We stained gels with Pro-Q™ Emerald/Diamond dyes immediately after 2-DGE and prior to CBB staining, and because this allows us to perform direct detection of glycoproteins/phosphoproteins on the same 2-D gels ***(9,10)***. Gel-separated glycoproteins are further subjected to the structural analysis using MALDI-QIT-TOF MS. MALDI-QIT-TOF MS is capable of structural characterization of various PTMs through highly sensitive fragmentation, or MS/MS, analysis ***(11,12)***. In MALDI-QIT-TOF MS, two mass analyzers (i.e., QIT and TOF) are connected to MALDI ion source, and the combination of MALDI and QIT renders a unique opportunity to perform multistage fragmentation (MS^n) analysis with high-energy collision-induced

dissociation (CID) ***(11,13)***. In this chapter, we will describe proteomic techniques that we use to analyze *N*-linked glycosylation. However, the protocol can be applied to other PTM analyses with some modifications.

2. Materials

1. MALDI-QIT-TOF MS (AXIMA QIT; Shimadzu Biotech, Manchester, UK)
2. MALDI-TOF MS
3. MALDI stainless sample target
4. Acetonitrile (HPLC grade)
5. Ammonium bicarbonate
6. Trifluoroacetic acid (TFA)
7. Milli-Q water (Millipore, Bedford, MA, USA)
8. Sequencing-grade trypsin (Promega Madison, WI, USA).
9. Stock solutions for in-gel digestion:
   a. 50% (v/v) acetonitrile/100 mM ammonium bicarbonate (pH 8.9)
   b. 50% (v/v) acetonitrile/5% (v/v) TFA
   c. 0.2% (v/v) TFA solution
   d. 10 mM ammonium bicarbonate (pH 8.9)
10. Recrystalized 2,5 dihydroxybenzoic acid (DHB)
11. DHB solution for MS analysis: 2% (w/v) DHB in 50% (v/v) acetonitrile/0.1% (v/v) TFA (*see* **Note 1**)

3. Methods

Figure 1 shows a schematic diagram of our glycoprotein analysis. Protein samples are first separated using 2-DGE, and glycoprotein spots are detected using a glycoprotein staining reagent **(Subheading 3.1)**. Glycoprotein spots are in-gel digested with trypsin **(Subheading 3.2)** (*see* **Note 2**), and identified by peptide mass fingerprinting analysis **(Subheading 3.3)**. In order to characterize their glycan structures and modification sites, tryptic glycopeptides are further subjected to fragmentation analysis in MALDI-QIT-TOF MS **(Subheading 3.4)**. Because human keratin contamination interferes with MS analysis, it is recommended that powder-free latex gloves be worn throughout the procedure.

3.1. Gel Electrophoresis and Glycoprotein Staining

1. Perform 2-DGE to resolve glycoproteins. We perform isoelectric focusing for the 1st dimension and SDS-PAGE for the 2nd dimension (*see* **Note 3**). Instead of 2-DGE, one-dimensional gel electrophoresis (e.g., SDS-PAGE) can be used for this protocol. However, the resolution of proteins on a one-dimensional gel is generally inadequate for the separation of complex protein mixtures.
2. Following 2-DGE, gels are stained with a glycoprotein staining reagent for detection of glycoproteins (*see* **Note 4**) or followed by Coomassie Brilliant Blue (CBB) for visualization of all protein spots (see example in **Fig. 2**).

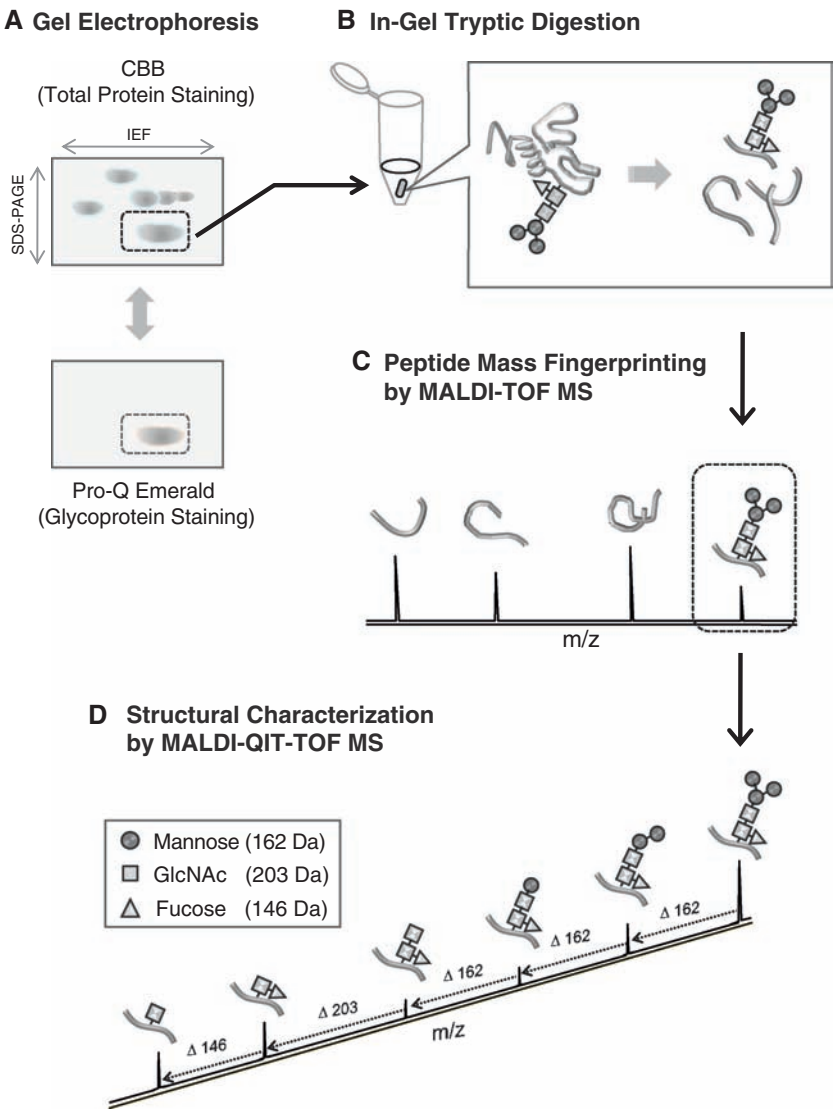

Fig. 1. A schematic drawing of glycoprotein analysis using 2-DGE and MALDI-QIT-TOF MS. **(A)** Proteins are separated by 2-DGE based on their isoelectric focusing points and molecular weights in the first and second dimension, respectively. A glycosylated protein spots are detected by staining with Pro-Q Emerald dye. **(B)** After in-gel digestion of the glycoprotein spot with trypsin, the tryptic peptides are subjected to peptide mass fingerprinting analysis. **(C)** Peptide mass fingerprinting analysis provides the mass profiles and sequence information of the tryptic peptides. **(D)** A glycopeptide thus detected is further fragmented by MALDI-QIT-TOF MS. Using the information from fragment ions, the structure of a glycan moiety can be deduced.

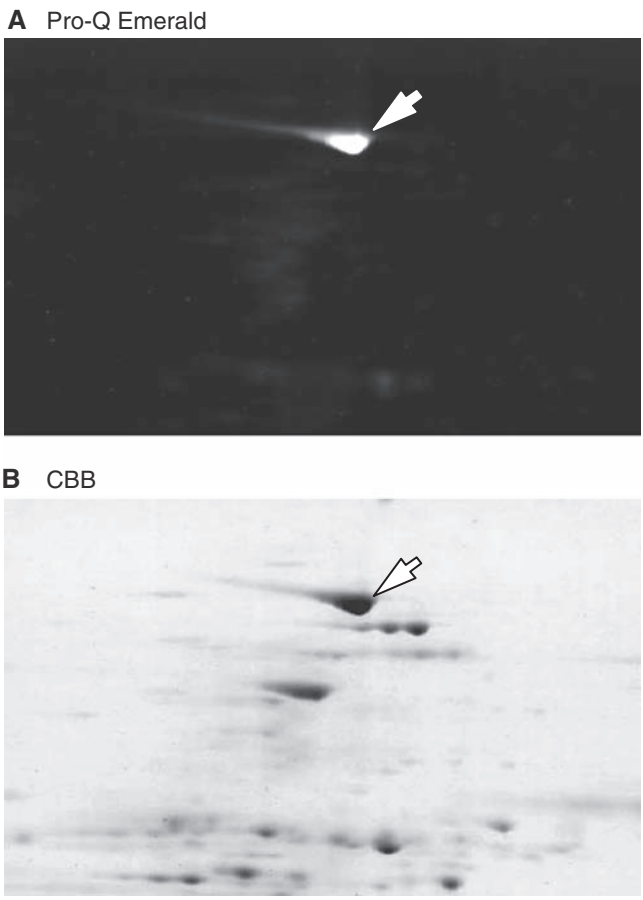

Fig. 2. Differential staining of *Drosophila* proteins with a fluorescent glycosylation sensor dye, Pro-Q™ Emerald **(A)** and Coomassie blue **(B)**. *Drosophila* eye proteins were separated on 2-D gel. Glycosylated protein spot *(arrow)* was identified by staining with Pro-Q Emerald dye. Our peptide mass fingerprinting analysis identified the spot as chaoptin.

3.2. In-Gel Tryptic Digestion

1. After detection of protein spots positive for glycoprotein staining, corresponding protein spots stained with CBB are excised by a razor blade and transferred into a 1.5 ml polypropylen tube. Excised gel pieces are shaken in 1 ml of 50% (v/v) acetonitrile/100 mM ammonium bicarbonate (pH 8.9) at room temperature to remove CBB.
2. Distained gel pieces are incubated with 1 ml of acetonitrile for 30 min to dehydrate the gels. After removing acetonitrile, the gel pieces are rehydrated with 2 µl of trypsin solution for 30 min at 4°C. Add 50 µl of 10 mM ammonium bicarbonate (pH 8.9) and incubate at 37°C for 5–10 hrs. During the incubation, trypsin continues

to digest a protein in a gel piece and while some of the tryptic peptides come out of the gel piece.

3. Transfer the solution containing tryptic digests into a new 0.65 ml polypropylen tube. To extract the rest of the tryptic digests from the gel, vigorously shake the gel in 50 µl of 50% (v/v) acetonitrile/5% (v/v) TFA for 20 min. After a brief centrifuge, collect and transfer the supernatant into the new tube to mix with the original digest solution.
4. Concentrate the collected peptide solution down to near dryness using vacuum centrifuge (*see* **Note 5**).

3.3. Peptide Mass Fingerprinting Analysis using MALDI-TOF MS

1. Each peptide sample is reconstructed with 5 µl of 0.2% (v/v) TFA solution. Load the peptide solution (0.5 µl) onto a MALDI-TOF sample target plate with a fresh DHB solution (0.5 µl) and dry the mixture completely at room temperature.
2. Peptide samples on the MALDI sample target are subjected to peptide mass fingerprinting analysis using MALDI-TOF MS. After measuring the masses of the tryptic peptides by MALDI-TOF MS, the observed masses are submitted to MASCOT PMF search program (Matrix Science, London, UK) at http://matrixscience.com.
3. We routinely perform MASCOT search against the latest version of the National Center for Biotechnology Information (NCBI) nonredundant database using the following parameters; (a) unlimited protein molecular weight and pI ranges, (b) presence of protein modifications including acrylamide modification of cysteine, methionine oxidation, protein N-terminus acetylation, and pyroglutamic acid, and (c) mass tolerance of ± 0.25 Da. We consider the confirmation to be positive when a significant MOWSE score ($p < 0.05$) is generated.
4. After the protein identification by peptide mass fingerprinting analysis, the masses of the observed peptides are compared to that of the theoretical tryptic peptides. The peptides which contain glycans will be detected as the unassigned ion peaks because glycosylation leads to a predictable increase in the mass of a modified amino acid residue. When unassigned ion peaks are detected in MS spectrum, the masses of the unassigned peaks are subjected to ExPASy-GlycoMod Tool (http://au.expasy.org/tools/glycomod) to predict possible glycan structures and modification sites. To calculate the theoretical fragment ions resulting from CID fragmentation of the predicted peptide, we use MS-Product program (http://prospector.ucsf.edu/).

3.4. Structural Characterization of Protein Glycosylation Using MALDI-QIT-TOF MS

1. Load peptide solution (0.5 µl) onto a MALDI-QIT-TOF sample target with a fresh DHB solution (0.5 µl) and dry the mixture completely at room temperature. Each peptide sample is subjected to MALDI-QIT-TOF MS analysis.
2. In general, an ionized glycopeptide is fragmented without CID in MALDI-QIT-TOF MS, and as a result, a precursor glycopeptide together with some of its fragment ions will be detected in MS mode. Sugar components are readily

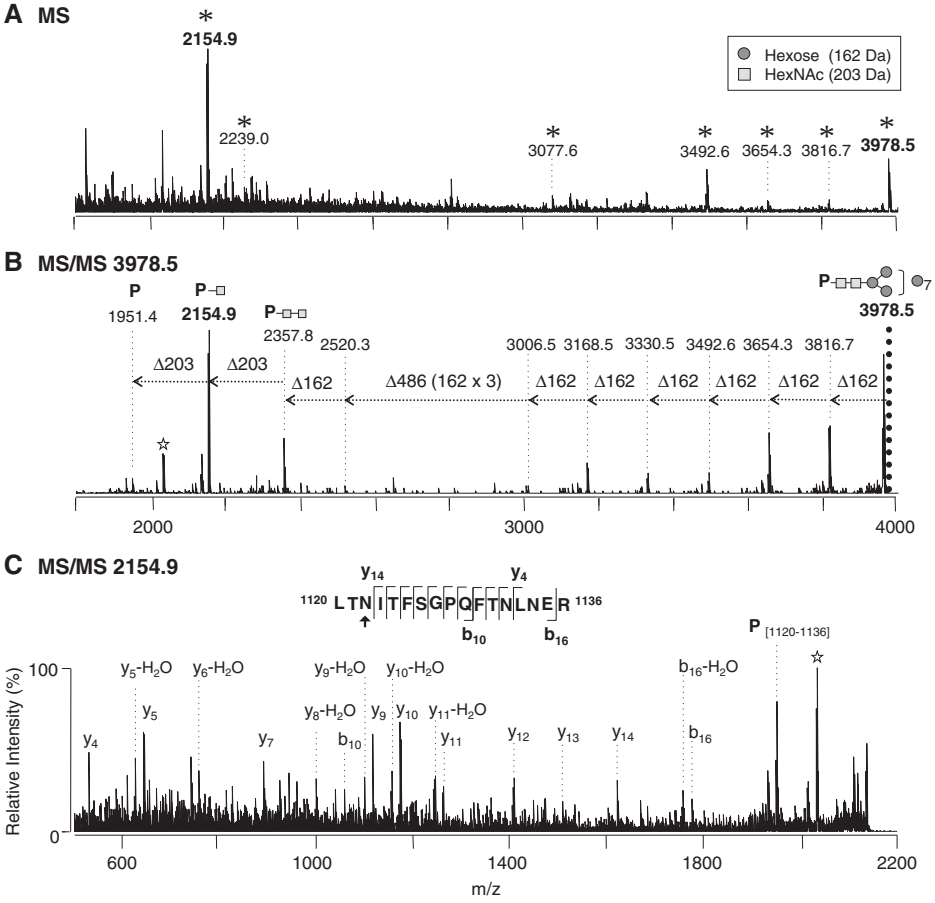

Fig. 3. Structural characterization of chaoptin glycopeptide using MALDI-QIT-TOF MS. The tryptic peptides of chaoptin (*Drosophila* glycoprotein) separated on 2-D gel (**Fig. 2**) were subjected to a series of CID fragmentation to deduce the glycan sequence and glycosylation site. **(A)** MS spectrum of the tryptic digests. *, peptide ions not assigned as tryptic peptides of chaoptin. **(B)** MS/MS spectrum of an unassigned ion peak at m/z 3978.5 observed in MS mode. CID fragmentation resulted in a series of fragment ions separated by 162, 203, or 486 (162 × 3) Da. **(C)** MS/MS spectrum of a fragment ion at m/z 2154.9. The y ion and b ion series derived from the peptide corresponded to the amino acid residues 1120 to 1136 of chaoptin. ↑, a putative *N*-linked glycosylation site. ⊠, a peptide ion with a cross-ring cleavage of HexNAc residue. ⊠ in dark gray, hexose residue; ⊠ in light gray, *N*-acetylhexosamine (HexNAc) residue. (With permission from ***ref. 11***)

distinguishable from amino acid residues and other post-translationally modified residues based on their masses. As a result, we can easily distinguish glycopeptides from other nonglycopeptides.

3. To determine the actual glycan structure, an ionized glycopeptide is further subjected to fragmentation analysis in MS/MS mode. As compared with peptide-bonds, glycosidic bonds are susceptible to CID fragmentation resulting in a sequential loss of sugar components from the terminal end of a glycan moiety (see example in **Fig. 3**).
4. Because some peptide-bonds seldom undergo total dissociation in a single run of MS/MS analysis, further fragmentation analysis by MS^n analysis may be required to determine the amino acid sequence and modification site(s).

4. Notes

1. Prepare fresh DHB solution just before use.
2. Some glycoproteins are not susceptible to tryptic cleavage due to the sterical hindrance of their glycans. Digestion with other proteases may improve the recovery of glycopeptides.
3. In our laboratory, isoelectric focusing gel electrophoresis is carried out using IPGphor (GE Healthcare/Amersham, Buckinghamshire, UK) with a cup loading strip holder. Immobiline Dry Strip (pH 3–10, 13 cm in length) is rehydrated for 15 hr at room temperature with 250 µl of lysis solution (8.5 M urea, 2% (w/v) CHAPS, 0.2% (w/v) Bio-Lyte 3/10 (BIO-RAD, Hercules, CA, USA), and 5% (v/v) β-mercaptoethanol). The same lysis solution (100 µl) is used for sample homogenization. After centrifugation at 15,000 × *g* for 10 min, the supernatant is loaded into a sample cup. Electrophoresis is performed at 500 V for 3 min, 4,000 V for 2 hr, and 8,000 V up to a total of 22,000 Vhr.
4. Several glycoprotein staining reagents are commercially available. We use Pro-Q™ Emerald glycoprotein gel stain (Molecular Probes, Eugene, OR, USA) because of its high sensitivity. Regarding the details of the Pro-Q staining, refer to manufacture's instructions.
5. Peptide samples can be stored at −20°C at least for several months.

Mapping protein N-Glycosylation by COFRADIC

Bart Ghesquière, Joël Vandekerckhove, and Kris Gevaert

1. Introduction

The majority of proteins require co- and posttranslational modifications to become functional entities. Such modifications fulfill a plethora of tasks (e.g., modulation of enzyme activity and directing proteins to cellular compartments).

One of these protein modifications that, amongst many others, plays an essential role in determining a protein's structure and functionality is N-glycosylation, which is the enzymatic attachment of a glycan to an asparagine in the consensus motif NXS/T/C ***(1,2)***. Next to asparagines, glycosylation can also occur on serine and threonine (O-glycosylation) ***(3–6)*** and tryptophan (C-glycosylation) ***(7)***. Protein N-glycosylation has intrinsic as well as extrinsic functions. Intrinsic functions brought about by this modification are the creation of structural modules and changes of the solubility, antigenicity and stability of the affected protein. Examples of extrinsic functions are the routing of proteins to a specific subcellular localization, and the guiding and modulation of cell adhesion and intracellular communication.

Congenital Disorders of Glycosylation (CDG) are a group of diseases caused by glycan synthesis errors ***(8)***. Several CDG subtypes are distinguished based on the malfunctioning of a specific enzyme in the protein-N-glycosylation pathway. Other states such as the malignant transformation of cells to cancerous cells portray altered glycan chains on glycoproteins ***(9–14)***. Both examples show the importance of protein glycosylation in the normal physiology and pathophysiology of organisms and illustrate the value of monitoring protein N-glycosylation sites on a proteomic scale.

Several methods for studying protein N-glycosylation have been described. Lectin based methods rely on the affinity of lectins for subsets of glycans to isolate glycosylated proteins or peptides ***(15,16)***. However, to identify the broadest possible range of N-glycosylated molecules, different lectins must be combined,

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

either in parallel or serial, to a multilectin affinity column ***(14,17–20)***. Hydrazide based techniques chemically enrich N-glycosylated peptides and are not biased towards any specific glycan structure ***(21–23)***. Although the hydrazide technology offers a straightforward analysis of N-glycosylation sites, all information about the actual nature of the N-glycan is lost.

We recently developed a gel-free technique for analyzing protein-N-glycosylation ***(24)*** based upon combined fractional diagonal chromatography (COFRADIC ***25***) and we here describe a detailed protocol for isolating N-glycosylated peptides for MS/MS analysis. Briefly, proteins in a complex sample such as serum are digested with trypsin. These peptides are separated a first time on a RP-HPLC column (*primary COFRADIC run*) and time-based collected into several primary fractions. Sufficiently spaced primary fractions are combined, treated with PNGase F and reseparated by the same RP-HPLC setup (*secondary COFRADIC runs*). PNGase F cleaves N-glycans from asparagines and hereby converts these to aspartic acid, thus creating a marker (1 Da difference) that can be used to interpret results of database searches using MS/MS-spectra. Deglycosylated peptides display different retention on the reverse-phase column during the secondary HPLC separations and thus shift away from nonglycosylated peptides. These shifts finally lead to the specific collection of formerly in vivo N-glycosylated peptides which may then be analyzed by MS techniques.

2. Materials

2.1. Protein Preparation

1. Tris(2-carboxyethyl)phosphine (TCEP, Pierce, Rockford, IL).
2. Iodoacetamide (IA).
3. Hydrogen peroxide:(30% (w/w) in water.
4. Disposable desalting columns packed with Sephadex™ G-25 (GE Healthcare Bio-Sciences, Uppsala, Sweden).
5. Sequencing grade modified trypsin (Promega, Madison, WI, USA).

2.2. COFRADIC Protocol for the Isolation of N-Glycopeptides

1. Analytical RP-HPLC column: 2.1 mm internal diameter (I.D.) × 150 mm (length) 300SB-C18 column, Zorbax® (Agilent, Waldbronn, Germany).
2. HPLC grade water and acetonitrile.
3. PNGase F from *Elizabethkingia (Chrysobacterium/Flavobacterium) meningosepticum* (Sigma-Aldrich).
4. Acetic acid glacial, analytical reagent grade.

3. Methods

The methods described below use a serum proteome for characterization of N-glycosylation sites. It should be clear that any proteome or peptidome in which N-glycosylated asparagines are present can be sampled by these methods.

3.1. Preparation of Serum Proteins Prior to COFRADIC

1. 1 mL of mouse serum proteins (*see* **Note 1**) deprived of its three most abundant proteins is desalted on a NAP-10 column and eluted in 1.5 mL of 2 M guanidinium hydrochloride in 50 m*M* Tris-HCl pH 8.6.
2. Reduce the sample volume to 1 mL by vacuum drying.
3. Add freshly prepared TCEP.HCl and iodoacetamide solutions to 10 and 20 m*M* final concentrations respectively. Let the reduction and alkylation of cysteines proceed in the dark for 1 h at 37°C (*see* **Note 2**).
4. Desalt the mixture of modified proteins in 1.5 mL of freshly prepared 20 m*M* NH_4HCO_3 (pH 7.6) using a NAP-10 column.
5. Heat the protein mixture for 10 min at 95°C followed by cooling for 10 min on ice.
6. Add sequence grade modified trypsin (the enzyme/substrate ratio should be 1/50 to 1/100 (w/w)) and incubate overnight at 37°C.
7. Reduce the volume to 500 µL by vacuum drying.

3.2. COFRADIC Sorting of N-Glycosylated Peptides

1. Acidify 98 µL of the peptide mixture with 2 µL of a 50% (w/v) acetic acid solution (f.c. of 1%).
2. Add 2 µL of a 30% (w/v) hydrogen peroxide solution (f.c. of about 0.6% of H_2O_2) to oxidize methionines to sulfoxides. The peptides are incubated for 30 min at 30°C (*see* **Note 3**).
3. Load the sample immediately on the reverse-phase column (*see* **3.3**) for the primary COFRADIC separation and collect peptides in 56 consecutive fractions of 1 min each starting 25 min after sample injection (*see* **Note 4**).
4. Pool primary fractions that are spaced by 14 min and dry them under vacuum.
5. Redissolve the dried peptides in 97 µL of 50 mM NH_4HCO_3 (pH 7.6) and add 1 µL of a 0.5 U/µL stock solution of PNGase F. This mixture is incubated for 3 hours at 37°C to fully deglycosylate the N-glycosylated peptides.
6. Add 2 µL of a 50% (w/v) acetic acid solution and reseparate each PNGase F treated pool of primary fractions on the same RP-HPLC column under the same conditions. Per primary fraction, deglycosylated peptides are collected in two intervals: one 11 to 3 min prior to and one 2 to 10 min following the original collection interval. Thus, per secondary run, 5 such secondary intervals are collected, each consisting of 4 secondary fractions of 2 min (or 160 µL) (**Fig. 1** and **Table 1**).
7. Such isolated secondary fractions are dried and stored at −20°C until further MS/MS-analysis (*see* **Note 5**).

3.3. Reverse Phase HPLC Separation in COFRADIC

The solvent gradient described below is applied both for the primary and the secondary runs. We found it important to use a HPLC solvent system buffering around a pH of about 5. In contrast to lower pH values, at pH 5 the extent of the chromatographic shift of deglycosylated versus glycosylated peptides is primarily based on the removal or gain of charges. Due to the nature of the glycans, both hydrophilic and hydrophobic shifts can be expected. When the

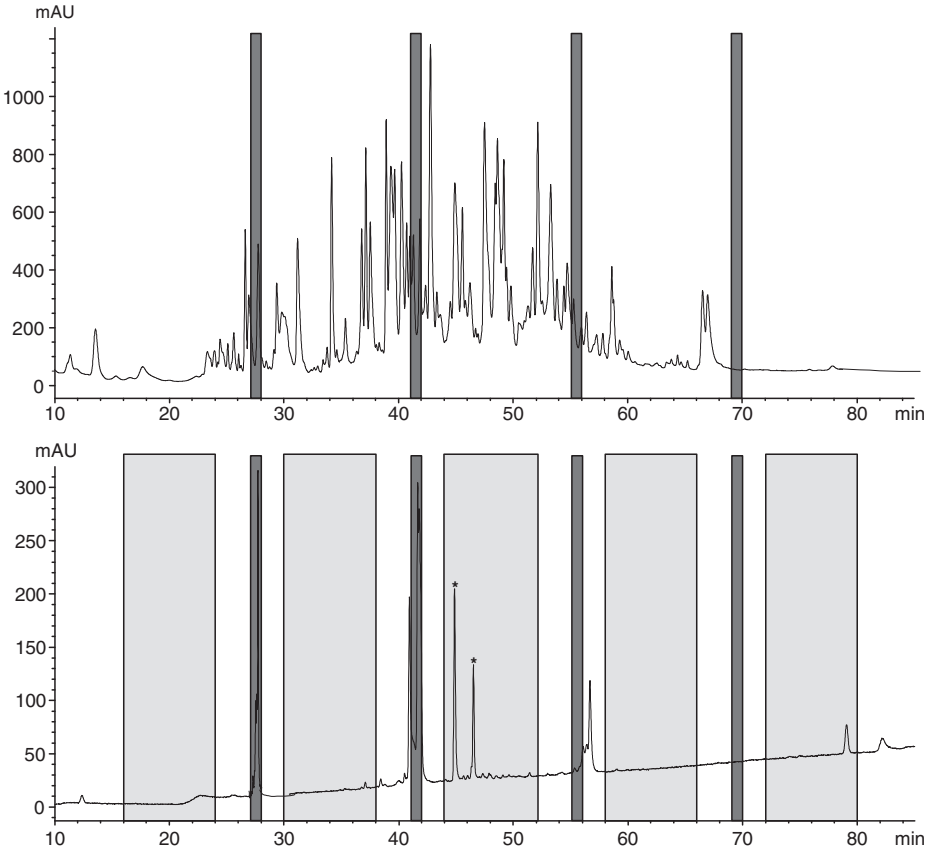

Fig. 1. Example of a primary and a secondary COFRADIC RP-HPLC run for isolating N-glycopeptides. The upper panel shows the primary RP-HPLC separation (UV absorbance at 214 nm) of a tryptic digest of human alpha-1-acid-glycoprotein and bovine fetuin; primary fractions were collected between 25 and 81 min and pooled as described in **Subheading 3.2**. Such collected peptides were then treated with PNGase F to remove N-linked glycan chains. The lower panel shows the secondary RP-HPLC separation of the PNGase F treated primary fractions that eluted between 27–28, 41–42, 55–56 and 69–70 min (indicated in dark grey boxes). The secondary collection intervals containing the shifted, deglycosylated peptides (indicated in light grey boxes) were collected 11 to 3 min prior to and 2 to 10 min following each primary fraction. There is a clear shift of peptides (indicated with an asterisk) that elute in the secondary collection interval between the primary fractions collected at 41–42 and 55–56 min. Further MS and MS/MS analyses identified tryptic peptides carrying known N-glycosylation sites of bovine fetuin (N99 and N176) and human alpha1-acid glycoprotein (N93).

Table 1
Fraction Pooling Scheme for COFRADIC Isolation of N-Glycosylated Peptides

One example of the pooling of secondary fractions is given (*see* Figure 1) in which it is made clear that peptides undergoing a hydrophobic shift following PNGase F treatment of fraction X overlap with fractions undergoing a hydrophilic shift from fraction X + 14 following the same treatment.

POOLING SCHEME OF PRIMARY FRACTIONS

POOLING SCHEME OF SECONDARY FRACTIONS FROM PRIMARY POOL C (*cfr. Figure 1*)				
	fraction 3	fraction 17	fraction 31	fraction 45
C	16–24 min	30–38 min	44–52 min	58–66 min	72–80 min

glycan is not charged, the evoked shift will be hydrophilic by the deamidation of the asparagine to aspartic acid (gain of negative charge). If the glycan was charged (e.g., sialic acid, phosphate …) the glycopeptide looses charged residues and undergoes a hydrophobic shift. Lowering the pH of the solvent system (e.g., using TFA instead of ammonium acetate) will have minor effect on acidic residues (these will mainly be neutral) and was found to lead to insufficient chromatographic shifts and inefficient collection of deglycosylated peptides.

1. Prepare HPLC solvent A (10 m*M* ammonium acetate (*see* **Note 6**) (pH 5.5) in water/acetonitrile, 98/2 (v/v)) and HPLC solvent B (10 mM ammonium acetate (pH 5.5) in water/acetonitrile, 30/70 (v/v)).
2. The following RP-HPLC solvent gradient is applied:
   a. Following injection of the sample onto the column, apply a 10 min isocratic separation with 100% of solvent A at a constant flow rate of 80 µl/min.
   b. Apply a linear gradient to 100 % over 100 min (i.e. an increase of 1 % solvent B per minute).

c. Apply a 10 min isocratic wash with 100% of solvent B, followed by a linear gradient over 5 min to 0% of solvent B (100% of solvent A).
d. Reequilibrate the column for another 20 min with 100% of solvent A before injection of another sample.

4. Notes

1. For the studies mentioned above, we were specifically interested in identifying low-abundant N-glycosylated serum proteins. Therefore, we performed MARS (multiple affinity removal system) depletion of abundant serum proteins (albumin, transferrin and IgG's) to increase the possibility of identifying low-abundant glycoproteins (26). MARS depletion (Agilent, Waldbronn, Germany, #5188–5218) was applied to 90 µL serum from a male C57 black strain mouse according to the manufacturer's protocol and yielded a protein mixture with a concentration of about 1 mg/mL. We then typically load a peptide amount equivalent to about 200 µg of protein material on the RP-column for the primary COFRADIC run.
2. Blocking cysteine residues by iodoacetamide avoids the formation of disulfide bridges between different cysteinyl peptides further on in the experiment. For the alkylation of cysteines we use an estimated 750-fold molar excess of TCEP and a 1500-fold molar excess of IA over the proteins (an average molecular weight of 60,000 g/mol for proteins is considered here). Addition of TCEP-HCl can change the pH of the protein solution and it is therefore necessary to check the pH and correct it by adding the appropriate volumes of a 1 M stock solution of NaOH. It is crucial to keep the pH at around 8 since a more acidic pH may result in an incomplete alkylation.
3. Oxidation of methionines by hydrogen peroxide prior to the primary COFRADIC run prevents unwanted shifts of methionine peptides during the secondary runs. Spontaneous oxidation of methiones between the two runs will cause a hydrophilic shift of nonglycosylated methionyl peptides ***(25)*** that will finally get sampled by the mass spectrometers. Methionine oxidation should be carried out strictly as described in **Subheading 3.2.2** since prolonged incubation lead to nonquantitative formation of methionine-sulphon, oxidation of tryptophan and cysteine.
4. Most of the peptides separated using the described RP-HPLC gradient and solvents will elute between 25 min and 81 min. Intuitively, depending on the peptide elution profile during the primary run, the collection scheme should be adapted.
5. Following COFRADIC, N-glycosylated peptides are characterized by deamidation of deglycosylated asparagines in NXS/T motif. However, spontaneous deamidation between the primary and secondary runs (especially at Asn-Gly and Asn-Ser sites ***(27)***) also leads to hydrophilic shifts of non-glycosylated peptides into the secondary collection intervals.

However, such peptides will be identified with a deamidated asparagine that resides outside the NXS/T motif and should be filtered out of the final list of identifications.

6. For the ammonium acetate buffer system we use a 500 mM ammonium acetate stock solution that is prepared as follows: for 2 L of this stock solution we titrate 57.19 mL of acetic acid with NH_4OH to a pH of 5.5 (about 60 mL of NH_4OH should be added).

Mass Spectrometric Analysis of *O*-Linked Glycans Released Directly from Glycoproteins in Gels Using β-Elimination

Adrian M. Taylor and Jane Thomas-Oates

1. Introduction

Extensive posttranslational modification of proteins through the glycosidic attachment of carbohydrate moieties to the backbone of polypeptides makes glycosylation an important area of study. The function of these glycan chains may be to affect the conformation and stability of a protein ***(1)***, or to perform essential roles in cell surface or intracellular recognition and cell adhesion and therefore play important roles in mediating biological activity ***(2)***.

Analysis of glycoproteins is made difficult by the sheer structural diversity of glycans attached to proteins, and because each glycosylated polypeptide is generally associated with a population of different glycan structures frequently attached at more than one site, possibly via more than one different type of chemical linkage. Consequently, detailed structural analysis of one or more glycans is impractical while the glycans are still attached to the polypeptide; release of the glycan is therefore required. Traditional methods used for glycan release employ both chemical and enzymatic approaches. The most commonly used chemical methods for the release of *O*-linked glycans are based on β-elimination in solution. Once the glycans have been released from the protein, methods for the analysis of glycoprotein glycans generally require a combination of techniques that include mass spectrometry, nuclear magnetic resonance (NMR) spectroscopy, monosaccharide compositional analysis and linkage analysis.

Protein characterisation has been revolutionised by proteomics approaches, in which mixtures of proteins and glycoproteins are routinely separated using SDS-PAGE. The need to identify not only the polypeptide but also its posttranslational

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

modifications has driven a whole range of method developments aimed at identifying posttranslational modifications on proteins that have been separated by gel electrophoresis.

We, and others, have described blotting glycoproteins from gels onto polyvinylidene fluoride (PVDF) membranes prior to either PNGase F release of *N*-linked glycans ***(3,4)*** or reductive β-eliminative release of *O*-linked glycans ***(5,6)***, and one paper has described the success of directly performing in-gel protein de-*N*-glycosylation using PNGase F ***(7)***. Kilz and coworkers have described an analogous in-gel HF-pyridine de-*O*-glycosylation ***(8)***. However, such reagents are toxic, so that alternative in-gel protein de-*O*-glycosylation methods were sought. One such procedure, a modification of the nonreductive base-catalysed β-elimination method developed by Rademaker *et al.* ***(9)***, has been used for in-gel de-*O*-glycosylation/ethylaminylation ***(10)***, but was employed for glycoprotein identification and localisation of *O*-glycosylation sites; no attempt was made to recover the released glycans for further analysis.

In this chapter we detail a method ***(11)*** for reductive β-eliminative release of the intact *O*-linked glycans from SDS-PAGE separated glycoproteins, and their mass spectrometric analysis. The method leaves the deglycosylated polypeptide in the gel for identification using established proteomic approaches, based on in-gel tryptic digestion and mass spectrometric analysis of the released peptides.

2. Materials

2.1. SDS-Polyacrylamide Gel Electrophoresis (SDS-PAGE)

1. Resolving buffer: 0.5 M Tris-HCl, pH 6.8, 0.1% SDS. Store at room temperature.
2. Stacking buffer: 0.5 M Tris ((hydroxymethyl) methylamine)-HCl, pH 6.8, 0.1% SDS. Store at room temperature.
3. 30% degassed acrylamide/Bis (N,N-bis-methylene-acrylamide) (30% T, 2.67% C), where for acrylamide gels:

   %T = {g (acrylamide + bisacrylamide)/100 mL} 100
   %C = {g (bisacrylamide)/g (acrylamide + bisacrylamide)} 100

This acrylamide solution is a neurotoxin when unpolymerised and precautions should be taken to limit direct exposure.

4. TEMED (N,N,N,N-tetra-methyl-ethylenediamine), best stored at room temperature in a desiccator.
5. Ammonium persulfate: Prepare 10% solutions in water and immediately freeze in aliquots appropriate for single use at −20°C.
6. Sample Buffer: DDI H_2O (3.55 mL), 0.5 M Tris-HCl, pH 6.8 (1.25 mL), glycerol (2.5 mL), 10% w/v SDS (2.0 mL), 0.5% (w/v) bromophenol blue (0.2 mL):

Total volume 9.5 ml. Add 50 µL β-mercaptoethanol to 950 µL sample buffer prior to its use.

7. 10x Electrode (Running) Buffer, pH 8.3 (1 L) Stock Solution: Tris base (30.3 g), glycine (144.0 g), SDS (10 g). Prior to use in electrophoresis, a 1:10 dilution of this stock solution is performed.
8. Standard Marker: BioRad SDS-PAGE standard control 91621 is used as a low M.W. range marker. Contains the following:

Standard	*M.W.* /Da
Phosphorylase	97, 000
Serum albumin	66, 200
*Ovalbumin	45, 000
*Carbonic anhydrase	31, 000
Trypsin inhibitor	21, 000
*Lysozyme	14, 400

* glycosylated – gives positive result on Con A-Blot

2.2. Protein Staining/Destaining

1. Bio-Safe G250 Coomassie Brilliant Blue stain (Bio-Rad, USA).
2. Rapid Silver Stain based on the Amersham Biosciences Plus One Silver Stain Kit.
3. 1:1 (v/v) solution of 30 mM potassium ferricyanide and 100 mM sodium thiosulfate.

2.3. Lectin Blotting

1. 10x Transfer buffer stock solution: 1.32 M glycine (144.1 g/L), 250 mM Tris (30.3 g/L). The stock solution is diluted 1:10 prior to use with 0.5:3.5:1 ratio, stock solution:DDI H_2O:methanol.
2. Concanavalin A Lectin Blot: Concanavalin A is stored at −20°C (1 mg/mL).
3. Tris-buffered saline with Tween (TBST) buffer: 20 mM Tris (2.4 g/L), 150 mM NaCl (8.7 g/L), adjust to pH 7.5 with 25% HCl, 0.1 mM $MnCl_2$ (12.6 mg/L), 0.1 mM $CaCl_2$ (11.1 mg/L), 0.1% Tween 20 (1 mL/L).
4. Developing solution: 7 mL 4-chloro-1-naphthol (3 mg/mL in methanol, prepare freshly), 39 mL DDI H_2O, 2 mL 0.2 M Tris-HCl, pH 7.5, 20 µL 30% H_2O_2 (add directly before use).

2.4. In-Gel Reductive β-Elimination

1. β-elimination reagent: a freshly made aqueous solution of 0.1 M $NaBH_4$ in 0.3 M NaOH.
2. Glacial acetic acid.
3. Heating block.
4. Vacuum centrifuge.

2.5. In-Gel Nonreductive β-Elimination in Aqueous Ammonia

1. β-elimination reagent: 25% aqueous ammonium hydroxide solution.
2. Heating block.
3. Vacuum centrifuge.

2.6. Acid-Catalyzed Acetylation

1. Round-bottomed glass tubes (11 × 100 mm) with Teflon™-lined screw top.
2. Acetylation reagent: a freshly made mixture of trifluoroacetic acid anhydride (2 vols), glacial acetic acid (1 vol) mixed in a round glass bottomed tube, capped and allowed to cool to room temperature.
3. Vacuum centrifuge.
4. Dichloromethane.

2.7. De-O-Acetylation

1. 1:1 (v:v) conc. NH_4OH/methanol.
2. Heating block.

2.8. Per-O-Methylation

1. 99.9 % A.C.S. dimethyl sulfoxide.
2. NaOH pellets.
3. Pestle and mortar.
4. Iodomethane – as a methylating reagent, this has potential to be a carcinogen, and so should be used with caution; protective clothing should be worn and, since it is volatile, it should be used in a fume cupboard.
5. Freshly made sodium thiosulfate solution, 100 mg/mL in water.
6. Dichloromethane.

3. Methods

3.1. Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE)

The instructions that follow are based on separating bovine submaxillary gland mucins Type I-S (BSM) (Sigma, USA) using NuPAGE™ 10% Bis-Tris precast gels (1.0 mm × 10 well) (Invitrogen, USA) in an Xcell *Surelock*™ Mini-Cell. Other formats are equally appropriate.

1. Insert a precast minigel into the Xcell *Surelock*™ Mini-Cell and remove the pre-inserted comb.
2. Dissolve the standard (glyco)protein mixture in NuPAGE® LDS sample buffer (4x) and NuPAGE® reducing agent (10x) with quantities between 5 and 25 µg of protein.
3. Heat the mixture at 70°C for 10 min.
4. Prepare SDS running buffer by adding 50 mL NuPAGE® 2-morpholinethane-sulfonic acid (MES) to 950 mL of HPLC grade water. Fill the lower buffer chamber of the Invitrogen Xcell *Surelock*™ Mini-Cell.
5. Add 500 µL NuPAGE® antioxidant solution to 200 mL 1x SDS running buffer and fill the upper buffer chamber of the Xcell *Surelock*™ Mini-Cell.
6. Load 20 µL of each sample into separate wells (*see* **Note 1**). Include in one well a prestained molecular weight marker.

7. Complete the assembly of the gel unit and connect to a power supply set at 200 V for 60 min.
8. The gel unit is disconnected from the power supply and disassembled. The stacking gel is removed and discarded. Cut a small triangle about 0.5 cm in from the top right corner of the resolving gel to allow the gel's orientation to be tracked.

3.2. Protein Staining/Destaining (*see* **Note 2**)

(Glyco)proteins can be visualised by staining with Bio-Safe G250 Coomassie Brilliant Blue (Bio-Rad, USA) or by silver staining.

3.2.1. Staining with Coomassie Brilliant Blue

1. In the case of Coomassie Brilliant Blue staining, simply add enough of the commercially preprepared stain to submerge the gel, which is in an appropriate-sized tray.
2. Place the tray on a rocking platform for 30 min.
3. Pour off the stain.
4. Wash the gel with water for 30 min using a rocking platform. Remove the water and repeat the wash step.
5. After visualisation, excise individual Coomassie-stained protein bands from the gel by manually cutting out the appropriate bands, and place into separate 1500 µL microcentrifuge tubes.
6. Dehydrate the gel piece in the microcentrifuge tube using a vacuum centrifuge.

3.2.2. Silver Staining

To visualise the proteins with silver staining, mass spectrometry-compatible Rapid Silver Stain based on the Amersham Biosciences PlusOne Silver Stain Kit is an appropriate stain to use. (*see* **Note 3**)

1. Prepare the fixing solution by mixing 100 mL ethanol with 25 mL concentrated acetic acid and make up to 250 mL with HPLC grade water. Add to the gel and leave for 30 min at room temperature on a rocking platform.
2. Prepare the sensitizing reagent by mixing 75 mL ethanol, 10 mL sodium thiosulfate (5% w/v) and 17 g sodium acetate and make up to 250 mL with HPLC grade water. Add to the gel and leave for 30 min at room temperature on a rocking platform.
3. Pour off the sensitizing reagent solution.
4. Wash the gel for 5 min with HPLC-grade water. Repeat twice.
5. Prepare the silver reagent by mixing 25 mL silver nitrate (2.5% w/v) with HPLC-grade water to give a final volume of 250 mL and add to the gel for 20 min.
6. Pour off.
7. Wash the gel with water for 30 min using a rocking platform. Remove the water and repeat the wash step.
8. Prepare a developing solution by mixing 6.25 g sodium carbonate with 0.05 mL formaldehyde (37% w/v) and make up to 250 mL with HPLC-grade water. Add to the gel for 5–15 min while on a rocking platform.

9. Prepare a stopping solution by dissolving 3.65 g EDTA-Na_2.$2H_2O$ in 250 mL with HPLC-grade water. Add to the gel for 10 min.
10. After visualisation, excise individual silver stained protein bands from the gel by manually cutting out the appropriate bands and place into separate 1500 µL micro-centrifuge tubes.
11. Destain using 1:1 (v/v) solution of 30 mM potassium ferricyanide and 100 mM sodium thiosulfate by adding 50 µL of this solution to each of the 1500 µL micro-centrifuge tubes that contain the excised protein gel bands. Perform occasional vortexing. The colour of the gel bands is monitored until the brownish colour disappears.
12. The gel pieces are subsequently washed several times with HPLC-grade water.
13. Add 100 µL 200 mM ammonium bicarbonate solution to the gel pieces for 20 min and then discard.
14. Wash the gel pieces with HPLC-grade water and then dehydrate with changes of acetonitrile (Fischer Scientific, Loughborough) until the gel pieces turn opaque white.

3.3. Lectin Blotting

To identify potential glycoprotein bands, prepare a second gel of the same samples. This second SDS-PAGE-separated sample is then transferred by electroblotting the separated proteins on to a polyvinylidene fluoride membrane support activated with methanol, and incubated with Concanavalin A lectin. These directions are based on the use of an Invitrogen Xcell II™ blot module to perform the western blot, which is placed in the Invitrogen Xcell *SureLock*™ Mini-Cell buffer chamber.

1. Prepare a 10x transfer buffer stock solution (1.32 M glycine, 250 mM Tris) and dilute 1:10 with 0.5:3.5:1 ratio stock solution:DDI H_2O:methanol prior to use.
2. Prepare a tray of transfer buffer large enough to lay out a transfer cassette with its pieces of foam and with two sheets of 3 MM paper submerged on one side. Cut a sheet of PVDF membrane so that it is larger than the size of the separating gel and lay it on the surface of a separate tray of distilled water and allow the membrane to wet via capillary action. Then submerge the membrane in the transfer buffer on top of the 3 MM paper. Lay the resolving gel on top of the PVDF membrane.
3. Wet two further sheets of 3 MM paper in the transfer buffer and carefully lay them on top of the gel, ensuring that no bubbles are trapped in the resulting sandwich. Lay the second wet foam on top and close up the cassette.
4. Insert the cassette into the buffer chamber ensuring that the PVDF membrane is located between the gel and the anode.
5. Assemble the apparatus prior to connecting to the power supply. Transfer can be achieved using 30 V constant for 1 h using a Bio-Rad Power Pac 1000.
6. Once the transfer is complete, remove the cassette from the buffer chamber and disassemble it.

7. Prior to incubating the blot with Concanavalin A lectin, wash the PVDF membrane 3 times with TBST buffer.
8. Incubate the membrane with 100 µg lectin/20 mL TBST buffer at room temperature with constant shaking for 1 h.
9. Wash the membrane 5 times with DDI H_2O.
10. Prepare the developing solution and develop the blot by incubating the membrane for 15 min in the dark.
11. Wash the blot in H_2O for 1 min and then dry the blot between two pieces of Whatman No. 1 paper.

3.4. In-Gel Release Using Reductive β-Elimination of O-Glycans

1. Place the excised dehydrated gel piece (*see* **Note 4**) into a 1500 µL microcentrifuge tube and add 70 µL 0.5 M $NaBH_4$ in 0.3 M NaOH Incubate at 50°C for 16 h (*see* **Note 5**). Quench the reaction by adding glacial acetic acid dropwise, until the evolution of hydrogen gas ceases.
2. Remove the liquid surrounding the gel piece (*see* **Note 6**) and place in a round-bottomed glass tube with a Teflon™-lined screw cap.
3. Wash the gel piece several times with 100 µL HPLC grade water with a few seconds of vortexing.
4. Pool the water washes with the original liquid from around the gel piece. Dry the combined extracts using a vacuum centrifuge.

3.5. β-Elimination in Aqueous Ammonia (*see* Note 7)

Place the excised dehydrated gel piece into a 1500 µL microcentrifuge tube and add 70 µL 25% NH_4OH and incubate at 45°C for 16 h.

3.6. Acetylation of the Dried Extracted Material (*see* Notes 8 and 9)

1. Acetylate the dried extracted material by adding 250–500 µL acetylation reagent to the dry sample, cap tube and mix well.
2. Allow the reaction to proceed at room temperature for 15–20 min.
3. Evaporate to dryness in a vacuum centrifuge or under a stream of nitrogen.
4. Use 1 mL of dichloromethane to redissolve the residue, cap the tube and vortex.
5. Add ~1 mL deionised water, vortex and centrifuge at low speed to separate the phases.
6. Remove the upper aqueous phase with a Pasteur pipette and discard.
7. Repeat **steps 5** and **6**.
8. Evaporate the dichloromethane using a vacuum centrifuge or stream of air or nitrogen.

3.7. De-O-Acetylation (*see* Note 9)

1. Mix dry acetylated material in a round-bottomed glass tube with a Teflon™-lined screw cap with 250–500 µL freshly made 1:1 (v:v) conc. NH_4OH/methanol and incubate at 20–22°C for 18 h.
2. Dry the reaction mixture under nitrogen.

3.8. Per-O-Methylation (see Note 9)

1. Dissolve the dry de-*O*-acetylated sample in 0.5 mL 99.9 % A.C.S dimethyl sulfoxide (Sigma-Aldrich, St. Louis. USA) in a round-bottomed, Teflon™-screw-capped glass tube.
2. Rapidly grind a few pellets of NaOH in a pestle and mortar and add two micro-spatulas (~50 mg) of the ground NaOH to the glass tube and a few drops (50–100 µL) of iodomethane using a Pasteur pipette, and recap the tube.
3. Allow to stand for 10 min at room temperature, after which add a further 5–10 drops of iodomethane to the tube.
4. Allow to stand for a further 10 min at room temperature, after which add 20 more drops of iodomethane and recap the tube.
5. After 20 min, quench the reaction by cautiously adding 1 mL freshly made 100 mg/mL sodium thiosulfate solution to the sample.
6. Immediately add 1 mL dichloromethane. Recap the tube and mix the reagents thoroughly to form an emulsion.
7. Centrifuge the sample for 10–15 s. Remove the upper aqueous layer with a pipette and then wash the dichloromethane three times with water. During each wash, form an emulsion, followed by centrifuging for 10–15 s to separate the phases and then remove the upper aqueous phase.
8. After the third washing, dry the dichloromethane under nitrogen.

3.9. Mass Spectrometry of Per-O-Methylated and Per-O-Acetylated Released O-Glycans

The following conditions are based on acquiring mass spectra on an Applied Biosystems/MDS SCIEX API QSTAR Pulsar i (Ontario, Canada) quadrupole orthogonal acceleration time of flight tandem mass spectrometer. Other mass spectrometers are equally appropriate to use.

3.9.1. Electrospray

1. For electrospray applications the ion source contains a microelectrospray arm mounted in an Applied Biosystems ion source housing.
2. A 100 µL Hamilton 1710N syringe (1.46 mm inside diameter) was used with the integral syringe driver to deliver the sample, dissolved in methanol (Fischer Scientific, Loughborough), to the ion source in a continuous flow at 1 µL/min.
3. The ion source gas reading is set to 4, the curtain gas to 20 and the capillary is held at 5500 V.
4. The instrument is operated in the positive mode with declustering and focusing potentials of 65 and 265 V respectively.
5. For Pulsar operation the Ion Release Delay is set to 6 and the Ion Release Width to 5.
6. In MS mode, the collision gas is set to read 3 and increased to 6 during tandem MS.
7. The collision energy offset for tandem MS is varied between 25 V and 70 V. Nitrogen is used for both the collision gas and for the curtain gas.

8. The detection of ions is performed using a microchannel plate detector system with a time to digital converter.
9. The data are recorded and analysed using the Applied Biosystems/ MDS SCIEX Analyst QS Software.

The electrospray mass spectrum (**Fig. 1A**) of per-*O*-acetylated glycans released using reductive β-elimination from a bovine submaxiliary mucin SDS-PAGE band, following staining with Coomassie Brilliant Blue, contains an intense $(M+Na)^+$ ion at *m/z* 456 for per-*O*-acetylated HexNAc-ol. A less intense ion at *m/z* 743 is also observed for $(M+Na)^+$ of HexNAc-HexNAc-ol.

The product ion spectrum of the ion at *m/z* 456 (**Fig. 1B**) contains intense fragment ions at *m/z* 314 ($M+H^+ - 2 \times 60$), 336 ($M+Na^+ - 2 \times 60$) and 396 ($M+Na^+ - 60$) and less intense ions at *m/z* 374 ($M + H^+ - 60$) and 254 ($M+H^+ - 3 \times 60$), the 60 mass unit loss corresponding to the elimination of the elements of acetic acid. Other confirmatory fragment ions (*m/z* 110 ($M+H^+ - (2 \times 42) - (4 \times 60)$), 152 ($M+H^+ - 42 - (4 \times 60)$), 212 ($M+H^+ - 42 - (3 \times 60)$), 230 ($M+H^+ - (2 \times 42) - (2 \times 60)$), 254, 272 ($M+H^+ - 42 - (2 \times 60)$), 314, 336, 374 and 396) are also present.

Tandem mass spectrometric analysis of the precursor ion at *m/z* 743 (**Fig. 1C**) contains intense fragment ions at *m/z* 683 ($M + Na^+ - 60$), 623 ($M+Na^+ - 2 \times 60$) and 563 ($M+Na^+ - 3 \times 60$), and two less intense fragment ions at *m/z* 601 ($M+H + - 2 \times 60$) and 541 ($M+H^+ - 3 \times 60$). There are less intense fragment ions at *m/z* 352, 370 and 414, which correspond to diagnostic sodiated carbohydrate fragment B_1, C_1 and Y_1 ions respectively for a per-*O*-acetylated HexNAc-HexNAc-ol.

Mass spectrometric analysis of the glycans released from a silver-stained BSM glycoprotein gel band also resulted in the detection of ions at *m/z* 456 and 743 corresponding to the HexNAc-ol and HexNAc-HexNAc-ol BSM glycans. Product ion analyses of these ions yielded fragment ions indistinguishable from those produced on CID of the $(M+Na)^+$ per-*O*-acetylated HexNAc-ol and HexNAc-HexNAc-ol species released from the Coomassie stained gel (**Fig. 1B** and **1C**).

3.9.2. MALDI

1. When the QSTAR is being operated with the MALDI source a standard stainless steel PerSeptive flat microtiter target plate sample introduction system is used.
2. The dried sample is dissolved in methanol (typically 5–10 μL).
3. The dried-droplet method is used for preparing the sample-matrix spots. 1 μL sample solution is mixed with 1 μL of 10 mg mL^{-1} α-cyano-4-hydroxycinnamic acid (in 50 % aqueous acetonitrile 0.1 % TFA solution) in a plastic, 1500 μL microcentrifuge tube, in order to produce a matrix to sample ratio of about 5000:1. An aliquot of this mixture (0.5–2.0 μL) is then applied to the stainless steel sample target and allowed to air dry.

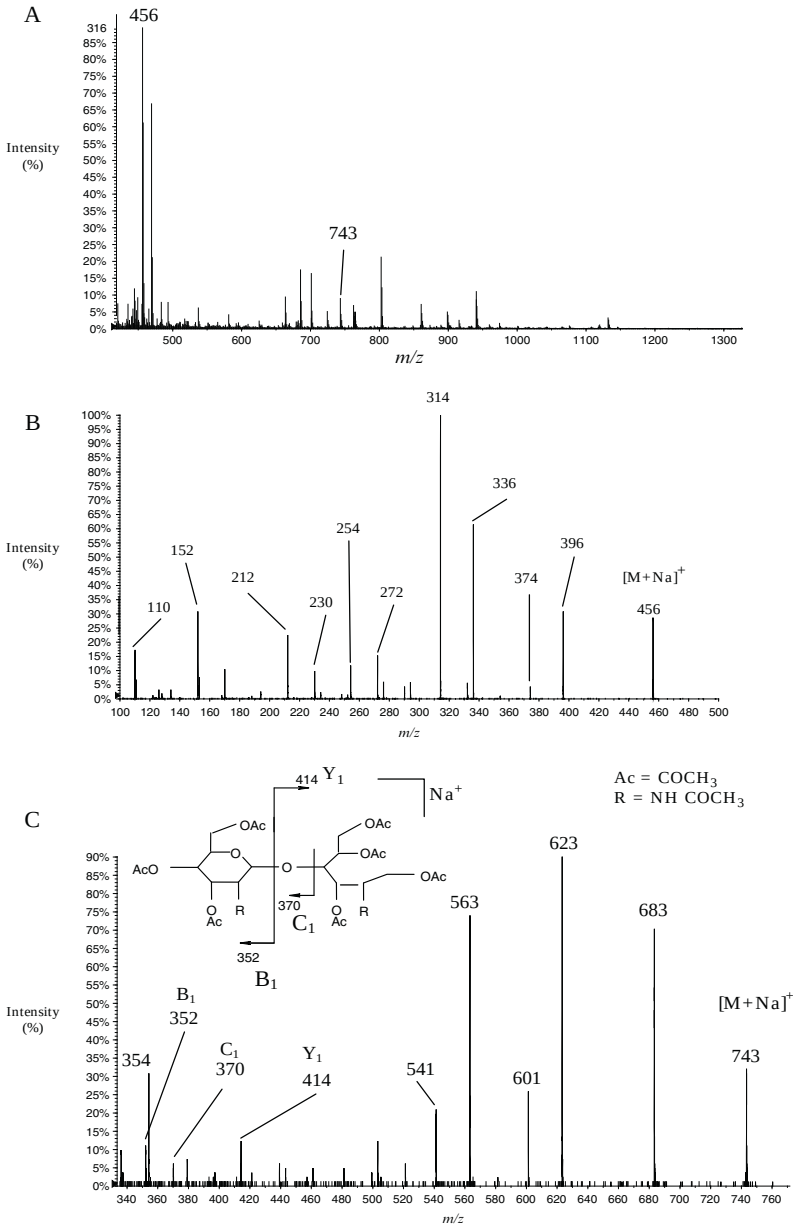

Fig. 1. Electrospray Mass Spectra of Per-*O*-Acetylated Glycans Released In-Gel using Reductive β-Elimination from an SDS-PAGE-separated Bovine Submaxillary Mucin Glycoprotein. **(A)** Positive ion mode electrospray mass spectrum recorded in methanol; **(B)** CID product ion mass spectrum of $(M+Na)^+$ Per-*O*-Acetylated HexNAc-ol ion at *m/z* 456; **(C)** CID product ion mass spectrum of $(M+Na)^+$ Per-*O*-Acetylated HexNAc-HexNAc-ol ion at *m/z* 743 (Reproduced with permission from ***ref. 11***).

4. Ionisation of the matrix and sample is performed using a nitrogen UV laser with a wavelength of 337 nm, 1 to 30 Hz pulsing rate and 200 µJ laser power output, although for most applications a laser power of 25 µJ is sufficient.
5. The data are recorded and analysed using the Applied Biosystems/MDS SCIEX Analyst QS Software. The laser power and plate position are controlled using the Applied Biosystems oMALDI Server 2.2 software. Instrumental and detection parameters used are similar to those described above for electrospray operation.

4. Notes

1. The smallest amount of BSM protein that could be applied to a gel yielding a band from which a BSM glycan could be detected by ESI-MS after in-gel reductive β-elimination and extraction was 5 µg (**Fig. 2**).
2. Not performing destaining of the Coomassie stained bands does not seem to have any adverse effect on the chemical de-*O*-glycosylation and detection of the released glycans. On the other hand, destaining of silver stained

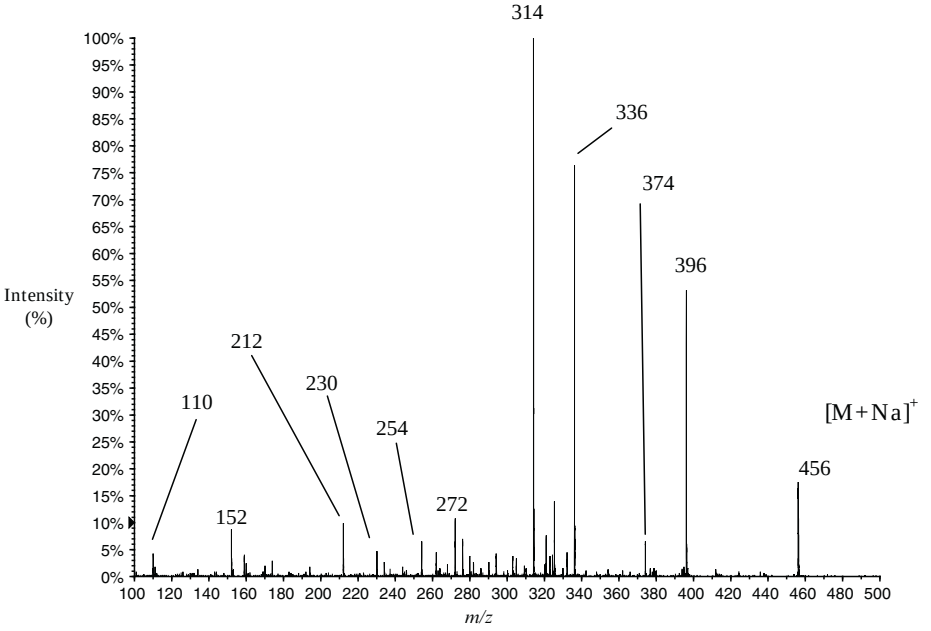

Fig. 2. Electrospray CID Product Ion Mass Spectrum of HexNAc-ol from an SDS-PAGE BSM Glycoprotein Band, visualised using silver staining after In-Gel De-*O*-Glycosylation and Per-*O*-Acetylation. The BSM glycoprotein band was excised from a gel lane that had 5 µg BSM applied to it. (Reproduced with permission from ***ref. 11***).

bands is required prior to chemical de-*O*-glycosylation. The removal of SDS prior to chemical de-*O*-glycosylation does not appear to have an effect on the chemical release or detection of *O*-linked glycans.

3. Silver staining provides more sensitive staining of proteins than does Coomassie Brilliant Blue and is a very widely used staining technique. In silver stained gels, glycan release appears not to be as efficient as that obtained from a BSM glycoprotein in a band that has been visualised by Coomassie staining, since poorer signal:noise ratios for the $(M+Na)^+$ per-*O*-acetylated HexNAc-ol and HexNAc-HexNAc-ol ions (*m/z* 456 and 743) were obtained. Silver staining relies on cross-linkage in the gel, which may restrict access of the reagent to the protein, or restrict the extraction of released glycans from the gel, as well as potentially modifying the glycans. We therefore propose that this may explain the poorer signal:noise of the ions observed on in-gel release using silver stained bands.
4. The hydration state of the gel piece prior to the addition of the β-elimination reagent has the biggest impact of all experimental variables on the effectiveness of glycan release. It is preferable to have the gel piece dried (we use a vacuum centrifuge) prior to performing the in-gel de-*O*-glycosylation. This is understandable, as in this way there is no dilution of the reagent. In addition, if the gel piece is dried, the aqueous reagent readily enters the gel, so accessing the protein more easily. We have noted that the use of dried bands provides an increase in the glycan release over shorter reaction times.
5. The strength of the alkali and the reaction time have less of an impact on the extent of glycan release; the intensity of glycan ions is not increased by increasing reaction time and reagent concentration. Indeed, longer reaction times may allow the alkaline conditions to destroy the glycan, or may produce something that interferes with either the extraction of the glycans or their mass spectrometric detection. A shorter reaction time provides for better detection of the glycan ions. A compromise between losses of disaccharide and failure to release it was achieved by carrying out glycan release reactions for no longer than 16 h.
6. Released glycans were effectively extracted from the gel pieces by vortexing in water; no improvement in the amount of glycan extracted with use of further extractions with 1:1 v:v acetonitrile/water was achieved
7. In-gel nonreductive β-elimination release has been performed on a gel band from a Coomassie Brilliant Blue stained SDS-PAGE separation of *M. avium* capsular proteins. This was then followed by in-gel tryptic digestion of the residual polypeptide following glycan release. Analysis of the

tryptic peptides using a RP capillary monolithic column coupled off-line with MALDI-ToF/ToF analysis, yielded an NCBI database hit for an *M. avium* protein, by matching two peptides. The significance of this modified approach is that using ammonium hydroxide to release the glycans nonreductively from the protein in-gel is compatible with subsequent in-gel tryptic digestion of the protein, enabling identification of the protein from its released peptides. It is also a convenient means of labelling the amino acid in the protein to which the glycan had been attached, thus having the potential to allow glycosylation site analysis ***(9)***. This variant of our approach could therefore be used not only to profile the glycan moieties but also to identify the protein and determine the site of glycan attachment as part of a gel-based proteomics experiment, allowing comprehensive glycoprotein characterisation.

8. The extraction into dichloromethane acts as a sample clean-up step to remove water-soluble reagents and interferents ***(13)***.
9. While per-*O*-acetylation is readily carried out in the presence of a range of salts and other reagents ***(13)***, the mass spectrometric response of peracetylated glycan is not as good as that of the permethylated derivative, and the mass spectrometric fragmentation tends to be less informative. However, the permethylation reaction is less tolerant of noncarbohydrate impurities, and so is best carried out on a purer sample – peracetylation and organic-aqueous partition is a convenient way to produce an appropriately purified sample. Although permethylation is carried out in strongly basic conditions, we have observed that better data were obtained if the peracetylated glycan was first de-*O*-acetylated prior to permethylation.
10. To demonstrate the utility of the developed in-gel de-*O*-glycosylation procedure, the reductive β-elimination method has been applied to a protein gel band (**Fig. 3A**, band X) from a Coomassie-stained SDS-PAGE separation of capsular glycoproteins from *M. avium* strain 2151 with smooth transparent (SmT) morphotype ***(11)***. The band chosen had produced a positive result in a duplicate Concanavalin A lectin blot, which suggested that this ~32 kDa protein was glycosylated. The MALDI mass spectrum of the glycans obtained after per-*O*-acetylation did not contain any ions for per-*O*-acetylated glycans. The mixture was de-*O*-acetylated and per-*O*-methylated in order to improve the mass spectrometric response, and analysed using ESI-MS. An ion at *m/z* 493 for $(M+Na)^+$ of Hex_1Hex-ol was observed. Tandem mass spectrometric analysis of the ion at *m/z* 493 (**Fig. 3B**) yielded an intense ion at *m/z* 275 for the diagnostic sodiated Y_1 carbohydrate fragment ion for Hex-Hexitol.

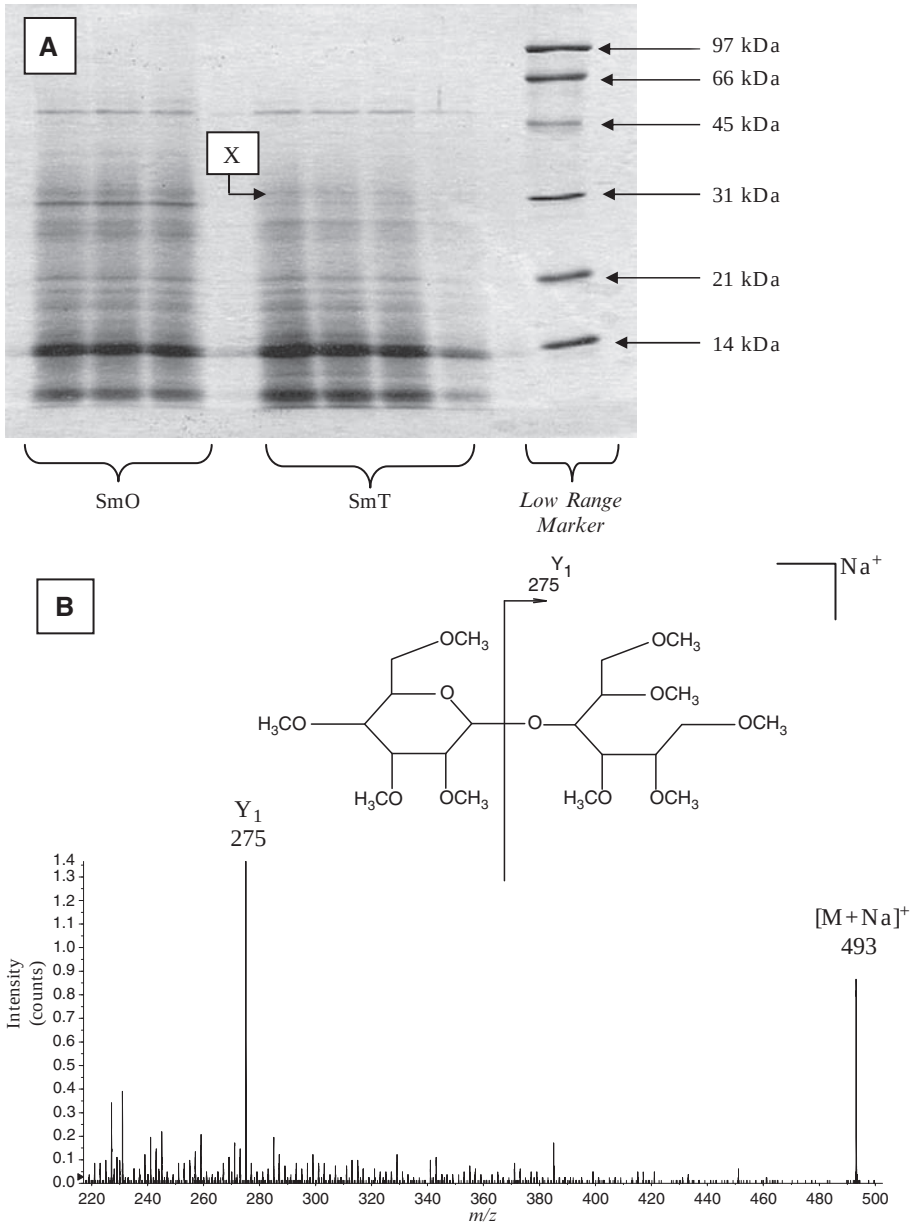

Fig. 3. **(A)** Coomassie Stained SDS-PAGE Separation of Proteins Fractionated from the Capsules of Two *M. avium* Morphotypes, Smooth Transparent (SmT) and Smooth Opaque (SmO). **(B)** Positive ion mode CID tandem electrospray mass spectrum of $(M+Na)^+$ per-*O*-methylated Hex_1Hexitol ion at *m/z* 493 obtained from *M. avium* 2151 SmT Capsular Glycoprotein After In-Gel De-*O*-Glycosylation and Per-*O*-Methylation. (Reproduced with permission from ***ref. 11***).

Acknowledgments

We are very grateful to Prof Otto Holst and Astrid Gruhl of the Research Center Borstel, Borstel, Germany, for the productive and very enjoyable *Mycobacterium avium* collaboration, and to Astrid for carrying out the SDS-PAGE shown in Figure 3A and providing band X. We gratefully acknowledge AMT's studentship provided by the Royal Society of Chemistry (RSC) and the Engineering and Physical Sciences Research Council (EPSRC), and the British Council (ARC project 1126) and the Deutscher Akademischer Austauschdienst (DAAD) (ARC project ARC-Holst) for funding the Anglo-German collaboration. JTO gratefully acknowledges funding from the Analytical Chemistry Trust Fund, the RSC Analytical Division and EPSRC.

Glycopeptide Analysis Using LC/MS and LC/MS^n

Site-Specific Glycosylation Analysis of a Glycoprotein

Satsuki Itoh, Daisuke Takakura, Nana Kawasaki, and Teruhide Yamaguchi

1. Introduction

A glycoprotein consists of heterogeneous molecules attached to diverse oligosaccharides at multiple glycosylation sites. Glycosylation analysis at each glycosylation site is important for understanding the function of carbohydrate moiety in glycoproteins. MS of glycopeptides is a commonly used method for the analyses of glycosylation sites and site-specific glycosylations ***(1–4)***. Since glycopeptide ions sometimes fail to be acquired by MS in the presence of excess peptides due to their lower ionization efficiency, separation or enrichment of glycopeptides is crucial for the MS of glycopeptides to be performed. LC/MS that allows for separation of glycopeptides from a mixture of peptides and acquisition of their mass spectra is one of the most effective means in use for the site-specific glycosylation analysis of glycoproteins.

Fig. 1 outlines the site-specific glycosylation analysis by using LC/MS and LC/MS^n. Disulfide bonds in the glycoproteins are reduced and alkylated with monoiodoacetic acid to facilitate the complete digestion with proteinases (*see* **Subheading 3.1.1**). The alkylated glycoprotein is incubated with an appropriate proteinase that provides glycopeptides containing a single glycosylation site (*see* **Subheading 3.1.2**). The complex mixture of peptides is separated by reversed-phase LC and subjected to on-line electrospray ionization (ESI) MS (*see* **Subheading 3.2.1**). The predominant ions acquired are automatically subjected to MS^n for sequencing of carbohydrates and peptides (*see* **Subheading 3.2.2**). After acquisition of the data, the MS/MS spectra of glycopeptides are picked out by matching the all acquired MS/MS spectra for the predicted MS/MS

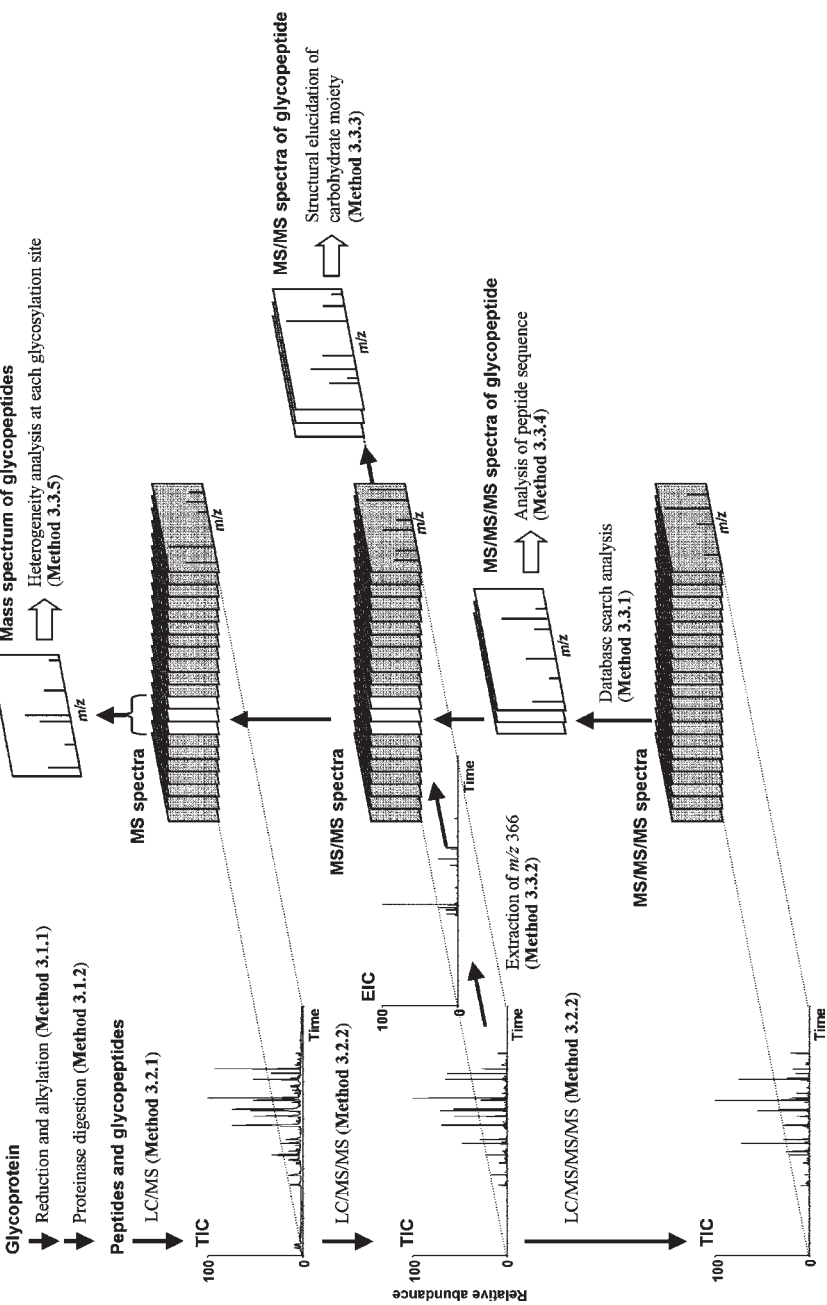

Fig. 1. Flow chart of typical site-specific glycosylation analysis by LC/MS and LC/MS^n.

spectra of the object glycoprotein by using a search engine (*see* **Subheding 3.3.1**) ***(5)***. Even if database search analysis failed to locate the MS/MS spectra of glycopeptides, tracing carbohydrate-distinctive ions, such as $HexNAc^+$ (*m/z* 204) and $Hex\text{-}HexNAc^+$ (*m/z* 366), acquired in MS/MS provides a clue to locate the desired spectra (*see* **Subheding 3.3.2**) ***(6,7)***. The carbohydrate structure can be deduced from the fragment pattern appearing in the extracted MS/MS spectra (*see* **Subheding 3.3.3**). The peptide-related ions, which bear reducing-end HexNAc at peptides ((Peptide-HexNAc + H)$^+$), often arise from the glycopeptide molecular protonated ions. The peptide sequence can be estimated by further MS^n acquired from the peptide-related ions as precursors (*see* **Subheding 3.3.4**). Since glycopeptides containing identical sequences are retained at close position, preliminary site-specific carbohydrate heterogeneity can be estimated from the integrated mass spectrum acquired at the glycopeptide peaks (*see* **Subheding 3.3.5**).

Tissue-plasminogen activator (t-PA) is a secreted serine protease which converts the plasminogen to plasmin, a fibrinolytic enzyme. This protease consists of 527 amino acid residues and is supposed to be digested into 51 peptides by trypsin **(Fig. 2)**. Previous studies suggest the fucosylation at Thr61 (peptide T8), the attachment of high-mannose type oligosaccharides to Ans117 (peptide T11),

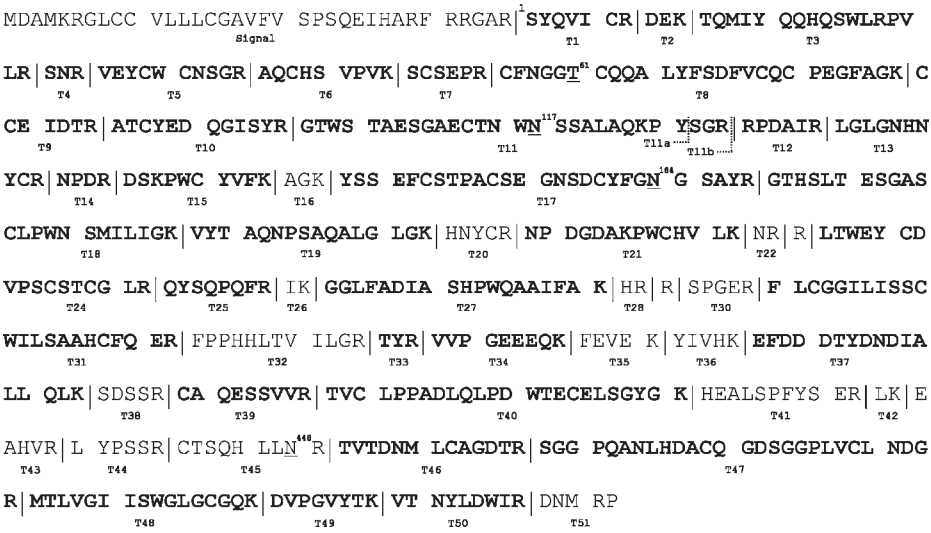

Fig. 2. Amino acid sequence of t-PA and tryptic peptides T1-T51. Boldface type indicates the peptides identified by the database search analysis with the search engine: SEQUEST (Thermo Fisher Scientific). Potential *N*-glycosylation sites are underlined. Thr61 is fucosylated.

and the linkage of sialylated complex type oligosaccharides to Asn 184 and 448 (peptide T17 and T45) ***(8)***. Using t-PA as a model glycoprotein, we here illustrate the protocol for the mass spectrometric peptide/glycopeptide mapping for the site-specific glycocylation analysis of a glycoprotein.

2. Materials

2.1. Sample Preparation

2.1.1. Reduction and Carboxymethylation

1. Buffer: 0.5 *M* Tris-HCl (pH8.6) containing 8 *M* guanidine hydrochloride and 5 m*M* EDTA.
2. Reducing reagent: 2-mercaptothanol, dithiothreitol, and Tris(carboxyethyl)phosphin (TCEP) are used instead.
3. Alkylation reagent: sodium iodoacetate (5 mg) is suspended in 40 µl of the reduction and carboxymethylation buffer. Iodoacetamide is used instead.
4. Gel filtration column for desalting: Sephadex G-25 column (e.g., NAP-10, and PD-10 column, GE Healthcare).
5. Freeze-drying device or vacuum centrifuge (e.g., SpeedVac concentrator).

2.1.2. Proteolytic Digestion

1. Proteinase: Trypsin, Lys-C, Glu-C and Asp-N are commonly used. For the tryptic digestion, Trypsin-Gold (Promega, Madison, WI, USA) is dissolved in 50 m*M* acetic acid at the concentration of 1 mg/ml (*see* **Note 1**). The solution is divided into several tubes and stored at −70°C.
2. Tryptic digestion buffer: 0.1 *M* Tris-HCl (pH 8.0).

2.2. LC/MS^n

1. LC equipment: HPLC system capable of binary gradient formation at a flow rate of 0.3–5.0 µl/ml.
2. On-line cartridge: A reversed-phase cartridge guard column (e.g., Microcolumn, C18, 0.3 mm × 5 mm, particle size 5 µm, Chemicals Evaluation and Research Institute, Japan.).
3. Column: A reversed-phase column (0.075–0.3 mm i. d. × 50–150 mm length, 3 or 5 µm particle size). A C18 or C30 column is commonly used for the peptide/glycopeptide mapping (e.g., L-column, 0.075 mm i. d. × 150 mm length, particle size 3 µm, Chemicals Evaluation and Research Institute). A graphitized carbon column (e.g., Thermo Fisher Scientific, Waltham, MA, USA) can be used for the analysis of hydrophilic glycopeptides.
4. Nanospray tip and x-y-z translational stage: Commercially available from analytical instrument manufacturers (e.g., New Objective, Inc., Woburn, MA, USA).
5. Ion trap type mass spectrometer equipped with nanoESI source (e.g., LTQ, Thermo Fisher Scientific).

6. LC mobile phase: HPLC grade H_2O, acetonitrile and formic acid. Solvent A: 0.1% formic acid in 2% acetonitrile. Solvent B: 0.1% formic acid in 90% acetonitrile.

2.3. Data Analysis

1. Search engine: e.g., TurboSEQUEST (Thermo Fisher Scientific) or Mascot (Matrixscience, London, UK).
2. Database: Swiss-Prot or NCBI-nr.

3. Methods

3.1. Sample Preparation

3.1.1. Reduction and Alkylation of a Glycoprotein

1. A glycoprotein (10 µg) is dissolved in 68 µl of reduction and carboxymethylation buffer.
2. To the solution, 2-mercaptethanol (0.5 µl) is added. The mixture is incubated at room temperature for 2 h.
3. Sodium monoiodoacetate solution (11.3 µl) is added to the sample solution, and the mixture is incubated at room temperature for 2 h in the dark.
4. The reaction mixture is applied on a Sephadex G-25 column equilibrated with water. The excess reagent is passed through the filter to remove.
5. Elution was carried out with water, and the eluant containing the alkylated glycoprotein is collected.
6. The eluant is lyophilized.

3.1.2. Proteolytic digestion

1. The alkylated glycoprotein is dissolved in 100 µl of proteolytic digestion buffer.
2. Trypsin solution (0.5 µl) is added to the sample solution. The mixture is incubated at 37°C for 16 h.
3. The mixture is stored at −20°C until just before the analysis.

3.2. LC/MS^n

3.2.1. LC/MS

1. The column is equilibrated by running 98% of solvent A through it at an appropriate flow rate for 20–30 min (*see* **Note 2**).
2. The nanospray tip is attached to the outlet of the column and set in the x-y-z translational stage. The spray tip is aligned with the capillary of the mass spectrometer for accurate spray direction by moving the x-y-z translational stage.
3. The mass spectrometer (ESI voltage, electron multiplier, gas pressure, and capillary temperature, etc.) is set up and the stable spray is checked with elution buffer.
4. A sample (1 µl) is injected onto the column and both the chromatography gradient and mass spectrometer data collection are simultaneously started (*see* **Notes 3** and **4**). The column is typically eluted by a linear gradient from 2% to 45% of

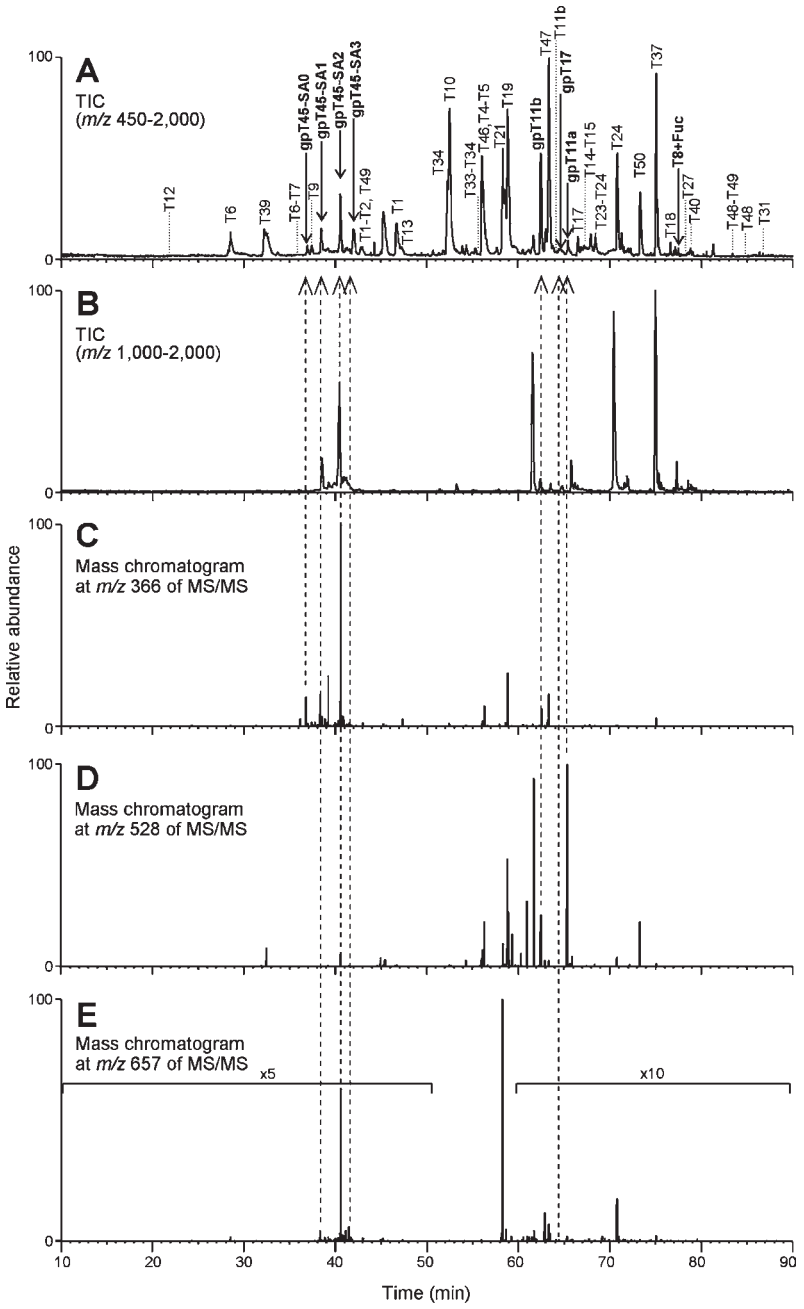

Fig. 3. Mass spectrometric peptide map. **(A)** Total ion chromatogram (TIC) obtained by mass scan (*m/z* 450–2,000) in the positive ion mode. **(B)** TIC obtained by mass scan (*m/z* 1,000–2,000). **(C–E)** Mass chromatograms at *m/z* 366, 528 and 657 obtained by MS/MS

solvent B in 100 min. A mass scan (*m/z* 450–2,000) is performed for the acquisition of both peptides and glycopeptides. Since glycopeptides are relatively large, the mass scan at *m/z* 1,000–2,000 is effective for the specific acquisition of glycopeptides (*see* **Note 5**).

As a typical mass spectrometric peptide map, the total ion chromatogram (TIC) obtained by mass scan of the tryptic digested t-PA at *m/z* 450–2,000 and 1,000–2,000 are shown in **Fig. 3A** and **3B**, respectively.

3.2.2. LC/MS^n

The most intense ion at each mass scan is automatically subjected to MS^n as a precursor ion. Molecular related ions once used as precursor ions are not subjected to MS^n within 30 s.

3.3. Data Analysis

3.3.1. Database Search Analysis for Locating the MS/MS Spectra of Glycopeptides

The MS/MS spectra of glycopeptides are located by matching the acquired MS/MS spectra for the predicted MS/MS spectra from objective glycoprotein in a database using a search engine. *N*-glycosylated peptides are often identified by the database search analysis by using the following parameters: carboxymethylation (58 Da) at Cys, and a possible modification of HexNAc (203 Da) at Asn, and dHex (146 Da) at Ser and Thr ***(5)***.

Boldface type in **Fig. 2** indicates the peptides identified by the database search analysis. Nearly 85% of amino acid residues were identified (The peak assignment is illustrated in **Fig. 3A**). Thr61-fucosylated peptide T8 was found around 78 min. Glycosylated and deglycosylated peptide T11b were located around 62 and 64 min. Peptide T17 was identified as the deglycosylation form but not the glycosylated form. The database search analysis did not provide any clues to locate either glycosylated or deglycosylated peptide T45.

Fig. 3. (continued) Sample: Tryptic digest of carboxymethylated recombinant human t-PA (Wako Pure Chemical Industries, Osaka, Japan); Amount of injection, 0.1 µg (1 µl) LC: Column, C18 (L-column, 0.075 mm i. d. × 150 mm length, particle 3 µm, Chemicals Evaluation and Research Institute, Japan); Instrument: Paradigm (Michrom Bioresources, Inc.); cartridge, Micro column (0.3 mm × 5 mm, particle size 5 µm, Chemicals Evaluation and Research Institute); Pump A: 0.1% formic acid/2% acetonitrile; Pump B: 0.1% formic acid/ 90% acetonitrile; flow rate, 300 nl/min; gradient program, 2–45% of B in 100 min. MS: Instrument, LTQ-FT (Thermo Fisher Scientific); Tip: Fortis tip (AMR, Tokyo, Japan); Ion mode, positive.

3.3.2. Location of glycopeptides using carbohydrate-related ions

The MS/MS spectra of glycopeptides can be located by tracing the carbohydrate-related fragment ions acquired in MS/MS. The peaks appearing in mass chromatograms at *m/z* 366 (Hex-HexNAc$^+$) and 657 (NeuAc-Hex-HexNAc$^+$) afford a clue to locate the glycopeptide MS/MS spectra.

Fig. 3C, **3D**, and **3E** show the mass chromatograms of ions at *m/z* 366, 528 and 657, respectively. Glycopeptides T45 and T11a, which were overlooked by the database search analysis, were located by it.

3.3.3. Structural Estimation of Carbohydrate Moiety

The mass and MS/MS spectra are extracted from the acquisition positions of glycopeptides located by **Subheading 3.3.1** and/or **3.3.2**. The sequences of carbohydrates can be deduced from the fragment ions in the MS/MS spectra.

Fig. 4A and **4B** show the mass spectrum of the glycopeptide peak at 62 min and the MS/MS spectrum acquired from one of the protonated ions (*m/z* 1,412) as a precursor, respectively. The carbohydrate-related fragment ions at *m/z* 528, 690, and 852, and the peptide-related ion, (Peptide-HexNAc + 2H)$^{2+}$ (*m/z* 1,611) in **Fig. 4B** suggest the attachment of a high-mannose type oligosaccharide (Hex$_5$HexNAc$_2$) to peptide T11b (theoretical mass: 3016.33) (**Fig. 4A**).

3.3.4. Sequencing of Peptide Moiety

The peptide sequence can be confirmed by the b- and y-ions that arise in MS/MS/MS acquired from the peptide-related ions ***(9)***.

Fig. 4C shows the MS/MS/MS spectrum acquired from (Peptide-HexNAc + 2H)$^{2+}$ (*m/z* 1,611). *N*-glycosylation at Asn117 is proven by the presence of b- and y-ion series derived from peptide T11b bearing HexNAc at Asn.

3.3.5. Heterogeneity Analysis at Each Glycosylation Site

The heterogeneity of glycosylation can be estimated from the *m/z* values and intensities of protonated ions in the integrated mass spectrum acquired at the elution positions of glycopeptides. The carbohydrate structure is deduced from the molecular masses of individual molecules.

Fig. 5A shows the integrated mass spectrum of glycopeptide T45-SA2 which is attached to disialylated bi- and tri-antennary oligosaccharides. Glycopeptides T45 were separated in order of sialylation (T45-SA0, -SA1, -SA2, and -SA3). **Fig. 5B** is the integrated mass spectrum of the other glycopeptides and suggests the linkage of monosialylated biantennary form to peptide T17.

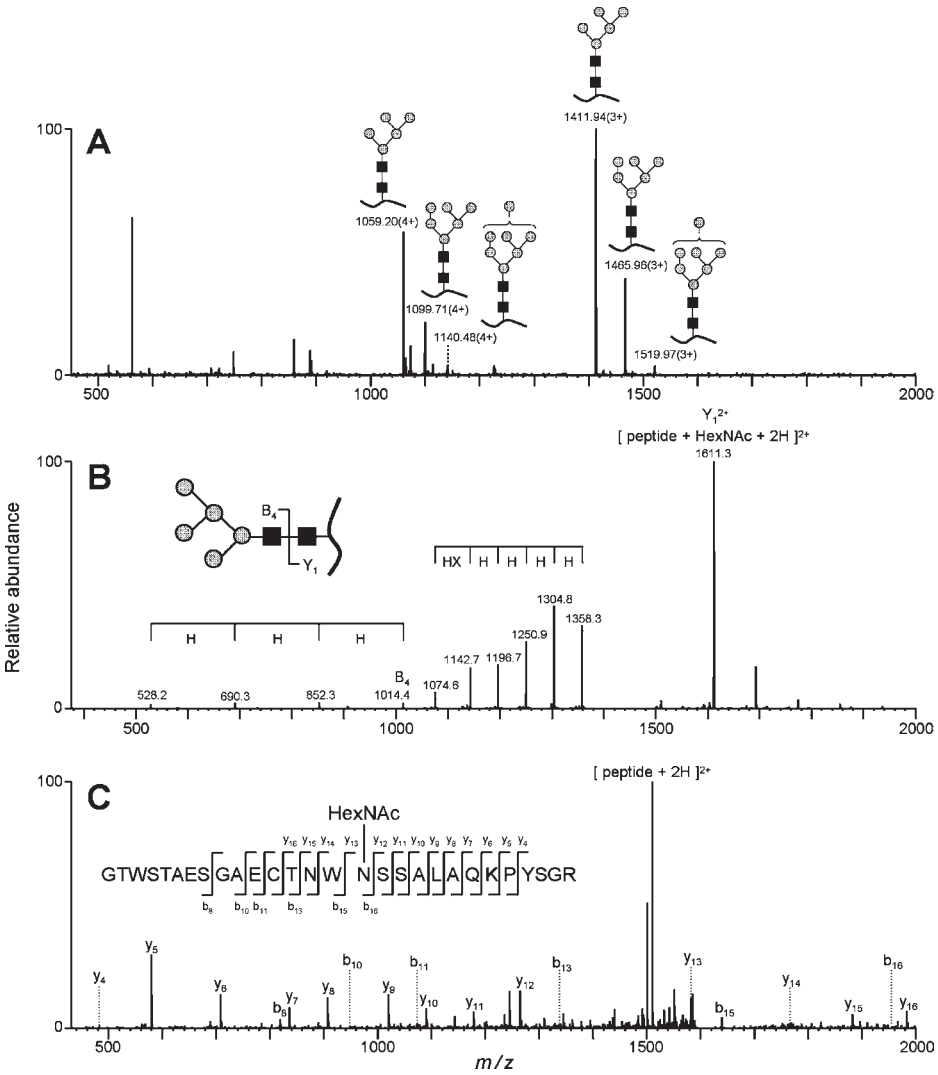

Fig. 4. MS~MS/MS/MS of glycopeptide T11b. **(A)** Mass spectrum acquired at 62.48 min. **(B)** MS/MS spectrum acquired from $(M + 3H)^{3+}$ (*m/z* 1411.94) as a precursor ion. Carbohydrate structure was deduced from the fragment pattern. **(C)** MS/MS/MS spectrum acquired from (Peptide-GlcNAc + $2H)^{2+}$ (*m/z* 1611.3) as a precursor ion. Peptide sequence and glycosylation site were identified by the database search analysis.

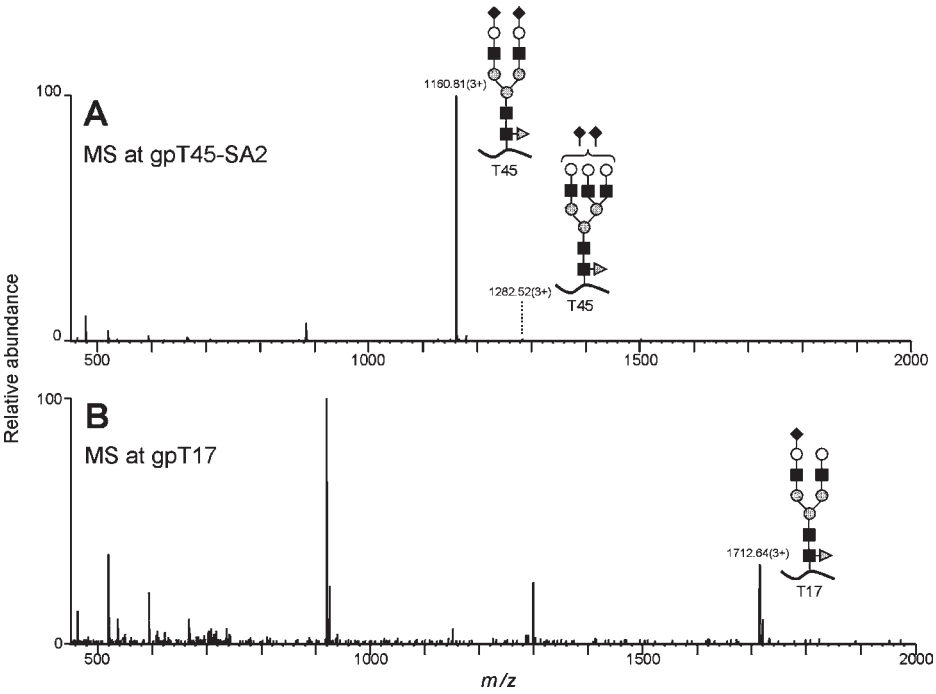

Fig. 5. Integrated mass spectra of glycopeptides derived from t-PA. **(A)** Integrated mass spectrum of glycopeptide T45-SA2 and structural assignment of glycopeptides. **(B)** Integrated mass spectrum of glycopeptide T17.

4. Notes

1. Enzyme specificity is as follows: Trypsin, Lys/Arg-↓-X (X≠Pro); Lys-C, Lys-↓-X; Glu-C, Glu (Asp)-↓-X; AspN, X-↓-Asp (Glu). Glu-C digests without cleavage of Asp-X at a 1:50 enzyme-to-substrate ratio at pH 8.0, and Asp-X can be hydrolyzed by Glu-C at a 1:4 enzyme-to-substrate ratio.
2. Typical flow rate against the column diameter is as follows: 0.3 mm, 5 µl/min; 0.2 mm, 3 µl/min; 0.1 mm, 0.5 µl/min; 0.075 mm, 0.3 µl/min.
3. It is recommended that a test run be conducted beforehand by using a standard sample, such as tryptic digested bovine serum albumin (BSA, commercially available. e.g., Michrom BioResources, Inc., Auburn, CA, USA). Database search analysis should be performed to check coverage of the amino acid sequence in BSA.
4. Positive ion mode is used for sequencing of both carbohydrate and peptide moieties. Negative ion mode is often used for the detection of highly sialylated or sulfated glycopeptides.

5. For the location of both *N*- and *O*-glycosylated peptides, monitoring of the oxonium ions at *m/z* 204 ($HexNAc^+$) produced in MS/MS is effective (10). However, in most cases, ion trap type mass spectrometer cannot detect small fragment ions, such as $HexNAc^+$, due to its low mass cut-off system. Hex-$HexNAc^+$ (*m/z* 366) and NeuAc-Hex-$HexNAc^+$ (*m/z* 657) can be used instead of $HexNAc^+$ (*m/z* 204). Monitoring $HexNAc^+$ (*m/z* 204) produced by in-source CID and the neutral loss of (*m/z* 162, 204, 291) by CID-MS/MS can be substituted for the locating the MS/MS spectra of glycopeptides ***(11, 12)***.

Identification of Vitamin K-Dependent Proteins Using a Gla-Specific Monoclonal Antibody

Karin Hansson

1. Introduction

γ-Carboxyglutamic acid (Gla) is unique among naturally occurring amino acids in that it possesses two carboxyl groups on its side chain. The biosynthesis of Gla occurs post-translationally from specific glutamate (Glu) residues in vitamin K-dependent proteins and involves γ-glutamyl carboxylase, a resident enzyme of the endoplasmic reticulum ***(1–4)***. Gla was first discovered in the N-terminal so-called Gla domain of certain mammalian proteins involved in the haemostatic process ***(5,6,7)***. In these proteins the Gla residues chelate calcium ions and induce a conformational transition that endows the proteins with phospholipid membrane binding properties. Since its initial discovery Gla has been identified in a wide range of vertebrates including mammals, birds, reptiles and fish. In addition, Gla has been shown to be present in neurotoxic venom peptides of the invertebrate marine snails of genus *Conus* ***(8,9)***. These discoveries indicate that the role of this post-translational modification in blood coagulation represents only a subset of Gla functions in animal phyla and it appears that other Gla-containing proteins with novel functions remain to be identified in the future.

Several approaches have been developed for the qualitative and quantitative identification of Gla in proteins including isotopic labelling, specific stains, modified protein sequencing, mass spectrometry, ion exchange chromatography of alkaline hydrolysates, and gas or thin layer methodologies ***(5,10–15)***. However, most of these procedures are restricted as they require purified proteins or highly enriched preparations since most currently used methods for the measurement of Gla are fairly insensitive. Furthermore, Gla is particularly difficult to identify as it easily decarboxylates to Glu. Thus Gla residues are decarboxylated to Glu when heated under acid conditions, the step that normally precedes

determination of amino acid composition. Alkaline hydrolysis is required to identify Gla and that is rarely done as several amino acids (but not Gla) are destroyed in this procedure. Also protein/peptide sequencing using the routine automated Edman degradation procedure does not provide straightforward identification of Gla. The phenylthiohydantoin (PTH) derivative of Gla is poorly extracted and it does not separate from other anionic amino acids during HPLC. Gla can routinely be identified during sequencing but this requires modification (methyl esterfication) of the peptide prior to sequencing to ensure adequate separation of Gla from other amino acids ***(12,16)***. Consequently, erroneous sequence assignments are likely unless the presence of Gla is expected and due precautions are taken. The approach described here circumvents these problems by identifying Gla-containing proteins prior to their analysis and allowing the protein to be traced easily during purification (*see* **Fig. 1**).

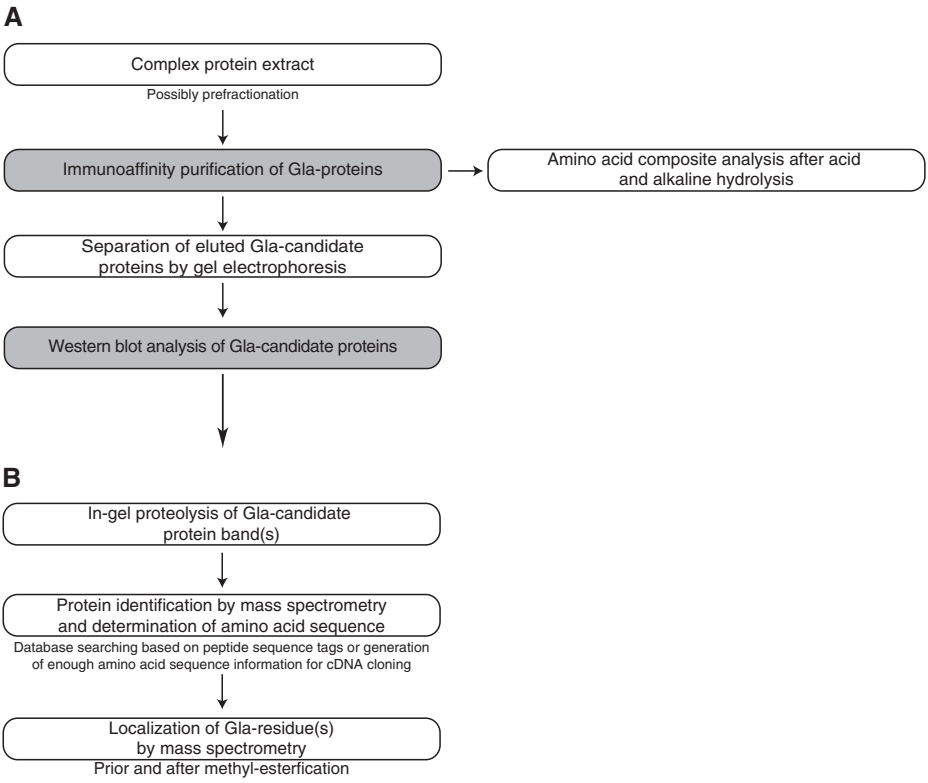

Fig. 1. Flow sheet showing the route for identification of Gla in proteins. Steps employing the Gla-specific antibody for the identification of vitamin K-dependent proteins are labeled with grey boxes. **(A)** Steps involved in the identification of Gla-candidate protein(s). **(B)** Steps involved in the localization of Gla-residue(s) in Gla-candidate protein(s).

The method depicted here is based on the development of mouse monoclonal antibodies that specifically recognize and bind Gla in proteins ***(17)***. The antibodies work well not only in Western blots but also with solution phase antigens, as has been shown by competitive immunoassays and surface plasmon resonance spectroscopy. Immobilized, the antibodies work well for affinity chromatography to purify Gla-containing proteins from complex protein extracts. The antibodies are unique and a highly functional tool that can be used to identify proteins containing one or more Gla residues ***(17–21)***. This tool in combination with modern mass spectrometry technique makes it possible to identify and localize Gla with high sensitivity in peptides and proteins.

2. Materials

2.1. Immunoaffinity Purification of Gla-Proteins

1. Mouse monoclonal antibody against Gla ***(17)*** (available from American Diagnostica Inc., CT).
2. Sulfolink coupling gel kit (Pierce Chemical Co., Rockford, IL).
3. Loading buffer: 20 m*M* Tris–HCl, 50 m*M* NaCl, 10 m*M* EDTA, pH 7.4 (*see* **Note 1**).
4. Column preservative: 0.05% (w/v) NaN_3 in Loading buffer.
5. Dialysis membrane (Spectra/Por 3, MW cutoff 3500, Spectrum Laboratories, Inc., CA) and 0.45-µm filter.
6. Wash buffer: 20 m*M* Tris–HCl, 300 m*M* NaCl, 10 m*M* EDTA, pH 7.4.
7. Elution buffer: 20 m*M* Tris–HCl, 50 m*M* $CaCl_2$, pH 7.4.
8. Protein storage buffer: 50 m*M* Tris–HCl, 100 m*M* NaCl, pH 8.0.

2.2. Separation of Eluted Gla-Candidate Proteins by Gel Electrophoresis

1. Separating buffer: 1.5 *M* Tris–HCl, pH 8.8.
2. Thirty percent acrylamide/Bis solution (37.5:1 with 2.6% C) (Bio-Rad Laboratories, Inc. CA) (*see* **Note 2**).
3. Twenty percent SDS.
4. N, N, N', N'-Tetramethyl-ethylendiamine (TEMED, Merck A/S, Oslo, Norway (*see* **Note 3**).
5. Ammonium persulfate: prepare 10% solution in water. Store at +4°C.
6. Stacking buffer: 0.5 *M* Tris–HCl, pH 6.8.
7. Electrophoresis buffer (5X): 250 m*M* Tris, 1.9 *M* glycine, 0.5% (w/v) SDS. Store at room temperature.
8. Sample buffer: 100 m*M* Tris–HCl pH 8.8, 0.015% (w/v) bromphenolblue, 36% (w/v) sucrose, 3% (w/v) SDS. Store in aliquots at −20°C.
9. 1 *M* dithiothreitol (DTT): prepare in water and immediately freeze in aliquots at −20°C.
10. Prestained molecular weight marker: MultiMark multi-colored standard (Invitrogen, Carlsbad, CA).

11. Silver stain reagents: fixation solution (50% (v/v) methanol, 5% (v/v) acetic acid), sensitizing solution (0.02% (w/v) sodium thiosulfate), staining solution (0.1% (v/v) silver nitrate), developing solution (2% (v/v) sodium carbonate), quenching solution (1% (v/v) acetic acid).

2.3. Western Blot Analysis of Gla-Candidate Proteins

1. Immobilone–P transfer membrane (Millipore, Bedford, MA) and 3 MM Chr chromatography filter paper (Whatman. Maidstone UK), two fiber pads.
2. Transfer buffer: 20 m*M* Tris, 150 m*M* glycine, 20% (v/v) ethanol.
3. Blocking buffer: 10% (w/v) skim milk powder in TBS.
4. Tris–buffered saline (TBS): Prepare 10X stock solution with 200 m*M* Tris–HCl, 1.54 *M* NaCl, pH 7.4. Dilute 100 mL with 900 mL water for use.
5. TBS with Tween (TBS–T): TBS supplemented with 0.2% (v/v) Tween 20.
6. Primary antibody: Mouse monoclonal antibody against Gla; M3B ***(17)*** (available from American Diagnostica Inc., CT).
7. Antibody dilution buffer: TBS–T containing 1% (w/v) fraction V bovine serum albumin (BSA).
8. Secondary antibody: Polyclonal rabbit anti-mouse IgG conjugated to alkaline-phosphatase (Dako A/S, Glostrup, Denmark).
9. 50 mg/mL BCIP (5-bromo-4-chloro-3-indolyl phosphate, Sigma chemical Co., MO) in DMSO. Prepare and store in the dark at +4°C.
10. 50 mg/ml NBT (2,2-di-*p*-nitrophenyl-5,5-diphenyl-3,3-[3,3-dimethoxy-4,4-diphenylene] ditetrazolium chloride (Nitro blue tetrazolium, Duchefa biochemie, Harleem, The Netherlands) in 50% (v/v) DMSO. Prepare and store in the dark at +4°C.
11. BCIP/NBT dilution buffer: 0.1 *M* Tris-HCl, 0.1 *M* NaCl, 5 m*M* $MgCl_2$, pH 9.0.
12. Stop solution: 0.02 *M* Tris-HCl, 5 m*M* EDTA, pH 8.0.

2.4. In-Gel Proteolysis of Gla-Candidate Protein Bands

1. Gel wash solution: 50% (v/v) acetonitrile.
2. Gel dehydration solution: 100% acetonitrile.
3. Reducing agent solution: 10 m*M* dithiothreitol (DTT), 0.1 *M* NH_4CO_3 pH 7.9.
4. Alkylating agent solution: 55 m*M* iodoacetic acid, 0.1 *M* NH_4HCO_3 pH 7.9.
5. Digestion buffer: 50 m*M* NH_4HCO_3 pH 7.9.
6. Endoproteinases: Trypsin (sequencing grade modified, Promega, Madison, WI), Asp-N (sequencing grade, Roche Diagnostics GmbH, Penzburg, Germany), Lys-C (sequencing grade, Roche Diagnostics GmbH, Penzburg, Germany).
7. Extraction solution: 5% (v/v) formic acid.

2.5. Mass Spectrometry

1. Micro-purification and desalting of peptides for mass spectrometry: $ZipTip_{C18}$ columns (Millipore Corporation, MA), Wetting solution: 50% (v/v) MeOH, Equilibration solution/Sample preparation solution/Wash solution: 1% (v/v) formic acid, Elution solution: 50% (v/v) MeOH, 1% (v/v) formic acid.

2. Quadropole-TOF hybrid mass spectrometer; we use a QSTAR pulsar-i quadropole-TOF tandem mass spectrometer (Applied Biosystems/MDS Sciex, Toronto, Canada) equipped with a nanoelectrospray ion source (MDS Protana, Odense, Denmark).
3. Nanoelectrospray capillaries (New Objectives, MA).

2.6. Methyl-Esterfication to Confirm the Presence of Gla

1. Methylating reagent: Put 3 mL of methanol in a beaker. Place the beaker in a freezer and cool to −80°C. Take the beaker from the freezer and place in an ice bath and immediately add 510 µl acetyl chloride dropwise under constant agitation (*see* **Note 4**).
2. Nitrogen gas.

2.7. In-Solution Proteolysis of Purified Gla-Candidate Protein and HPLC Peptide Isolation

1. Denaturating solution: 6 *M* guanidine hydrochloride, 1 *M* Tris-HCl, 10 m*M* EDTA, pH 8.6.
2. Reducing agent: 1 *M* dithiothreitol (DTT).
3. Alkylating agent: 134 mg/ml iodoacetic acid in 0.5 *M* NaOH. Prepare fresh.
4. Quench solution: β-mercaptoethanol.
5. Dialysis membrane (Spectra/Por 3, MW cutoff 3500, Spectrum Laboratories, Inc., CA).
6. Twenty percent acetic acid.
7. Digestion buffer: 100 m*M* NH_4HCO_3 pH 7.9 (trypsin), 50 m*M* sodium phosphate buffer pH 8.0 (Asp-N), 25 m*M* Tris-HCl, 1 mM EDTA pH 8.5 (Lys-C).
8. Endoproteinases: Trypsin (sequencing grade modified, Promega, Madison, WI), Asp-N (sequencing grade, Roche Diagnostics GmbH, Penzburg, Germany), Lys-C (sequencing grade, Roche Diagnostics GmbH, Penzburg, Germany).
9. Peptide separation with reversed phase HPLC: 0.1% (v/v) trifluoroacetic acid (Buffer A), 0.1% (v/v) trifluoroacetic acid, acetonitrile (Buffer B). Degas both buffers before use.

2.8. Edman Degradation of Isolated Gla-Peptide(s)

1. Automatic sequence analyzer; we use a Procise 494 automatic sequencer (ABI, Foster City, CA) with standard reagents (ABI, Foster City, CA).
2. Biobrene Plus (Applied Biosystems, Foster City, CA).
3. Micro TFA filter (Perkin Elmer, Foster City, CA).
4. Cartridge seal (Applied Biosystems, Foster City, CA).
5. 0.1% (v/v) trifluoracetic acid.

2.9. Amino Acid Composite Analysis After Acid and Alkaline Hydrolysis

1. Dialysis membrane (Spectra/Por 3, MW cutoff 3500, Spectrum Laboratories, Inc., CA).
2. 20% acetic acid.

3. Hydrolysis tubes (10 × 100 mm, Schott Duran, Mainz, Germany). Wash tubes and incubate at 400°C overnight.
4. Alkaline hydrolysis solution: 4 *M* lithium hydroxide.
5. Acid hydrolysis solution: 6 *M* hydrochloric acid, 0.1% (w/v) phenol, 100 µ*M* norleucine. Prepare in water and store at +4°C.
6. Alkaline internal standard: 62 µ*M* β-carboxyglutamic acid (β-Gla). Prepare in water and store at +4°C.
7. Precipitation solution: 6.7 *M* phosphorous acid.
8. Sample dilution solution: Na-S high performance hydrolyzate sample dilution buffer (Beckman Coulter Inc., CA).
9. Standard solution for alkaline hydrolysis; 0.5 m*M* γ–carboxyglutamic acid (γ-Gla). Prepare in water and store at +4°C.
10. Standard solution for acid hydrolysis; Std amino acid standard for hydrolyzate analysis, CM-cysteine 3.4 nmol/µl, Beckman Coulter Inc., CA). Prepare in NaS and store at +4°C.
11. Automatic amino acid analyzer; we use a Beckman 6300 amino acid analyzer (Beckman Coulter, Inc., CA) and System gold software (Beckman Coulter Inc., CA).
12. High performance buffers Na-A, Na-B, Na-C, Na-D, Na-R, Na-S, Fluo-R (Beckman Coulter, Inc., CA).
13. Sodium high performance column (12 cm) (Beckman Coulter, Inc., CA).

3. Methods

As described in the introduction, the key to the specific and sensitive identification of vitamin K-dependent proteins in the method presented here is the recently developed mouse monoclonal antibodies that specifically recognize Gla in proteins. This unique tool permits the Gla-residue(s) to be traced during purification and analysis. The method description is mainly divided into two parts. The first part explains the identification and purification of Gla-proteins from biological fluids and tissues using the Gla-antibody for affinity chromatography and Western blot analysis (*see* **Subheadings 3.1** to **3.3**; **Fig. 1A**). The second part outlines the localization of Gla residues(s) in the sequence(s) by enzymatic digestion of the protein followed by peptide sequencing by mass spectrometry and/or Edman degradation prior and after methyl esterfication (*see* **Subheadings 3.4** to **3.9**; **Fig. 1B**).

3.1. Immunoaffinity Purification of Gla-proteins

1. Couple the Gla-specific monoclonal antibody M3B to Sulfolink coupling gel according to the manufacturer's instructions. These instructions assume the use of ~4 mg of antibody coupled to 2 mL of coupling gel.
2. Use the M3B-coupled resin to prepare an immunoaffinity column. Store the column in loading buffer containing 0.05% (w/v) NaN_3 at +4°C. Before use equilibrate the column with loading buffer at a flow rate of 3 mL/min.

3. Prepare the protein extract from the relevant biological fluid, tissue or organism and possibly pre-fractionate the material (*see* **Fig. 2A**). (It is beyond the scope of the present paper to discuss the protein extract preparation step in detail).
4. Dialyze the protein extract against loading buffer and filter by passage through a 0.45-µm filter. Load the filtrate onto the immunoaffinity column at a flow rate of 3 mL/min and monitor the A_{280} of the effluent (*see* **Fig. 2B**). After the A_{280} decreases to near the baseline wash/elute the column with wash buffer at 10 mL/min and elute subsequently the column with elution buffer. (Proteins containing a single Gla residue might bind loosely and elute with the wash buffer while proteins that enclose several Gla residues, for instance Gla-domain proteins elute with the elution buffer).

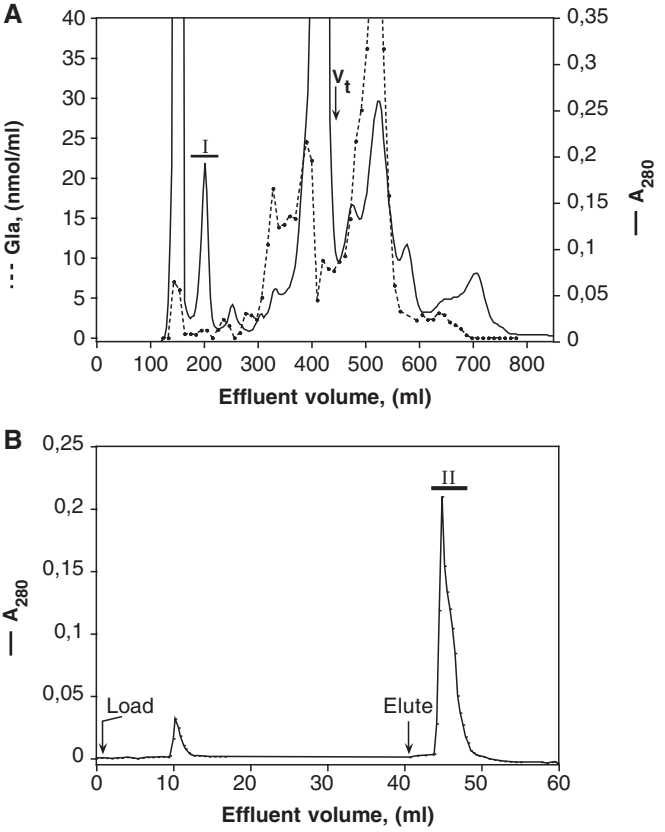

Fig. 2. Purification of a Gla-protein by immunoaffinity chromatography. **(A)** A complex protein extract prepared from the venom of the mollusc *Conus marmoreus* was pre-fractionated on a Sephadex G-50 Superfine gel filtration column. **(B)** The collected fractions denoted by a horizontal bar I (pool 1) were subjected to immunoaffinity chromatography on a column of monoclonal antibody M3B-coupled resin. The peak marked with a horizontal bar II contained the purified GlaCrisp protein containing a single Gla residue.

5. Dialyze the collected NaCl-eluted (wash-buffer) and/or $CaCl_2$-eluted (elution buffer) fractions extensively against protein storage buffer and store at −20°C.
6. Analyze the Gla-containing collected fractions by SDS-PAGE and Western blot analysis.

3.2. Separation of Eluted Gla-Candidate Proteins by Gel Electrophoresis

The protein(s) retained by affinity chromatography is subsequently analyzed by SDS-PAGE and Western blot employing the Gla-specific antibody. Prepare one gel for protein visualization and one gel for Western blot analysis.

1. This protocol is for two gels and assumes the use of a BioRad Mini-PROTEAN®3 Cell minigel system. Rinse the glass plates with distilled water and then with 95% ethanol and let them dry.
2. Prepare two 0.75-mm thick 12% gels by mixing 2.5 mL separating buffer with, 4.0 mL thirty percent acrylamide/Bis solution, 50 µL twenty percent SDS solution, 5.0 µL TEMED, 3.3 mL water, and 50 µL ammonium persulfate solution. Pour the gels, leaving space for stacking gel, and overlay immediately with water. Add the water slowly and evenly to avoid mixing. Allow the gels to polymerize for about 45 min.
3. Pour off the water and insert a piece of filter paper to dry the area in between the glass plates above the separating gels. Take care not to touch the surface of the gels.
4. Prepare the stacking gels by mixing 1.2 mL stacking buffer with, 0.6 mL thirty percent acrylamide/Bis solution, 25 µL twenty percent SDS solution, 5 µL TEMED, 3 mL water, and 25 µL ammonium persulfate solution. Pour the stacking gels until the top of the plates is reached and insert the desired combs. Allow the stacking gels to polymerize for 30 min.
5. Prepare the electrophoresis buffer by diluting 400 mL of the 5X electrophoresis buffer with 1600 mL of water in a cylinder. Cover with Para-Film and invert to mix.
6. Once the stacking gels have set, carefully remove the combs and use a 10-mL syringe fitted with a needle to wash the wells thoroughly with electrophoresis buffer.
7. Add the electrophoresis buffer to the inner chamber assembly and the lower buffer chamber.
8. Prepare the samples by mixing 20 µl (50 pmol; reduce the volume of the sample if necessary in a centrifugal vacuum concentrator) of each collected fraction with, 5 µl sample buffer, and 2 µl DTT solution (*see* **Note 5**). Incubate the samples for 5 min at 99°C. The samples are now ready for separation by SDS-PAGE.
9. Load the samples into the wells with a Hamilton syringe. Include one well for prestained molecular weight marker.
10. Run the gel at 150 V for 50 min or until the dye front is reaching the bottom of the gel.
11. Visualize the protein bands on one of the gels by silver staining (*see* **Fig. 3A**) (*see* **Note 6**). Fix the gel in fixation solution for 30 min. Rinse the gel with water (two changes, 2 min per change) and wash the gel with water for one hour on a shaking platform. Incubate the gel in sensitizing solution for 2 min with gentle shaking and rinse quickly with two changes of water (10 sec per change). Incubate the gel

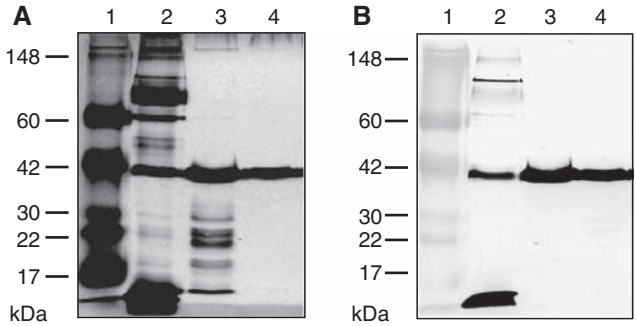

Fig. 3. Gel electrophoresis and Western blot analysis for the identification of Gla residues in proteins. **(A)** Protein samples from the purification steps of GlaCrisp (**Fig. 2**) were reduced, and resolved by 12% SDS-PAGE and silver stained. **(B)** The Gla-specific antibody M3B was employed to detect the Gla-containing components in the Western blot experiments. Key: lane 1, molecular weight marker; lane 2, crude *C. marmoreus* extract; lane 3, pool 1 from the Sephadex G-50 Superfine gel filtration column (**Fig. 2A**); lane 4, eluted fraction from the M3B immunoaffinity column (**Fig. 2B**).

in pre-chilled staining solution for 30 min at 4°C. Discard the staining solution and quickly rinse the gel with two changes of water (30 sec per change). Incubate the gel in developing solution at room temperature until adequate staining occurs. Quench staining by replacing the development solution with quenching solution. The gel can be stored in quenching buffer at +4°C.

3.3. Western Blot Analysis of Gla-Candidate Proteins

Transfer the protein bands on the second gel to an Immobilone–P transfer membrane electrophoretically.

1. Prepare a sheet of transfer membrane, cut just larger than the size of the separating gel by soaking it in 95% ethanol for a few seconds. Equilibrate the membrane, twelve pieces of 3 MM chromatography filter paper cut just larger than the transfer membrane, and two fiberpads in transfer buffer for a few minutes.
2. Remove the stacking gel from the separating gel with a razor blade.
3. Prepare the transfer sandwich by placing in the following order on the bottom anode electrode a fiber pad, six pieces of 3 MM chromatography filter paper, the transfer membrane, the gel, six pieces of 3 MM chromatography filter paper, a fiber pad, and on the top the cathode electrode. Avoid trapping of air bubbles between the gel and the transfer membrane.
4. Insert the transfer sandwich into the transfer tank. Fill the tank with transfer buffer. Attach the electrodes and electrophorese at 50 V overnight.
5. Once the transfer is complete take out the transfer sandwich of the tank and carefully disassemble it. Block the membrane in blocking buffer for 2 hrs at room temperature while shaking.

6. Remove the blocking buffer and rinse the membrane with TBS-T (four changes, 10 sec per change).
7. Incubate the membrane with 20 mL primary antibody M3B (10 µg/mL mouse monoclonal antibody against Gla diluted in antibody dilution buffer) for 2 hrs while shaking (*see* **Note 7**).
8. Wash the membrane with TBS-T (two changes with 10 sec per change, and four changes with 5 min per change).
9. Incubate the membrane with 20 mL secondary antibody (polyclonal rabbit anti-mouse IgG diluted 1:1000 in antibody dilution buffer) for 1 hr while shaking.
10. Wash the membrane with TBS-T (two changes with 10 sec per change, three changes with 5 min per change, and once for 10 min).
11. Incubate the membrane in 15 mL of BCIP/NBT substrate (prepare by mixing 100 µL 50 mg/mL BCIP solution with 50 µL 50 mg/ml NBT solution in BCIP/NBT dilution buffer) until adequate staining occurs (*see* **Fig. 3B**).
12. Stop development by replacing the BCIP/NBT substrate with stop solution.

3.4. In-Gel Proteolysis of Gla-Candidate Protein Bands

Wear gloves to reduce contamination with human keratins when preparing solutions and when handling samples. The described in-gel enzymatic digestion protocol is slightly modified from that described by Shevchenko et al. ***(22)***.

1. Rinse the silver stained gel with water two times for 10 min each.
2. Excise protein bands corresponding to immunoreactive protein bands in the Western blot analysis with a stainless steel cutting device. Cut as close to the edge of the band as possible to reduce the amount of background gel. Slice the gel band into small pieces (1 mm × 1 mm) and transfer them to a clean microcentrifuge tube.
3. Wash the gel with water (two times, 15 min each) and with gel wash solution (two times, 15 min each). The liquid volumes should be about five times the gel volume.
4. Remove the liquid and add 20 µL of gel dehydration solution. Incubate for 5 min until the gel pieces shrink and become white and stick together. Remove the gel dehydration solution.
5. Swell the gel pieces in 50 µL reducing agent solution and incubate for 1 h at 56°C to reduce disulfide bonds.
6. Cool the microcentrifuge tube to room temperature and remove the excess of reducing agent solution. Add quickly 50 µL alkylating agent solution and incubate for 30 min at room temperature in the dark.
7. Remove the alkylating agent solution and wash the gelpieces as described in step 3. Remove the liquid and add 20 µL of gel dehydration solution.
8. Rehydrate the gel pieces in enough digestion buffer containing 12.5 ng/µL trypsin to cover the gel pieces. Incubate on ice for 45 min. Add more digestion buffer if all liquid has been absorbed by the gel pieces. This protocol also applies to in-gel digestions with other commonly used endoproteinases such as Asp-N and Lys-C.
9. Remove the remaining liquid after 45 min and replace it with 20–25 µL of digestion buffer and incubate at 37°C overnight.

10. After overnight digestion spin the microcentrifuge tube shortly and extract the peptides from the gel pieces by adding 15 µL extraction solution and incubate for 15 min. Add an equal volume of acetonitrile and incubate for 15 min. Collect the supernatant. Repeat the extraction once and pool the extracts. Split the extract into two micocentrifuge tubes.
11. Dry down the pooled extracts using a vacuum centrifuge.

3.5. Protein Identification of In-Gel Digested Protein Bands by Mass Spectrometry

Localization of the Gla-residue(s) in the protein requires total coverage of the amino acid sequence followed by examination of the peptide masses, derived after enzymatic digestion, to target peptides that are carboxylated at their Glu residues. Mass spectrometric analysis is disturbed by the presence of salts and the sample must therefore be desalted. (It is beyond the scope of the present paper to discuss the identification of proteins by mass spectrometry analysis in detail). Analyze the extracted peptides by nano electrospray ionization (ESI) tandem mass spectrometry to obtain the entire amino acid sequence of the candidate Gla-protein.

1. Use a micro-purification and desalting microcolumn prior to the analysis of one half of the recovered peptides. Re-dissolve the dried peptides in 10 µL of sample preparation solution and desalt and concentrate the sample using a $ZipTip_{C18}$-column according to the manufacturers instructions. Elute the peptides in 1–5 µL elution solution.
2. Analyze the peptides by nano ESI tandem mass spectrometry where the peptides are first analyzed by full-scan MS and then by MS/MS. Program the software of the mass spectrometer to perform one scan to determine the peptide masses and then to sequence the two to four most abundant peptides.
3. Scan the spectra against a protein sequence database using a search algorithm such as Mascot or Sequest, which assigns peptide identifications based on matched criteria. If the protein is present in a protein sequence database and is identified the peptide assignments should be manually verified. If the protein proves to be unknown (i.e., not present in a sequence database) use the amino acid sequence tags obtained by *de novo* sequencing for subsequent construction of oligonucleotides to predict the complete amino acid sequence of the protein by cloning and cDNA sequencing. If necessary, sequence additional peptides manually by nano ESI MS/MS to generate enough sequence tags.

3.6. Localization of Gla-Residue(s) by Mass Spectrometry

1. Use the obtained amino acid sequence of the Gla-candidate protein to calculate the theoretical masses of the predicted peptides generated by in-gel digestion with the endoproteinase used.
2. Nano ESI mass spectrometry normally provides multiply charged peptide ions. Determine the mass of the peptides in the MS experiment described in **Subheading 3.5.**, by correcting the mass-to-charge values by the charge and the mass of added protons providing the charge.

3. Compare the observed peptide masses deduced from the ESI mass spectrometry analysis with the predicted theoretical peptide masses and target peptides that are carboxylated at their Glu residues. These peptides have a mass increase of 44 Da for each Gla residue as compared to the mass of the predicted Glu residue (*see* **Fig. 4A**). The ion signals in the MS spectrum corresponding to the Gla-containing peptides are typically accompanied by signals corresponding to loss of 44 Da caused by ejection of the γ-CO_2 by gas-phase decarboxylation or by loss of the γ-CO_2 during isolation and purification. To localize the peptide(s) containing Gla, it might be necessary to perform mass spectrometry analysis of peptides generated by endoproteinase in-gel digestions using two or more different enzymes, for example trypsin, Asp-N, and Lys-C.
4. Perform MS/MS fragmentation of the doubly and/or triply charged peptide ions corresponding to the Gla-peptide(s) (if this was not already performed in the MS/MS experiments described under **Subheading 3.5.**) to assign the position of the Gla residue(s) in the Gla-peptide(s).
5. Interpret the MS/MS fragment ion spectra and deduce the corresponding peptide sequences from the y and b ions. The peptidyl mass of Gla is 173 Da (*see* **Fig. 5**).

3.7. Methyl-Esterfication to Confirm the Presence of Gla

Confirm the presence of Gla-residue(s) in the protein by chemical derivatization of carboxyl groups in the peptides recovered from the in-gel digestion.

1. Add 50 µl of the methylating reagent to the other half of the dried peptides recovered after the in-gel digestion of the protein (*see* **Subheading 3.4.**).
2. Incubate for 2 hrs under nitrogen at room temperature.
3. Dry down the reaction mixture using a vacuum centrifuge.
4. Micropurify the derivatized peptides on a $ZipTip_{C18}$ column as described in Subheading 3.5. and analyze the peptides by nano ESI mass spectrometry. Acquire spectra in both MS and MS/MS mode and correlate peptide molecular ions corresponding to the Gla-peptide(s) in the unmodified (*see* **Subheading 3.5.** and **3.6.**) and derivatized digests. Methanolic HCl adds one methyl group of 14 Da to Asp, Glu, S-carboxymethylated Cys, and to the C-terminus of the peptide and two methyl groups to Gla (*see* **Fig. 4B**).

3.8. In-Solution Proteolysis of Purified Gla-Candidate Protein and HPLC Peptide Isolation

If a pure Gla-protein(s) in sufficient amounts is retained by affinity chromatography (*see* **Subheading 3.1.**) it can be enzymatically digested and the generated peptides fractionated by reversed-phase HPLC to isolate the Gla-containing peptide(s).

1. Dissolve the protein (1 nmol) in 500 µl of denaturating solution in a microcentrifuge tube.
2. Add 10 µl of reducing agent to a final concentration of 20 m*M* and incubate at 37°C for 2 hrs (*see* **Note 8**).

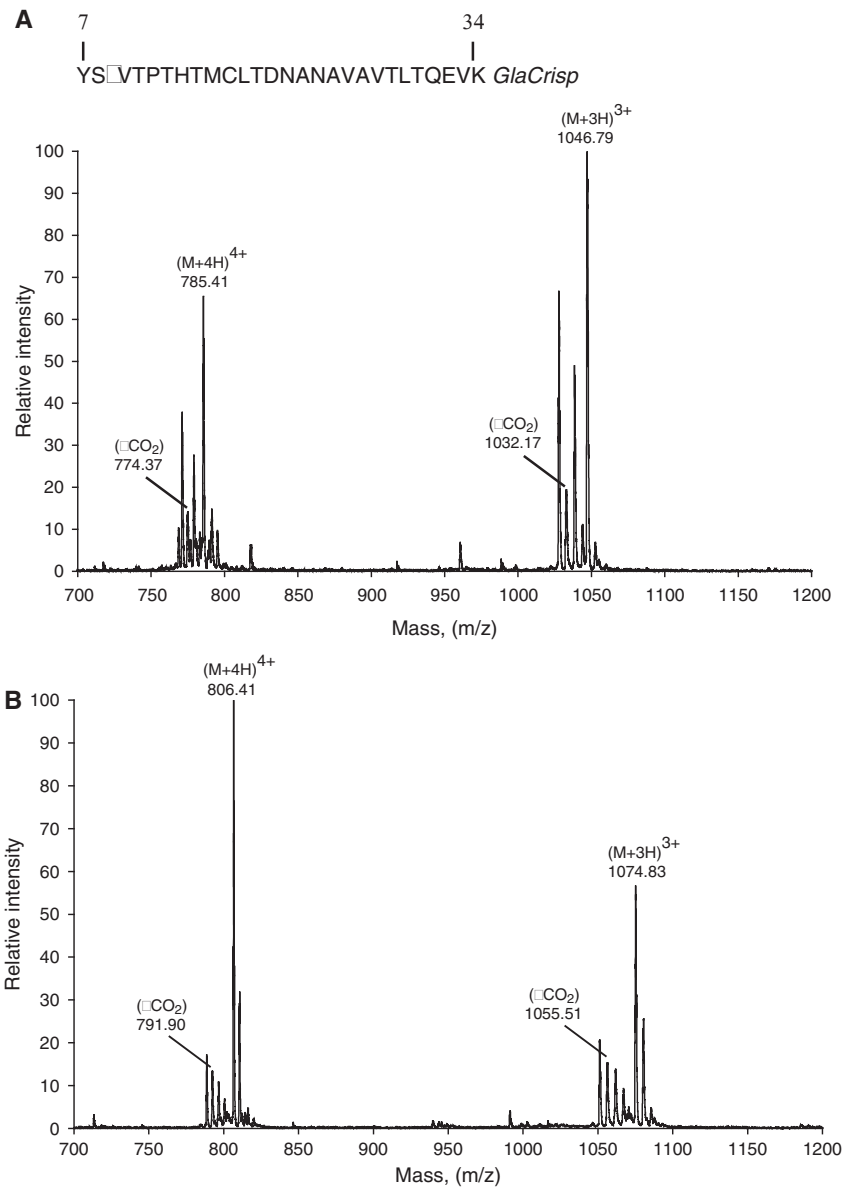

Fig. 4. Positive ion nano-ESI mass spectrometry analysis of a Gla-containing tryptic peptide fragment prior and after methyl-esterfication. The nanoESI-MS spectra of the S-carboxymethylated tryptic peptide fragment covering amino acid residues 7–34 of GlaCrisp prior **(A)** and after **(B)** methyl-esterfication. The ions at *m/z* 785.41 (4+), 1046.79 (3+), 806.41 (4+) and 1074.83 (3+) are accompanied by losses of 44 Da (corresponding to the mass of CO_2), which is consistent with a Gla residue in the peptide. After methyl esterfication an 84 Da increase in the monoisotopic molecular mass (corresponding to the methylation of all six carboxyl groups including the two at the Gla residue and the one at the C-terminus) was observed.

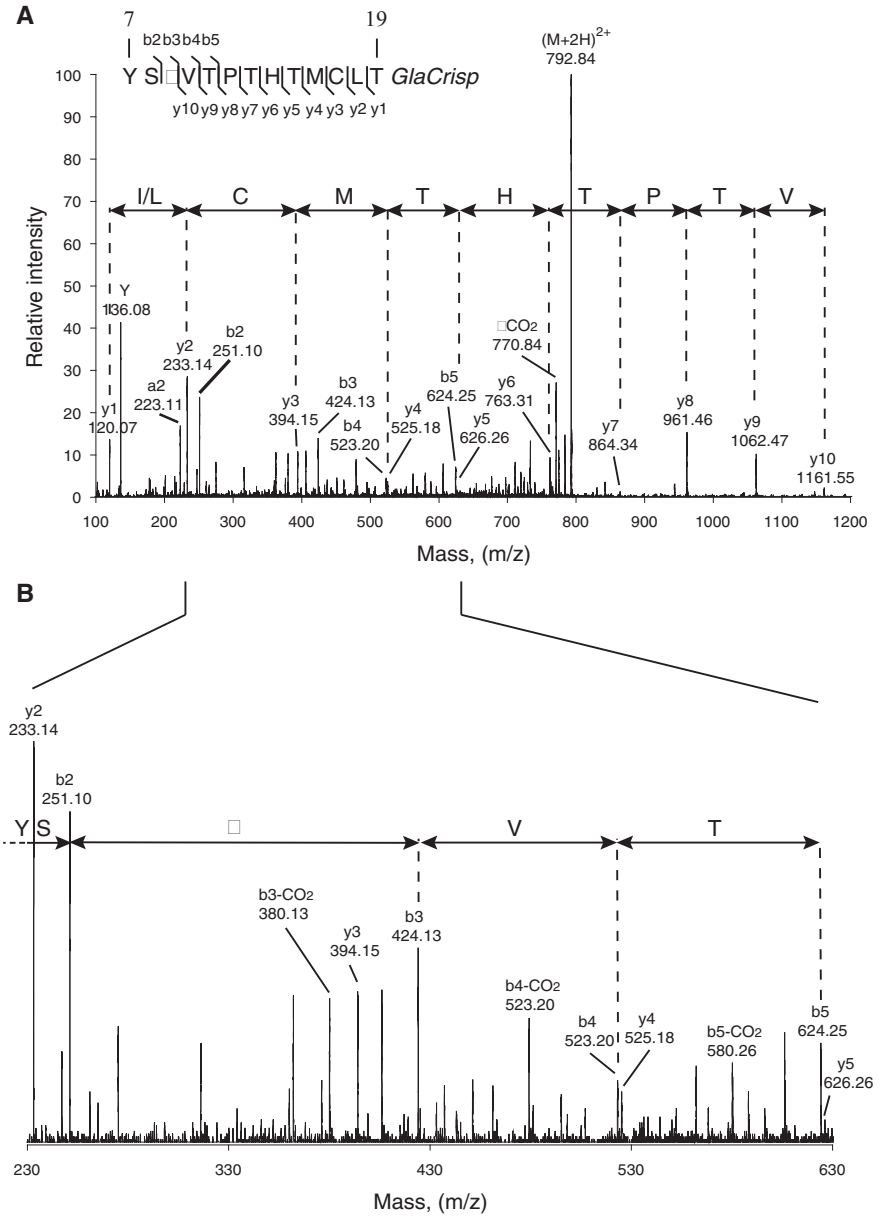

Fig. 5. Positive ion nanoESI-MS/MS analysis of the Gla-containing peptide fragment derived from digestions of GlaCrisp with trypsin and Asp-N. **(A)** The b and y ions according to the proposed sequence of the S-carboxymethylated internal peptide that covers amino acids 7–19 of GlaCrisp are labeled. **(B)** The *m/z* region from 230 to 630 has been expanded to show the b2, b3, b4, and b5 ions from which the N-terminal sequence of the peptide could be determined to localize the Gla residue.

3. Cool the microcentrifuge tube to room temperature and add 12.5 µl alkylating agent to a final concentration of 50 m*M*. Incubate in the dark at room temperature for 30 min.
4. Add 5 µl of quench solution to a final concentration of 1% (v/v).
5. Dialyze extensively against twenty percent acetic acid.
6. Dry down the reduced and alkylated protein using a vacuum centrifuge (*see* **Note 9**).
7. Add the endoproteinase in digestion buffer and incubate at 37°C for 18 hrs (*see* **Note 10**).
8. Dry down the digestion using a vacuum centrifuge.
9. Re-dissolve the dried peptides in 100 µl of buffer A and centrifuge for 1 min in a microcentrifuge at 10 000 rpm.
10. Remove the supernatant and inject onto an HPLC system equipped with a reversed-phase column (2.1 mm i.d.). After washing with buffer A elute the peptides using a linear gradient of acetonitrile in 0.1% (v/v) trifluoroacetic acid at a flow rate of 150 µl/min. Monitor the A_{214} and A_{280} of the effluent.
11. Analyze a small portion of the collected fractions of the HPLC separation by nano ESI tandem mass spectrometry, first by full-scan MS and then by MS/MS, to identify the fraction(s) containing the Gla-peptide(s) of the protein.

3.9. Edman Degradation of Isolated Gla-Peptide(s)

Verify the Gla residue(s) in the peptide sequence by Edman degradation. The current method for automated sequence analysis of Gla residues involves esterfication of the sample with methanolic HCl prior to sequencing.

1. Dry down two portions (100 pmol each) of the HPLC-isolated Gla-peptide(s) in microcentrifuge tubes using a vacuum centrifuge.
2. Perform methyl-esterfication as described in steps 1–3 in **Subheading 3.7.** of one of the portions of dried Gla-peptide(s).
3. Dry down the methyl-esterfied peptides using a vacuum centrifuge.
4. Re-dissolve the methylated and non-methylated portions of peptides in 0.1% trifluoracetic acid and load onto Biobrene Plus-pretreated micro TFA filters.
5. Analyze the Gla-peptide(s) both prior and after modification with methanolic HCl on an automatic sequence analyzer using the methods supplied by the manufacturer.
6. Evaluate the chromatograms and determine the amino acid sequence of the Gla-peptide(s). Compare the chromatograms of the peptide prior and after methylation. Methylation of the PTH derivatives of Glu and Asp causes a shift in the chromatographic elution time. The dimethyl ester of PTH Gla elutes between PTH proline and PTH methionine (*see* **Fig. 6**).

3.10. Amino Acid Composite Analysis After Acid and Alkaline Hydrolysis

Determine the amount of Gla in the isolated Gla-protein by performing amino acid analysis after acid and alkaline hydrolysis, respectively. Gla is extremely acid labile and is completely converted to glutamic acid during acid hydrolysis

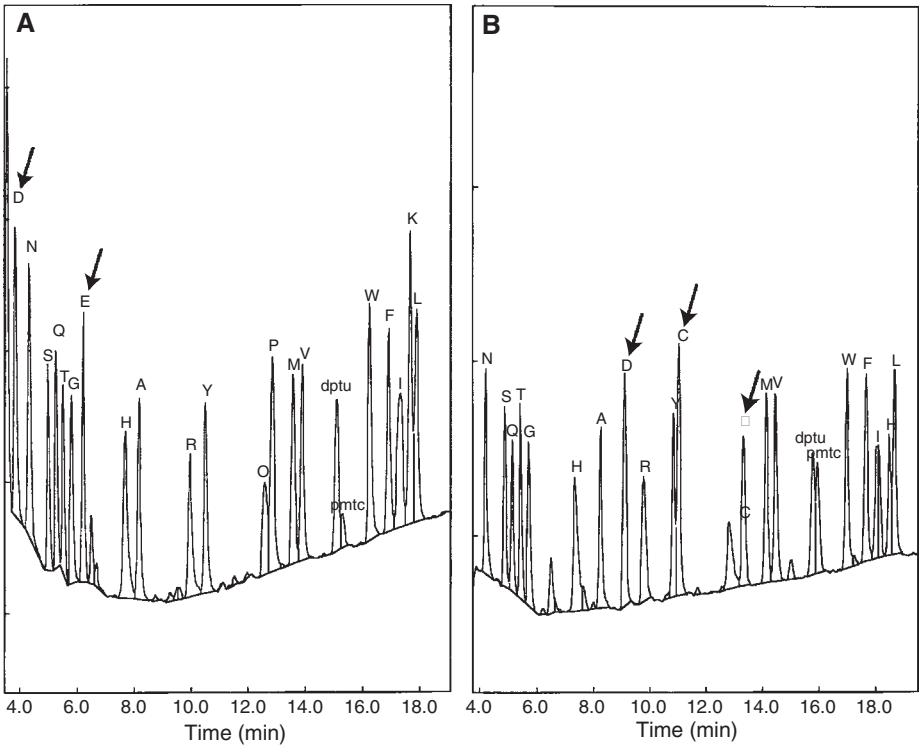

Fig. 6. C18 reversed phase HPLC chromatography of PTH amino acids. Separation of twenty-five picomoles of the standard mixture of PTH amino acids prior **(A)** and after **(B)** methyl-esterfication with methanolic HCl. The amino acid residues are designated by a one-letter code. γ denotes gamma-carboxyglutamic acid. DPTU and PMTC are by-products of the sequencing reaction and serve as useful reference peaks in the chromatogram. The arrows denote the PTH derivatives of Gla, Glu and Asp that show a shift in the chromatographic elution time caused by methylation. The absence of the Gla-derivative in the chromatogram prior to methyl esterfication is due to the low recovery from the extraction step prior to separation and inadequate separation from the other amino acid derivatives.

normally used for amino acid composite analysis. Alkaline hydrolysis provides quantitative release of Gla from peptide linkage without significant destruction.

1. Dialyze the purified protein (1 nmol as judged from A_{280}) suspected of containing Gla extensively against twenty percent acetic acid.
2. Divide the dialyzed protein into two hydrolysis tubes and dry down the samples using a vacuum centrifuge.
3. Add 100 µL of alkaline hydrolysis solution to one hydrolysis tube for alkaline hydrolysis. Add 100 µL of acid hydrolysis solution to the other hydrolysis tube for acid hydrolysis.

4. Seal the hydrolysis tubes under vacuum with a torch.
5. Heat the sealed tubes at 110°C for 24 hours.
6. Etch and crack the tubes at the top after hydrolysis.
7. Dry down the samples in a vacuum centrifuge.
8. For the alkaline hydrolysate: Add 100 µL alkaline internal standard and mix on a vortex for 15 sec. Add 20 µL precipitation solution and mix the sample on a vortex until a white precipitate is formed. Centrifuge the sample for 15 min at 10000 rpm and collect the clear supernatant. For the acid hydrolysate: Add 100 µL sample dilution solution.
9. For the alkaline hydrolysate: Mix 25 µL of the recovered supernatant with 35 µL of sample dilution solution and transfer to sample coil. For the acid hydrolysate: Mix 35 µL of the sample with 35 µL of sample dilution solution and transfer to a sample coil.
10. Analyze the samples on an automatic amino acid analyzer using the methods supplied by the manufacturer.
11. Evaluate the chromatograms and determine the amount of Gla in the protein.

4. Notes

1. Unless stated otherwise, all solutions should be prepared in water that has a resistivity of 18.2 MΩ-cm. This standard is referred to as water in the text.
2. Caution! Acrylamide and Bis are toxic in the monomeric form. Wear gloves to avoid skin contact.
3. TEMED is best stored at +4°C in a desiccator.
4. Caution! Put on safety goggles and gloves. The mixture may boil up instantly.
5. For many Gla-proteins we have noticed that reduction of disulphide bonds generates more intense Western blot signals employing the Gla-specific antibody. This is probably due to increased exposure of Gla residues to the environment.
6. This silver-staining protocol in which glutardialdehyde is omitted is compatible with mass spectrometric analysis ***(22)***.
7. The primary antibody can be re-used for up to ten times only adjustment being increased length of incubation at the developing step with the BCIP/NBT substrate.
8. Less DTT can be used, but a 20- to 100-fold molar excess over protein thiols is advised.
9. Drying should be performed in the same microcentrifuge tube that will be used for the enzymatic digestion.
10. The recommended amount of enzyme is for trypsin and Lys-C 1:100 and for Asp-N 1:200 of the protein by weight.

Acknowledgments

The author would like to thank Prof. Johan Stenflo for critically reading the manuscript. This work was supported by Grant K2001-03X-04487-27A from the Swedish Medical Research Council, the Swedish Foundation of Strategic Research, the Kock Foundations, and the Foundation of University Hospital, Malmö.

The Identification of Protein S-Nitrosocysteine

Todd M. Greco, Sheryl L. Stamer, Daniel C. Liebler, and Harry Ischiropoulos

1. Introduction

Nitric oxide ($NO^{\bullet}$) bioactivity regulates cellular function in most major mammalian organ systems. NO signaling either through soluble guanylate cyclase activation and cGMP production, or S-nitrosylation, the modification of cysteine residues to form S-nitrosocysteine, are currently the two most well studied nitric oxide signaling pathways. The emergence of S-nitrosylation as an intricate participant in cellular signaling is evidenced by the identification of endogenously S-nitrosylated proteins, including the NMDA receptor ***(1)***, caspase-3 ***(2)***, GAPDH ***(3)***, and NF-κB ***(4)***, which all participate in signal transduction pathways that regulate the fine balance between cell survival and cell death. The identification of novel S-nitrosylated proteins has traditionally stemmed from the observation that nitric oxide could modulate a protein's function, e.g. its enzymatic activity, and that these effects were often recapitulated when thiol reactive compounds such N-ethylmaleimide (NEM) or organomercury derivatives such as *p*-choloromercuribenzoic acid (PCMB) were used. Moreover, if the observed effects of nitric oxide could be reversed by reducantants such as dithiothreitol (DTT), cysteine modification was suspected. Researchers would then undertake the task of mutational analysis to identify which critical cysteine residue(s) was responsible for the observed effects.

While these methods are still critically important for establishing the functional role of S-nitrosylation, the development of proteomic techniques, namely the biotin switch method has accelerated the pace with which endogenously and potentially S-nitrosylated proteins have been identified. Here we describe an extension of the original biotin switch method ***(3)*** that incorporates peptide affinity capture, tandem mass spectrometry (MS/MS), and peptide sequence mapping,

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

permitting both the S-nitrosylated protein and the corresponding S-nitrosocysteine residue to be identified in a single experiment ***(5,6)***.

2. Materials

2.1. Cell Culture and Lysis

1. Dulbecco's Modified Eagle's Medium (DMEM, Gibco/Invitrogen, Carlsbad, CA) supplemented with 10% fetal bovine serum (FBS, Hyclone, Logan, UT).
2. Hydrochloric acid (0.5 *M*, HCl) containing 0.1 m*M* DTPA. Store at room temperature.
3. L-cysteine (1 *M*): Prepared fresh in 0.5 N hydrochloric acid/0.1 mM DTPA.
4. Sodium nitrite (1 *M*): Prepared fresh in water (*see* **Note 1**).
5. S-nitrosocysteine stock solution (CysNO, ~0.5 M): Prepared by mixing equimolar concentrations of L-cysteine solution (1 *M*) and sodium nitrite solution (1 *M*). Vortex immediately and incubate on ice for 5 min. Neutralize with 1 N NaOH to pH 7.2–7.4, immediately aliquot (20 uL) and store at −80°C. Aliquots are single use only. The concentration of each aliquot should be determined before use (*see* **Note 2**).
6. D-PBS-MC: Dulbecco's Phosphate Buffered Saline (D-PBS, Gibco) supplemented with 1 mM diethylenetriaminepentaacetic acid (DTPA) and 0.1 m*M* neocuproine.
7. TE solution: trypsin (0.05%) and ethylenediamine tetraacetic acid (EDTA) (0.02%) (Gibco).
8. Isolation buffer: 250 mM HEPES-NaOH, pH 7.7, containing 1 m*M* DTPA, 0.1 m*M* neocuproine. Store at room temperature. Prepare fresh every 2–3 months.
9. Methyl methanethiosulfonate (MMTS, 10 *M*) (Sigma, St. Louis, MO).
10. Lysis buffer: Prepared fresh from isolation buffer adjusted to contain 1% Triton X-100 and 1 m*M* MMTS (*see* **Note 3**).

2.2. Biotin Switch Assay: Derivitization of Protein S-nitrosocysteine (Pr-SNO)

1. SDS stock solution: Prepared at 25% (12.5 g in 50 mL final volume of water). Store at room temperature. CAUTION: Respiratory irritant, wear appropriate protective equipment.
2. Acetone (Fisher Scientific, Waltham, MA). Store at −20°C. CAUTION: Flammable.
3. Resuspension buffer: Prepared fresh from 1 part isolation buffer, 8.6 parts water, and 0.4 parts SDS stock solution.
4. Blocking buffer: Prepared fresh from isolation buffer adjusted to 2.5% SDS and 20 m*M* MMTS.
5. Biotin-HPDP (Pierce, Rockland, IL): Stock solution prepared at 20 m*M* in dimethylformamide (DMF). Aliquot and store at −20°C.
6. Labeling buffer: Adjust 25 m*M* HEPES-NaOH, pH 7.7, containing 1 m*M* DTPA amd 0.1 m*M* neocuproine (prepared as a stock) to contain 0.2 m*M* biotin-HPDP and 1% SDS immediately before use.
7. Sodium ascorbate solution: Prepared fresh at 0.5 *M* in water. Store on ice and protect from light.

8. Bicarbonate buffer: Freshly prepared at 100 mM ammonium bicarbonate containing 0.1% SDS.
9. Bradford reagent (Bio-rad) and BCA protein assay (Pierce).

2.3. SDS-PAGE and Western Blotting for Biotinylated Proteins

1. MOPS SDS running buffer (20X, Invitrogen)
2. NuPAGE Bis-Tris 4–2% mini gels (Invitrogen) (*see* **Note 4**).
3. XCell SureLock™ Mini-Cell (Invitrogen).
4. SeeBlue molecular weight marker (Invitrogen).
5. Nonreducing loading buffer (6X): 375 m*M* Tris-HCl, pH 6.8, 7.5% SDS, 50% glycerol, and 0.1% bromophenol blue (w/v).
6. Base buffer (10X): 0.25 *M* Tris base (do not adjust pH), 1.9 *M* glycine.
7. Transfer buffer (1X): Mix 700 mL water, 200 mL methanol, and 100 mL 10X base buffer.
8. Mini Trans-Blot cell (Biorad, Hercules, CA).
9. Immobilon-FL (PVDF) transfer membrane (Millipore) and chromatography paper (3 MM Chr, Whatman, Maidstone, UK).
10. Tris-buffered saline (TBS, 10X): 0.5 *M* Tris-HCl, pH 7.4, and 1.5 *M* NaCl.
11. Tween 20 (Biorad).
12. TBS-T wash buffer: Dilute 100 mL of 10X TBS with 900 mL water and adjust to 0.05% Tween 20.
13. Membrane blocking buffer: 5% (w/v) nonfat dry milk in 1X TBS.
14. Mouse antibiotin antibody (200 µg/mL, Spring Bioscience, Fremont, CA).
15. Primary antibody solution: Membrane blocking buffer adjusted to 0.05% Tween 20 and 0.1 ug/mL mouse antibiotin antibody.
16. Odyssey Infrared Imaging System (Licor Biosciences, Lincoln, NE) (*see* **Note 5**).
17. Alexa Fluor 680 antimouse IgG secondary antibody (2 mg/mL, Molecular Probes).
18. Secondary antibody solution: 1 part membrane blocking buffer, 4 parts TBS-t; adjust to 0.2 µg/mL secondary antibody. Protect from light.

2.4. Protein Digestion and Peptide Capture

1. Microcon YM-10 (10 kDa NMWL) filters (Millipore).
2. Trypsin gold, mass spectrometry grade (Promega, Madison, WI). Resuspend at 1 mg/mL in 50 m*M* acetic acid. Store at −20°C. Use within 5 freeze-thaw cycles.
3. Streptavidin-agarose suspension (Pierce).
4. Bicarbonate wash buffer: Prepared fresh at 1 *M* ammonium bicarbonate in water.
5. Formic acid, mass spectrometry grade (Sigma).
6. SpeedVac system.

2.5. Peptide Identification by Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS)

1. HPLC-grade water.
2. Acetonitrile, HPLC grade.

3. Thermo LTQ two-dimensional ion trap mass spectrometer equipped with a micro electrospray source and a Thermo Surveyor pump and autosampler (Thermo Scientific, San Jose, CA).
4. Capillary LC column (100 µm I.D. × 110 mm) packed with Jupiter C18 resin (5 µm, Phenomenex, Torrance, CA).
5. HPLC solvent A: 0.1% formic acid in HPLC-grade water.
6. HPLC solvent B: 0.1% formic acid in HPLC-grade acetonitrile.
7. Data analysis software: SEQUEST (Bioworks software, Thermo Scientific) and Scaffold (Proteome Software, Portland, OR) (*see* **Note 6**).

3. Methods

Protein S-nitrosocysteine (S-nitrosothiols or Pr-SNOs) are labile post-translational modifications, which are sensitive to reduction by ultraviolet (UV) light, transition metals, and reducing agents such as beta-mercaptoethanol or dithiothreitol. As a result, identification of Pr-SNOs are often performed by the biotin switch method, which blocks existing free thiols, then selectively reduces Pr-SNOs to the corresponding thiols using ascorbate while concurrently labeling the newly generated thiols with a biotin-containing dithiopyridine derivative ***(3)***. The biotin moiety allows selective enrichment and identification of proteins that previously contained S-nitrosocysteine residues.

As an extension of this method, the protocol described here uses affinity enrichment of peptides rather than proteins, taking advantage of liquid chromatography tandem mass spectrometry (LC-MS/MS) to identify both the site of S-nitrosylation as well as the protein (**Fig. 1**). The detection of Pr-SNO is described for cell culture (**Subheading 3.1**); however, the method can be used for the identification of Pr-SNO from tissues ***(5,7)***. Importantly, rapid isolation and processing of starting material should always be performed under reduced lighting conditions in buffers containing metal chelators and in the absence of reducing compounds. This method enables the identification of S-nitrosocysteine-containing peptides starting from 1 mg of protein that contains between 0.1–.5 nmol Pr-SNO/mg of protein. These levels can be generated by exposing cells to NO donor compounds such as the family of NONOates ***(6,8,9)***. In contrast, for the identification of endogenous Pr-SNO, between 10–50 mg of initial protein is recommended (*see* **Note 7**).

Also of critical importance is the inclusion of appropriate negative controls to confirm that the sites of S-nitrosylation were derived from authentic S-nitrosocysteine residues. For example, authentic Pr-SNO sites should not be identified from control samples that have been exposed to UV light (**Subheading 3.2, step 2**) or from control samples in which ascorbate has been omitted (**Subheading 3.2, step 7**). Although not discussed in detail, the suppression of nitric oxide production by pharmacological NOS enzyme inhibitors, such as L-NAME, or by genetic NOS knockout mice models can be used as negative controls. As an

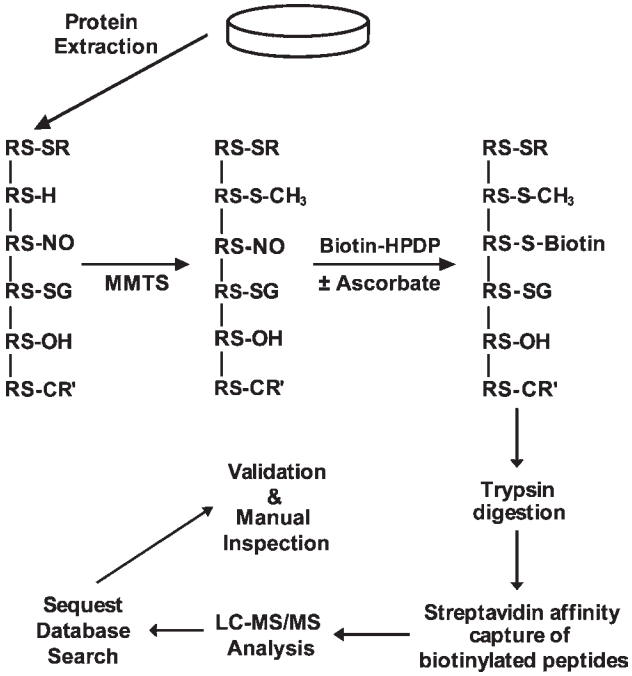

Fig. 1. Scheme of the biotin switch method, modified for the site-specific identification of Pr-SNO residues by peptide affinity capture and tandem mass spectrometry. Depicted are multiple cysteine oxidation states that can occur in proteins: RS-H, reduced thiol; RS-SR, disulfide; RS-NO; S-nitrosated; RS-SG, S-glutathiolated; RS-OH, sulfenated; RS-CR', alkylated.

optional step (**Subheading 3.3**), a Western blotting protocol for immunodetection of biotinylated proteins is provided, which can be used to optimize the biotin switch assay before performing protein digestion, peptide capture, and LC-MS/MS analysis (**Subheadings 3.4** and **3.5**).

3.1. Cell Culture and Lysis

1. Cells are maintained in appropriate growth medium containing serum (e.g., DMEM containing 10% FBS). As the speed and efficiency of sample processing is critical for preservation of Pr-SNO, 2–3 treatment conditions are recommended. For example, a typical experiment consists of four cell culture flasks (175 cm^2) that are grown to 90–95% confluence and are either untreated (endogenous Pr-SNO) or treated with an NO donor (supplemented Pr-SNO), in duplicate.
2. To prepare cultures for treatment, aspirate serum-containing media and wash the cultures with warm serum-free media. Replace the media with either serum-free media alone or a serum-free media that has been freshly supplemented with 100 µM CysNO (*see* **Note 2**) and incubate cultures at 37°C for 20 min in the dark.

3. Transfer cultures to reduced lighting conditions and aspirate the treatment media. Wash with D-PBS-MC (1 × 10 mL) and then incubate with TE solution (5 mL) to detach the cells from the flask. After the cells have detached, inactivate TE solution by addition of ice-cold media containing 0.1% FBS (5 mL). Transfer cell suspensions from a single flask (10 mL) to one 15 mL centrifuge tube. Wash the culture flasks with ice-cold D-PBS-MC (1 × 5 mL) and combine with the cell suspensions. Pellet the cells by centrifugation (200 × g, 6 min, 4°C), then wash cell pellets with ice-cold D-PBS-MC (3 × 10 mL).
4. Add ice-cold lysis buffer (1 mL) to the cell pellets and triturate with a P200 pipette followed by gentle vortexing. Rotate crude cell lysates at 4°C in the dark for 30 min, followed by centrifugation (14,000 × g, 10 min, 4°C). Recover supernatant and rapidly determine the protein concentration using the Bradford reagent and bovine serum albumin as a standard. If necessary, dilute cell lysates to a final concentration of 0.8–1 mg/mL with lysis buffer (*see* **Note 8**).

3.2. Biotin Switch Assay: Derivitization of Pr-SNO

1. Unless otherwise stated, perform all steps on ice and either protected from direct sunlight or in the dark.
2. If a UV transilluminator or UV photolysis instrument is available, a negative control sample can be generated as UV light effectively reduces the S-NO bond (7, 10) (λ_{max} = 330–340 nm). For example, to use a UV transilluminator to generate Pr-SNO depleted samples, divide equal aliquots (2 × 1 mL) of cell lysates into Petri dishes. For negative control samples that are to be depleted, leave the dishes uncovered. For the aliquots where Pr-SNO is to be preserved, wrap the Petri dishes in aluminum foil. Place both sets of dishes in an ice trough and expose to UV light for 60 min by placing an inverted UV transilluminator over the dishes *(7)*.
3. Transfer lysates (1 mL) to 15 mL centrifuge tubes, washing the Petri dishes with an equal volume of lysis buffer to maximize protein recovery.
4. Precipitate proteins with 2 volumes (4 mL) of acetone (–20°C) and incubate at −20°C for 10 min, followed by centrifugation (3,000 × g, 10 min, 4°C). Discard the supernatant.
5. Resuspend the protein pellet in blocking buffer (1 mL) and incubate at 50°C for 30 min with frequent mixing.
6. Precipitate blocked proteins with 4 volumes (4 mL) of acetone (*see* **step 4**). Discard supernatant and solubilize pellet in resuspension buffer. Repeat acetone precipitation, then wash pellet with acetone (3 × 4 mL).
7. Resuspend pellets in labeling buffer (1 mL) and aliquot (2 × 0.5 mL) in 1.5 mL centrifuge tubes. To one aliquot, add 5 uL of sodium ascorbate solution (*see* **Notes 9** and **10**). Incubate at room temperature with gentle rotation.
8. Precipitate biotinylated proteins with 2 volumes (1 mL) acetone (*see* **step 4**). Discard supernatant, then wash pellet with acetone (3 × 1 mL). Resuspend protein in bicarbonate buffer (0.5 mL) (*see* **Note 11**). Samples no longer need to be protected from light. Estimate protein concentration using either the Bradford reagent or BCA assay.

3.3. SDS-PAGE and Western Blotting for Biotinylated Proteins

1. Prepare 1X MOPS running buffer (1 L) and assemble XCell Surelock Mini-cell system using a NuPAGE 4–12% Bis-Tris gel.
2. If necessary dilute samples to 1 mg/mL. Remove an aliquot of each sample (30 ul) and add 6X nonreducing sample buffer (6 µL).
3. Load 5 uL of SeeBlue molecular weight marker, followed by 30 uL of each sample per lane.
4. Electrophorese samples for at 150 V for 5 min, then at 200 V for 55 min at room temperature.
5. Transfer electrophoresed proteins to PVDF membrane using a Mini Trans-blot apparatus filled with 1X Transfer buffer. Using an ice cooler tank insert, transfer at 100 V for 1 h at 4°C.
6. After transfer, incubate PVDF membrane in membrane blocking buffer (25 mL) for at least 1 h at room temperature or overnight at 4°C under rotation.
7. Incubate PVDF membrane in primary antibody solution (10 mL) for 1 h at room temperature under rotation. Meanwhile, prepare 1X TBS-T wash buffer (0.5 L).
8. Discard primary antibody solution and wash PVDF membrane with TBS-T wash buffer (25 mL; 2 × 5 min, 2 × 10 min).
9. Incubate PVDF membrane with secondary antibody solution (10 mL) for 1 h at room temperature under rotation. Protect membrane from light.
10. Discard secondary antibody solution and wash PVDF membrane with TBS-T wash buffer (25 mL; 2 × 5 min, 1 × 10 min). Perform a final wash with TBS (25 mL; 1 × 10 min).
11. Scan PVDF membrane on the Odyssey Infrared Imaging system (*see* **Note 12**). A representative anti-biotin Western blot from CysNO-treated lysates that were processed by the biotin switch is shown (**Fig. 2**). Omission of ascorbate served as a negative control (**Fig. 2**, *lanes 1, 3, 5*).

3.4. Protein Digestion and Peptide Capture

1. Rinse Microcon YM-10 filters with 100% methanol (0.2 mL), and centrifuge (5,000 × g, RT). Wash with water (0.2 mL) and repeat centrifugation.
2. Immediately transfer biotinylated proteins (from **Subheading 3.2, step 8**) to prerinsed Microcon YM-10. Digest proteins by addition of trypsin (1:100 enzyme:protein) for 16 h at 37°C.
3. Centrifuge (5,000 × g, RT) until entire volume (~0.45 mL) has passed through the filter. Discard retentate and recover the filtrate containing a mixture of biotinylated and non-biotinylated peptides.
4. Remove 0.1 mL of streptavidin-agarose suspension from the stock (1:1 as supplied by Pierce) per mg of initial protein that was digested (across all samples). Wash streptavidin-agarose beads with 10 volumes of 0.1 M ammonium bicarbonate. Centrifuge (500 × g), discard supernatant, and resuspend beads in 0.1 M ammonium bicarbonate, preparing a homogenous 1:1 beads:bicarbonate suspension. Add 0.1 mL of streptavidin-agarose suspension per mg of initial protein that was digested (single sample) to each peptide mixture and incubate for 1 h at RT with gentle rotation.

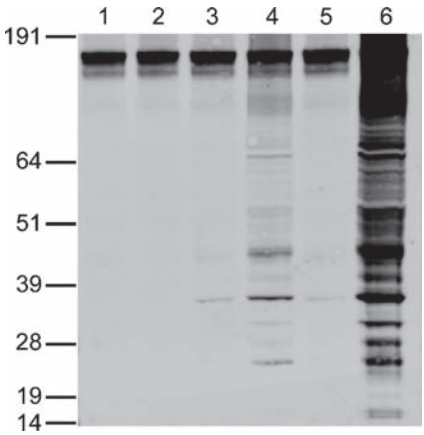

Fig. 2. Biotin switch Western blot for biotinylated proteins. Brain lysates were untreated (control) **(1**,**2)** or treated with 20 µM CysNO **(3–6)**, then processed by the biotin switch (**Subheading 3.2– 3.3**). All samples were incubated in labeling buffer containing biotin-HPDP. The detection of Pr-SNO is observed in both ascorbate-treated (**4**) and copper(II)/ascorbate-treated **(6)** samples (*see* **Note 9**). The absence of signal from the copper(II)/ascorbate-treated control sample **(2)** is due to the low levels of endogenous Pr-SNO (< 0.01 nmol/mg protein), which are below the limit of detection for this approach (~1 nmol/mg protein). Importantly, the omission of ascorbate from aliquots of **2**, **4**, and **6** displayed little to no signal (**1**, **3**, and **5**).

5. Centrifuge (500 × g, 1 min) and carefully aspirate the supernatant. Resuspend the beads in bicarbonate wash buffer (0.5 mL) and centrifuge (500 × g, 1 min). Repeat washing an additional 4 times, followed by 5 washes with water (0.5 mL).
6. Add 70% formic acid (100 µL) to the dry, washed streptavidin-agarose beads and incubate for 30 min at RT with gentle rotation to elute the biotinylated peptides. Centrifuge samples (1,000 × g, 5 min) and transfer the supernatant to clean microcentrifuge tubes. Repeat centrifugation and supernatant transfer to ensure agarose beads are removed from the sample.
7. Concentrate eluted peptides *in vacuo* to near dryness and resuspend in 0.1% formic acid (20 µL). If desired, peptides can be stored at −80°C for several months.
8. Transfer an aliquot of resuspended peptide mixture (10 µL) to an autosampler injection vial.

3.5. Peptide Identification by LC-MS/MS

Liquid chromatography coupled to electrospray ionization (ESI) tandem mass spectrometry (MS/MS) affords significantly improved sensitivity compared to matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) or three-dimensional ion trap instruments. In particular, two-dimensional ion traps, such as the Thermo LTQ, are ideal for the identification of low abundance post-translational

modifications from complex mixtures. This is due to its low femtomole limit of detection achieved by improved ion capacity, shorter duty cycle, and data-dependent MS^2 acquisition, as well as its ability to site-specifically map post-translational modifications via collision-induced dissociation (CID) peptide sequencing.

Yet this improved sensitivity, which typically results in the acquisition of 12,000–15,000 MS/MS spectra per sample, can be a double-edged sword. While the number of high quality, matched spectra is increased, the number of poor quality spectra resulting from the detection of low abundance peptides or simply noise is also increased. Therefore, this protocol employs a multistep analysis that uses both automated computational algorithms (SEQUEST and Scaffold) as well as manual inspection of MS/MS spectra to reduce false-positive peptide assignments (*see* **Subheading 3.5.2**).

3.5.1. LC-ESI/MS/MS Analysis

Liquid separation of peptides is achieved by reverse phase C18 using a Thermo Surveyor autosampler and pump, while ESI-MS/MS is performed by a Thermo LTQ ion trap mass spectrometer. Biotinylated peptides (7 µL) are subjected to reverse phase LC separation on a 0.1 × 110 mm fused silica capillary column fitted with a 60 mm frit (precolumn) packed with Jupiter C18 (5 µm particle size) using a flow rate of 0.7 µL/min. The mobile phase consisted of 0.1% formic acid in either HPLC grade water (A) or acetonitrile (B). Peptides are initially washed onto the column with 100% A for 10 min, followed 100 to 98% A for 5 min. Peptides are eluted with linear gradients of increasing solvent B from 2 to 25% B for 30 min, followed by 25% to 90% B for 15 min. As peptides are eluted from the capillary LC column they are subjected electrospray ionization (capillary voltage = 2 kV). Full scan (MS) spectra are acquired in positive ion mode from 400–2000 m/z, followed by data-dependent acquisition of MS/MS spectra on the four most intense ions from the MS scan.

3.5.2. Database Searching and Validation of Peptide Assignments

MS/MS spectra are extracted from the raw files using SEQUEST. SEQUEST output files are generated by searching raw spectra against theoretical MS/MS spectra generated from the *in silico* trypsinolysis of protein databases, such as the NCBI nr or IPI sequence databases, with a peptide mass tolerance of 2.5 amu and a fragment ion tolerance of 1.0 amu (*see* **Note 6**). Cysteine modification by methyl methanethiosulfonate (+46 atomic mass units) and by biotin-HPDP (+428 atomic mass units) are specified as variable modifications.

To compare SEQUEST sequence-to-spectrum assignments across several MS/MS experiments, SEQUEST output files are loaded into Scaffold. Only peptide assignments containing a biotin-HPDP-modified cysteine (+428 amu) are considered (*see* **Note 13**). Peptides assignments are first filtered by the following

SEQUEST threshold scores: $X_C \geq 2.5$ for doubly charged and ≥ 3.5 for triply charged ions; RSp ≤ 5; preliminary score (Sp) ≥ 350. Assignments that satisfy these criteria and are identified in at least 2 out of 3 independent experiments are manually reviewed ***(11)***. A peptide assignment with below threshold scores and/or marginal spectrum quality is accepted if it exhibits a pattern of fragmentation and relative ion peak intensity that is similar to an accepted peptide assignment present in another replicate. Shown in **Fig. 3** are representative MS/MS spectra that contain cysteine-modified biotin-HPDP, which were either accepted (**A**) or rejected (**B**). Finally, accepted peptide assignments are compared between controls (e.g. –ascorbate or +photolysis) and experimental treatments. Only peptides assignments unique to the experimental group are considered as authentic Pr-SNO peptide identifications.

4. Notes

1. Unless stated otherwise, "water" should be of > 18 MΩ-cm resistance and used for preparing all solutions.
2. After thawing the aliquot, the concentration is determined spectrophotometrically. First, blank a quartz cuvette against 999 uL of water, then add 1 uL of the stock solution, mix by inversion and read absorbance at 335 nm. Calculate the concentration of the stock solution by the following formula: $[CysNO] = (Abs_{335\,nm} \times 1000)/900\,M^{-1}cm^{-1}$. After determining the stock concentration store on ice and use within 30 min.
3. A moderate amount of MMTS is included in the lysis buffer to limit potential loss of Pr-SNO and/or artifactual transnitrosation chemistries that may occur during homogenization. However, if isolating tissue or cellular lysates for the purpose of post-lysis NO donor treatment, MMTS should be omitted.
4. Gel electrophoresis is described using NuPAGE Bis-Tris gradient mini gels, however, any standard SDS-PAGE system can be employed as long as the buffers (e.g., running and loading buffer) do not contain reducing agents. These gradient gels were used for their ability to efficiently resolve non-reduced protein samples as well as for their consistent transfer characteristics.

Fig. 3. (continued) This fragmentation pattern is consistent with the presence of glutamine residues (Q) in the sequence; therefore this assignment would be accepted. **(B)** Identified as the doubly-charged sequence TLEIEAC_{428}R with an X_c of 2.59. Although this spectrum had a reasonable series of continuous y-ions, several of the most intense peaks (*arrows*) could not be ascribed to singly or doubly-charged fragment ions or to fragment ions containing neutral losses of either water. Without additional evidence, this assignment would be rejected.$^{2+}$ indicates a doubly-charged y- or b-ion fragment. * designates fragments that have lost ammonia, while $^{@}$ designates fragments that have lost water.

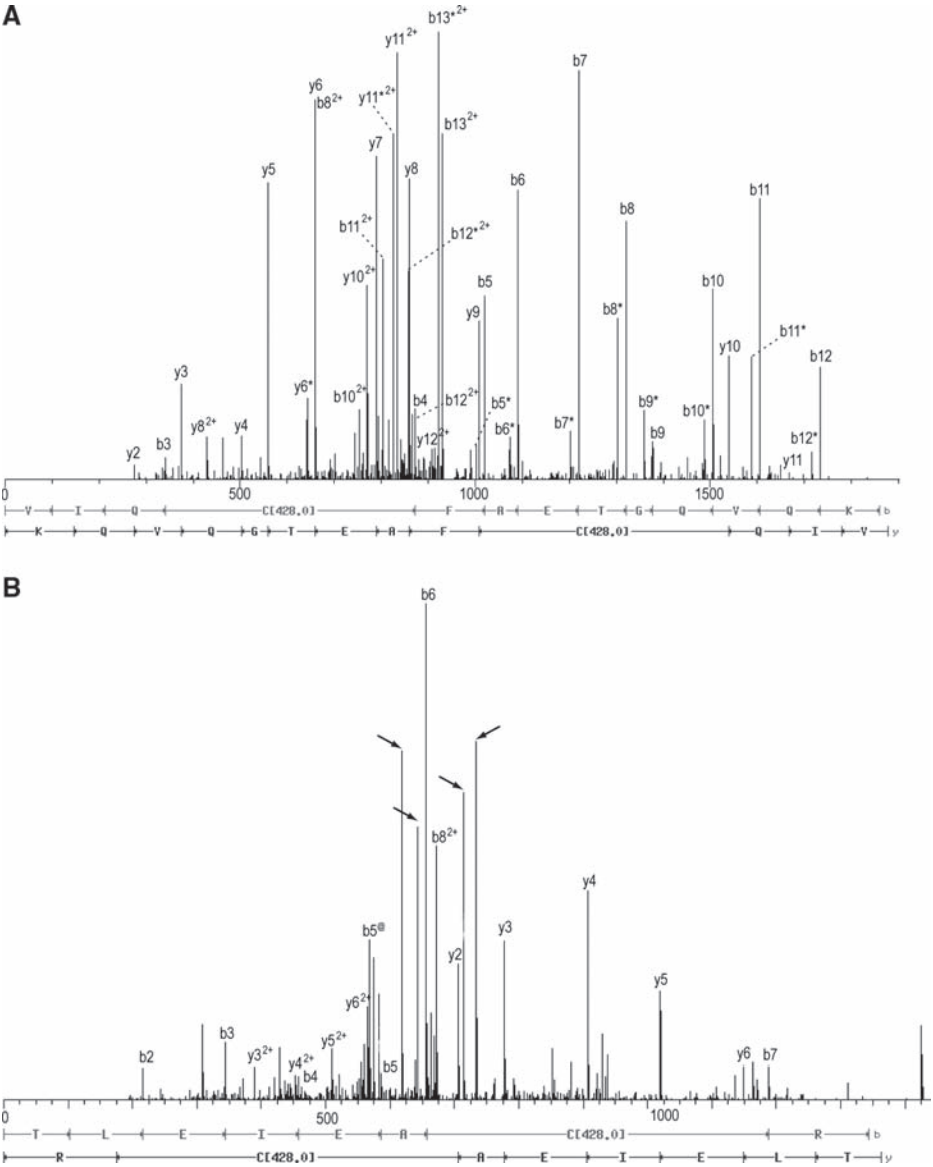

Fig. 3. Representative MS/MS spectra of Cys-biotin-HPDP labeled peptides. Both spectra passed the initial Sequest threshold scoring filter and were subjected to manual inspection (**Subheading 3.5.2**). **(A)** Identified as the doubly-charged sequence, $VIQC_{428}FAETGQVQK$, with an X_c = 4.45. This spectrum contains well-matched peaks containing several y- and b-ions in series with most major peaks matched. Diagnostic pairs of b-ion fragments (b5/b5*-b12/b12*) are observed; corresponding to the expected fragment (b6, m/z = 1090.3) and the fragment resulting from a loss of ammonia (b6*, m/z = 1073.3).

5. Visualization of anti-biotin reactivity has been successfully performed with anti-mouse IgG conjugated to hRP; however, antimouse IgG conjugated to Alexa Fluor 680 allows near-infrared detection via the Odyssey Imaging system. For Western applications, this system provides linear range over 4–5 orders of magnitude as well as superior reproducibility compared to chemiluminescent detection.
6. SEQUEST evaluates peptide assignments primarily by cross correlation scores (X_c). This threshold scoring system allows defined cutoffs to be set for "correct" and "incorrect" peptides. However, the appropriate threshold will likely vary between different experimental conditions, such as instrument type, sample complexity, and protein database size. Also, SEQUEST scores do not inherently provide the probability that a peptide assignment is correct or incorrect. Currently, there are several statistical methods that can address these issues. For example, SEQUEST database searches can be performed against *in silco* digests of "reversed" databases, which contain the protein sequences in the normal orientation and an inverted orientation, where the protein sequences are listed from the C to N terminus. Peptide assignments to the reversed sequences are considered incorrect assignments and can be used to calculate the false positive (FP) or error rate for a particular experiment ***((12, 13))***. Appropriate SEQUEST threshold scores are chosen to obtain a desired FP rate. Usually ≤ 5% peptide FP rate is satisfactory for two-dimensional ion traps. As a complementary method for evaluating the quality of peptide assignments, the PeptideProphet and ProteinProphet algorithms utilize Bayesian statistics to determine the probability that an individual peptide assignment is correct ***(14,15)***. By assuming that correct and incorrect peptide assignments follow normal distributions, these algorithms in combination with manual inspection, provide an effective strategy for validating MS/MS peptide assignments generated from database search algorithms such as SEQUEST and Mascot. These algorithms are available as open source packages, implemented in the Trans-Proteomic Pipeline (http://tools.proteomecenter.org) or utilized within commercial software such as Scaffold (Proteome Software, Portland, OR).
7. In various rat tissues, endogenous Pr-SNOs are present between 1–10 pmol per mg of total protein ***(16)***. Similarly, in a cell culture model of murine macrophages (RAW 264.7), LPS-induced iNOS induction generated approximately 25 pmol of Pr-SNO per mg of total protein ***(17)***. For the current approach, between 0.1–0.5 nmol **total** Pr-SNO isolated from cells or tissue is the lowest recommended amount of modification to perform the analysis. These estimates suggest a starting protein amount of between 10 and 50 mg of protein per sample is appropriate. Given a single experimental

condition could be split into as many as 4 samples (±photolysis and ±ascorbate), obtaining this amount of starting material from cellular cultures is challenging. Currently, for cell culture experiments this usually requires samples to be processed by the biotin switch (**Subheading 3.2**) and then pooled from several experiments before proceeding to mass spectrometry analysis (**Subheading 3.4**). As technological advancements in MS sensitivity, mass accuracy, and sample processing are made these experiments will likely become more manageable.

8. Although protein yield from a nearly confluent 175 cm^2 cell culture flask will depend on the cell line used, a reasonable expectation is 2–5 mg. As described in the method, the yield from a single 175 cm^2 flask was 2 mg (primary human aortic smooth muscle cells).
9. Recent studies have suggested that not all S-NO bonds are equally susceptible to ascorbate reduction ***(18,19)***. Therefore, it is important to note that Pr-SNOs identified by this method likely reflect the subset, which are most susceptible to ascorbate reduction. As an alternative approach, our lab has observed significantly increased efficiency of Pr-SNO reduction using copper(II)/ascorbate (100 μ *M*/50 μ *M*) compared to ascorbate alone (5 mM) (**Fig. 2**, *Lane 3 vs 5*). Thus far we have not observed any nonspecificity due to Cu/Asc treatment by Western blotting ***(Lane 1 vs 2)*** or by LC-MS/MS **(data not shown)**.
10. Several studies have suggested that high concentrations of ascorbate (>10 m*M*) can generate nonspecific biotin-HPDP labeling through the reduction of disulfide bonds. This direct reaction is unlikely as even the one electron reduction of cystine by the dehydroascorbate radical is thermodynamically unfavorable ***(10)***. While direct mechanistic evidence for the ascorbate-dependent nonspecificity has not been demonstrated in the context of the biotin switch, it is likely that inadvertent exposure to UV light underlies this observation ***(10)***, highlighting the importance of protecting samples from sunlight exposure.
11. After bicarbonate resuspension, ensure that large clumps of the protein pellet are disrupted. It is normal if the solution appears cloudy; the protein will be digested efficiently by overnight trypsin incubation.
12. The default instrument settings as specified by the "membrane" preset are usually sufficient. Nonetheless, increased sensitivity and lower background has been observed if the membrane is first dehydrated in methanol, and then allowed to dry before scanning. This may require a lower intensity setting compared to the default method.
13. The specificity of peptide identification for biotin-HPDP labeled cysteines should be ≥90%. If this was not achieved, consider increasing the volume or number of washes before eluting the biotinylated peptides from the

streptavidin-agarose beads. Alternatively, manual inspection may reveal that these assignments are low quality spectra. In this case, the SEQUEST threshold filters should be adjusted and/or searching against a reverse database is recommended to ensure false-positive rates are ≤5% (*see* **Note 6**).

Detection of Nitrotyrosine-Containing Proteins

Xianquan Zhan and Dominic M. Desiderio

1. Introduction

Tyrosine nitration in a protein results from the peroxynitrite anion ($ONOO^-$, generated from the chemical reaction of nitric oxide and superoxide anion) in a cell and from oxidative stress, and might be an important molecular event in the physiological and pathological processes of the human pituitary. The pituitary is main component of multiple hypothalamic–pituitary–target organ axis systems. Studies have indicated that nitric oxide (NO) ***(1)*** and nitric oxide synthase (NOS) participate in those axis systems ***(2–4)***, including luteinizing hormone (LH) ***(4–7)***, follicle-stimulating hormone (FSH) ***(5)***, prolactin (PRL) ***(8)***, growth hormone (GH) ***(9–11)***, and adrenocorticotropin (ACTH) ***(12)*** axis systems. We recently discovered several nitrotyrosine-containing proteins in human pituitary postmortem and nonfunctional adenoma tissues ***(1,13,14)***, and this chapter describes different methods for detecting nitrotyrosine containing proteins, using pituitary tissue as an example.

The detection and identification of an *in vivo* nitrotyrosine-containing protein is very challenging. Commercial antinitrotyrosine polyclonal/monoclonal antibodies, combined with different technologies such as enzyme-linked immunosorbent assay (ELISA) ***(15,16)***, one/two-dimensional sodium dodecyl sulfate polyacrylamide gel electrophoresis (1-D/2-D SDS-PAGE)-based Western blot assay ***(13,14,17,18)***, and immunoprecipitation ***(14)***, are effective methods to measure a nitrotyrsoine level, and to isolate, enrich, and detect an endogenous nitroprotein. ELISA has been extensively used to analyze redox production ***(15,16,19)***. ELISA is a classic method to measure the content of nitrotyrosine, and the ELISA assay kit is commercially available (Upstate Catalog No. 17–136). 1-D/2-D SDS-PAGE can separate and preferentially enrich nitroproteins based on the unique properties (molecular weight MW and electric point pI) of a protein. Western blot assay not only detects the

tyrosine-containing protein, but also determines the relative level of nitrotyrosine. Modern tandem mass spectrometry ***(1,13,14)*** methods can determine the amino acid sequence of proteolytic fragment of a protein to locate the nitrotyrosine sites in a protein sequence to clarify the function and role of endogenous tyrosine nitration.

2. Materials

2.1. Tissue Homogenization

1. Liquid nitrogen, freezer (−80°C), polytron homogenizer (Model P710/35; Brinkmann Instruments, Westbury, NY), and Fisher sonicator (Model FS30H; Fisher, Pittsburgh, PA).
2. Sodium chloride (0.9%) solution in deionized destilled water (*see* **Note 1**).
3. Homogenizing buffer (10 ml): 2 M acetic acid and 0.1% (v/v) mercaptoethanol. Store at 4°C.
4. Bicinchoninic acid (BCA) protein assay reagent kit (Pierce, Rockford, IL).

2.2. Enzyme-Linked immunosobent assay (ELISA)

1. Slide-A-Lyzer dialysis cassette 2K MWCO, 0.2–0.5 ml (Pierce Product number 66205).
2. Phosphate-buffered saline (PBS) (200 m*M*; 20 ×): 4.6 g NaH_2PO_4 (or 5.3 g $NaH_2PO_4 \bullet H_2O$), 23 g Na_2HPO_4, 175 g NaCl, and 0.2 g NaN_3 are dissolved in c.750 ml deionized destilled water. Adjust pH to 7.22. Add deionized destilled water to 1 liter. Store at room temperature. Dilute 50 ml of 20 × PBS with 950 ml deionized destilled water for use.
3. Bovine serum albumin (BSA), Fraction V (Sigma).
4. Tetranitromethane (Sigma Product Number T25003) (*see* **Note 2**).
5. 50 m*M* Tris-HCl, pH 8.0, 50 ml: 302.75 mg Tris-base is dissolved in 40 ml deionized destilled water, adjust pH value to 8.0 with hydrolytic chloride, and add deionized destilled water to 50 ml.
6. Mouse antinitrotyrosine monoclonal antibody, clone 1A6 (100 µg/100 µl Catalog number 05-233, Upstate Biotechnology, Lake Placid, NY). Store at −20°C.
7. Rabbit antimouse IgG conjugated with alkaline phosphatase. Store at 4°C.
8. Alkaline phosphatase substrate pNPP (Sigma Fast™ P-Nitrophenyl phosphate Tablet set: pNPP 1.0 mg/ml and Tris buffer 0.2 M) (Sigma). Store at 4°C.
9. Costar® EIA/RIA plate with 96-well flat bottom (Product number 122 06049; Corning Incorporated, Corning, NY).

2.3. 1-D Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (1-D SDS-PAGE)

1. Protein extraction buffer: 60 m*M* Tris-HCl pH 6.8, 2% SDS, 10 m*M* dithiothreitol, 100 µM butylated hydroxytoluene (BHT) (*see* **Note 3**), and 2 m*M* EDTA.
2. Resolving gel stock buffer: 1.5 *M* Tris-HCl, pH 8.8. Store at 4°C.

3. Stacking gel stock buffer: 0.5 *M* Tris-HCl, pH 6.8. Store at 4°C.
4. 30% Acrylamide/ 0.8% bisacrylamide solution (*see* **Note 4**).
5. 10% SDS: 10 g SDS is dissolved in 100 ml deionized destilled water.
6. N,N,N′,N′-tetramethyl-ethylenediamine (TEMED, Bio-Rad, Hercules, CA).
7. Ammonium persulfate (10%): 100 mg of ammonium persulfate is dissolved in 1 ml deionized destilled water prior to use (*see* **Note 5**).
8. 50% isobutanol in water: 50 ml isobutanol mix with 50 ml deionized destilled water. Store at room temperature. Mix well prior to use.
9. Electrophoresis running buffer (10×): 250 m*M* Tris, 1.92 *M* glycine, and 1% (w/v) SDS. Store at room temperature.
10. Sample loading buffer: 30% (v/v) glycerol, 2% SDS, 62.5 m*M* Tris pH 6.8, 50 m*M* DTT, 5 m*M* EDTA, 0.02% NaN_3. Store in 200 µl aliquots in −20°C.
11. Prestained molecular weight markers: All Blue Precision Plus ProteinTM Standards (Catalog No. 161-0373, Bio-Rad, Hercules, CA). Store in 20 µl aliquots at −20°C.

2.4. 2-D Gel Electrophoresis (2DGE)

1. Protein extracting buffer (1 ml): 7 *M* urea, 2 *M* thiourea, 4% (w/v) CHAPS, 100 m*M* DTT, 0.5% pharmalyte, and trace bromophenol blue (*see* **Notes 6** and **7**).
2. Rehydration buffer (1 ml): 7 *M* urea, 2 *M* thiourea, 4% (w/v) CHAPS, 60 m*M* DTT, 0.5% Pharmacia IPG buffer, and trace bromophenol blue (*see* **Note 7**).
3. Resolving-gel buffer stock (4×): 1.5 *M* Tris-HCl, pH 8.8. Store at 4°C.
4. Reducing equilibration buffer (50 ml): 375 m*M* Tris-HCl pH 8.8, 6 *M* urea, 2% (w/v) SDS, 20% (v/v) glycerol, 2% DTT, and trace bromophenol blue (*see* **Note 8**).
5. Alkylation equilibration buffer (50 ml): 375 m*M* Tris-HCl pH 8.8, 6 *M* urea, 2% (w/v) SDS, 20% (v/v) glycerol, 2.5% w/v iodoacetamide, and trace bromophenol blue (*see* **Note 8**).
6. 40% acrylamide/bisacrylamide stock solution (29:1): 40% w/v acrylamide, 1.38% w/v N, N′-methylenebisacrylamide (*see* **Note 4**) (Catalog No. 161-0146, Bio-Rad).
7. 10% Ammonium persulfate (3 ml) is made just prior to use (*see* **Note 5**).
8. SDS electrophoresis buffer (1 ×; 25 L): 25 m*M* Tris, 192 mM glycine, and 0.1% SDS. Store at room temperature. (*see* **Note 9**).
9. 1% Agarose sealing solution (100 ml) is made by heating until the agarose is completely dissolved and kept at 80°C prior to use. (*see* **Note 10**).

2.5. Western Blotting for Nitrotyrosine Based on 1-D SDS-PAGE

1. Transfer buffer (1 L): 25 m*M* Tris, 192 m*M* glycine, and 10% (v/v) methanol.
2. Polyvinylidene fluoride (PVDF) membrane: Immobilon-P transfer membrane (Catalog No. IPVH 081 00; Millipore, Bedford, MA) (*see* **Note 11**).
3. Mini Trans-blot filter paper (7.5 × 10 cm, Catalog No. 1703932; Bio-Rad).
4. Tris-buffered saline (TBS) stock solution (10×): 250 m*M* Tris-HCl pH 7.4, 1.37 *M* NaCl, 27 m*M* KCl. Dilute 100 ml with 900 ml deionized water for use.
5. Blocking solution: 1% (w/v) fraction V bovine serum albumin in TBS.

6. Primary antibody: mouse antinitrotyrosine monoclonal antibody, clone 1A6 (100 µg/100 µl Catalog number 05-233, Upstate Biotechnology, Lake Placid, NY). Dilute in 1:2000 with 3% BSA in TBS solution (0.5 µg Ab/mL) for use (*see* **Note 12**).
7. Secondary antibody: Sheep antimouse IgG conjugated with horse radish peroxidase (Catalog No. NXA931, Amersham). Dilute 1:7500 in 5% nonfat dry milk (NFDM) in TBS solution for use.
8. Enhanced chemiluminescent (ECL) reagents (Catalog No. RPN2106; Armersham Amersham Biosciences, Piscataway, NJ) and Bio-Max ML film (Kodak, Rochester, NY).

2.6. Western Blotting for Nitrotyrosine Based on Large-Format 2DGE

1. Gel equilibration buffer (1 L): 25 m*M* Tris and 192 m*M* glycine.
2. PVDF membrane equilibration buffer (1 L): 25 m*M* Tris, 192 m*M* glycine, and 20% (v/v) methanol.
3. Polyvinylidene fluoride (PVDF) membrane: Hybond-P 20 × 20 cm (Product No. RPN2020F; Amersham), or Immobilon-P transfer membrane (IPVH 20200; Millipore, Bedford, MA).
4. NovaBlot Electrode Filter Paper (Product No. 80-1105-19; Amersham).
5. Anode transfer buffer R (1 L): 3.63% (w/v) Tris, 20% (v/v) methanol, pH 10.4.
6. Anode transfer buffer S (1 L): 0.303% (w/v) Tris, 20% (v/v) methanol, pH 10.4.
7. Cathode transfer buffer T (1 L): 0.52% (w/v) 6-amino-n-hexanoic acid, 20% (v/v) methanol, pH 7.6).
8. Phosphate-buffered saline (PBS) (200 m*M*; 20 ×): 4.6 g NaH_2PO_4 (or 5.3 g $NaH_2PO_4 \bullet H_2O$), 23 g Na_2HPO_4, 175 g NaCl, and 0.2 g NaN_3 are dissolved in c.750 ml deionized destilled water, adjust pH to 7.22, add deionized destilled water to 1 liter. Store at room temperature.
9. PBS: 10 m*M* PBS. 50 ml of 20 × PBS is diluted with 950 ml deionized water.
10. PBST: 10 m*M* PBS, 0.2% (v/v) Tween-20, and 0.01% sodium azide.
11. 0.3% BSA/PBST: 0.3% w/v BSA, 10 m*M* PBS, 0.2% v/v Tween-20, and 0.01% w/v sodium azide.
12. Primary antibody: Rabbit anti-human nitrotyrosine antibody (Sigma, N0409, St. Louis, MO). Dilute (1:1000=v:v) in a 0.3% BSA/PBST solution (1 µg Ab/mL) for use.
13. Secondary antibody: goat antirabbit alkaline phosphase-conjugated IgG (Product No. 31340; Pierce, Rockford, IL). Dilute (1:5000 = v:v) in a 0.3% BSA/PBST solution for use.
14. Development reagent: 5-bromo-4-chloro-3-indolyl phosphate/nitro blue tetrazolium (BCIP/NBT) (1-Step™ NBT/BCIP; Pierce, Rockford, IL).

2.7. Immunoprecipitation of Nitrotyrosine-Containing Protein

1. M-PER® mammalian protein extraction reagent (Pierce).
2. ImmunoPure® Immobilized Protein G plus (Pierce). Store at 4°C (*see* **Note 13**).

3. Binding/washing buffer: 140 m*M* NaCl, 8 m*M* sodium phosphate, 2 m*M* potassium phosphate, and 10 m*M* KCl, pH 7.4.
4. Rabbit Anti-nitrotyrosine polyclonal antibody (Chemicon® International, Inc.), or mouse anti-nitrotyrosine monoclonal antibody (Chemicon® International, Inc.).
5. Disuccinimidyl suberate (DSS), 2 mg/tube (Pierce) (*see* **Note 14**).
6. ImmunoPure® IgG Elution Buffer (Pierce), pH 2.8 contains primary amine.
7. Handee™ Spin Cup Columns (Pierce Product No. 69700).
8. Handee™ Microcentrifuge Tubes (Pierce Product No. 69715).
9. The pH-neutralized solution: 1 *M* Tris, pH 9.5.

2.8. Tandem Mass Spectrometry Characterization of Nitrotyrosine-Containing Protein

1. Sequencing grade modified trypsin (Catalog No. V511A, 5 × 20 µg aliquots; Promega). Store at −20°C (*see* **Note 15**)
2. Trypsin resuspension buffer (Promega Catalog No. V542A): 50 m*M* acetic acid.
3. 30 m*M* potassium ferricyanide (100 ml) is stored at 4°C.
4. 100 m*M* sodium thiosulfate (100 ml) is stored at 4°C.
5. 100 m*M* ammonium bicarbonate (100 ml) is stored at 4°C.
6. 50 m*M* ammonium bicarbonate (100 ml) is stored at 4°C.
7. 1% trifluoroacetic acid (TFA) (100 ml) is stored at 4°C.
8. 0.1% TFA (1 ml) is made prior to use.
9. 50% acetonitrile/0.1% TFA (1 ml) is made prior to use.
10. ZipTipC18 microcolumn (Millipore ZTC18S096, Bedford, MA).
11. 85% v/v acetonitrile/0.1% v/v TFA (1 ml) is made prior to use.
12. 2% actonitrile/0.5% acetic acid (1 ml) is made prior to use.

3. Methods

Tyrosine nitration in a protein is a relatively stable redox product that is produced due to oxidative/nitrative stress associated with physiological and pathology processes. The chemical structure of nitrotyrosine is a nitro (NO_2) group added to position 3 of the phenolic ring of a tyrosine residue. Commercially available anti-nitrotyrosine monoclonal and polyclonal antibodies enable one to determine the level of nitrotyrosine by ELISA (amount of nitrotyrosine per unit weight tissue), to detect the profile of nitrotyrosine-containing proteins by Western blotting based on 2DGE ***(1,13)*** (*see* **Fig. 1**) or 1-D SDS-PAGE ***(17,18)***, and to isolate and enrich nitroproteins by immunoprecipitation ***(14)*** and 2DGE Western analysis ***(1,13)***. For those isolated and enriched nitroproteins, tandem mass spectrometry is used to obtain each amino acid sequence and to identify each nitrotyrsoine-containing protein and nitration-sites ***(1,13,14)*** (*see* **Fig. 2**).

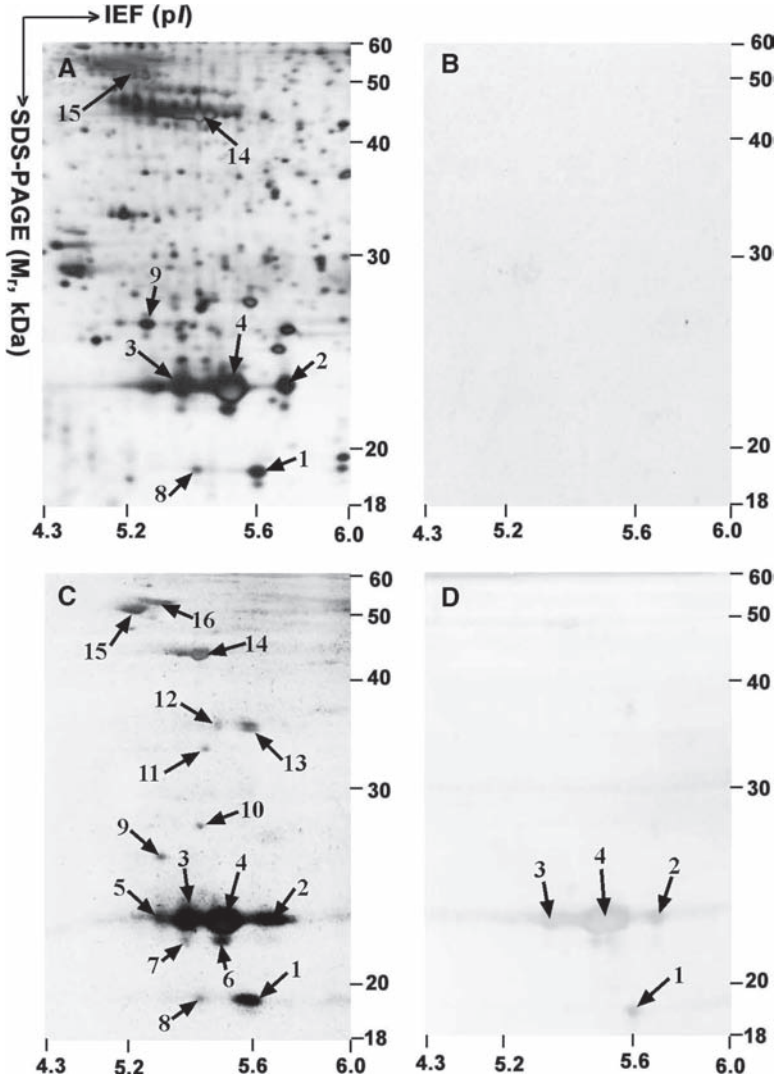

Fig. 1. Two-dimensional Western blot analysis of anti-3-nitrotyrosine proteins in a human pituitary (70 µg protein per 2-D gel). **(A)** Silver-stained image on a 2D gel before transfer of proteins to a PVDF membrane. **(B)** Silver-stained image on a 2D gel after transfer of proteins to a PVDF membrane. **(C)** Western blot image of anti-3-nitrotyrosine proteins (anti-3-nitrotyrosine antibodies + secondary antibody). **(D)** Negative control of Western blot to show the cross-reaction of the secondary antibody (only the secondary antibody; no anti-3-nitrotyrosine antibody). (Reproduced from ***ref. 1*** with permission from Elsevier Science).

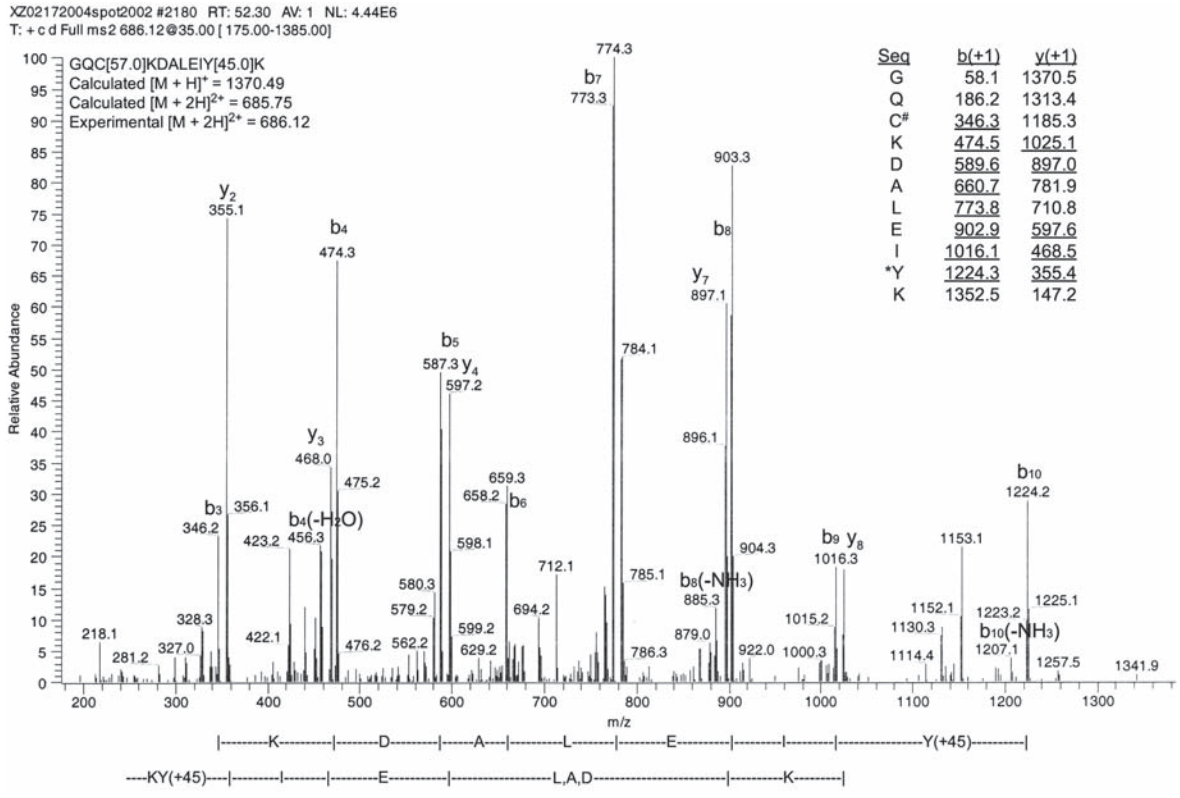

Fig. 2. SEQUEST **(top-right)** and de novo **(bottom)** analysis of an MS^2 spectrum of the precursor ion ($(M+2H)^{2+}$, at *m/z* = 686, RT = 52.3 min, and scan number 2180) for a nitrotyrosyl peptide (Tyr-237) ^{228}GQC$^{\#}$KDALEI*YK^{238} that contained 11 amino acids, and that derived from synaptosomal-associated protein. (Reproduced from ***ref. 1*** with permission from Elsevier Science).

3.1. Preparation of Samples

1. The human normal (control) pituitary tissue that is obtained from autopsy or the pituitary adenoma tissue that is obtained from neurosurgery is frozen immediately in liquid nitrogen, stored at − 80°C until processed.
2. Weigh the wet tissue: weigh an empty clean 15-ml tube (WT1), transfer the frozen tissue quickly and carefully, weigh the tube with tissue (WT2). The tissue weight = WT2-WT1.
3. Add 2 ml of 0.9% sodium chloride, and lightly shake to remove the blood on the surface of tissue. Repeat 3 times (*see* **Note 16**).
4. Add 10 ml homogenization buffer for c.0.5–0.6 g tissue, and homogenize fully (1 min × 10) with a Polytron homogenizer (13 000 rpm) in 4°C cold room. The homogenate is sonicated with a Fisher sonicator (Power setting = 5) for 20 s.
5. 1 ml of homogenate is centrifuged (10,000 g, 10 min). The supernatant is used for ELISA analysis to determine the nitrotyrosine concentration (see **step 1** in **Subheading 3.2**).
6. The remaining homogenate is lyophilized in 1 ml aliquots, and stored at − 80°C.
7. The total protein content in the lyophilized pituitary is measured with a bicinchoninic acid (BCA) protein assay reagent kit. (*see* **Note 17**).

   (a) 280 µg of lyophilized pituitary sample is added into 264 µl solution that contains 8 *M* urea and 4% CHAPS. Stand for 2 h, sonicate for 5 min, rotate for 1 h, sonicate for 5 min, rotate for 1 h, centrifuge at 12,000 rpm for 20 min. The supernatant is used for the BCA analysis.
   (b) Preparation of BSA standard solution: Dilute BSA standard (2 mg/ml) for the following dilution series: 2000, 1500, 1000, 750, 500, 250, 125, 25, 0 µg/ml.
   (c) BCA working solution: 50 part of reagent A + 1 part of reagent B (50:1), mix fully prior to use.
   (d) 0.1 ml sample or standard dilution is mixed with 2 ml BCA working solution (1:20). Incubate at 37°C for 30 min. Cool to room temperature (c.10 min). Measure the O.D. value ($A_{562\,nm}$) on the spectrophotometer.
   (e) Use linear regression to make the standard line (BSA concentration vs. $A_{562\,nm}$), and obtain a regression equation that use $A_{562\,nm}$ to estimate the protein concentration. The regression equation is used to calculate the protein concentration of a lyophilized pituitary sample.

3.2. ELISA for Tissue Nitrotyrosine Level

1. The supernatant of 1 ml homogenate of pituitary tissue is dialyzed with a Slide-A-Lyzer dialysis cassette in 1000 ml PBS for 120 min. Change fresh PBS every 40 min.
2. Preparation of 20 µM standard nitrated BSA (50 ml): 66 mg BSA is dissolved in 50 ml of 50 m*M* Tris-HCl pH 8.0. Add 599 µl tetranitromethane into the above BSA solution, react for 5 min at room temperature. For removal of salt and tetranitromethane, the nitrated BSA solution is dialyzed with a Slide-A-Lyzer dialysis cassette in 1000 ml PBS for 120 min; change fresh PBS every 40 min. The dialyzed nitrated BSA is stored at − 80°C.

3. Make coating reagent: dilute 20 µ*M* nitrated BSA with PBS in 1:20 dilution.
4. Add 100 µl coating reagent per well into Costar® EIA/RIA plate with 96-well flat bottom. Incubate at 37°C for 1 h. Wash with 300 µl PBS/well for 3 times.
5. During coating, prepare the blocking solution: 1% Chicken ovalbumin in PBS.
6. Add 300 µl blocking solution per well, and incubate at 37°C for 1 h (Note: this step can be incubated longer). Wash with 300 µl PBS/well for 3 times.
7. During blocking, prepare 11 standard dilution series (0.4 dilution) of 20 µM (20000 pmol/ml) nitrated BSA: 20,000, 8,000, 3,200, 1,280, 512, 205, 82, 33, 13, 5, 2 pmol/ml, and each concentration 125 µl. Prepare 6 sample dilution series (0.2 dilution) of pituitary samples, and each concentration 125 µl. Meanwhile, prepare primary antibody: dilute mouse anti-nitrotyrosine monoclonal antibody in 1:2,000 dilution with 0.2% chicken ovalbumin in PBS.
8. Mix 125 µl of diluted primary antibody and 125 µl standard nitrated-BSA serial sample (or sample dilution series); incubate at 37°C for 1 h.
9. Add 100 µl of mixture above per well (duplicates), and shake at room temperature for 1 h. Wash with 300 µl PBS/well for 3 times.
10. Dilute secondary antibody (anti-mouse IgG-alkaline phasphatase) in 1:2000 dilution with 1% chicken ovalbumin in PBS. Add 100 µl diluted secondary antibody/well, shake at room temperature for 1 h. Wash with 300 µl PBS for 3 times.
11. Add alkaline phosphatase substrate pNPP solution (100 µl/well). Stand at room temperature until maximum absorbance reaches 0.6–1.0. Measure the absorbance at 405 nm and 655 nm.
12. Make the standard curve (log value of nitrated BSA concentration vs. O.D.) with the SigmaPlot software, and obtain a curve equation. Use sample O.D. value to calculate the nitrotyrosine concentration of pituitary sample (*see* **Note 18**). Convert the nitrotyrosine concentration to the nitrotyrosine amount per gram pituitary tissue.

3.3. 1-D SDS-PAGE and Western Blot for Nitrotyrosine Immunoactivity

1. Protein extraction for SDS-PAGE: An amount of lyophilized pituitary that contains 100 µg protein is dissolved in 100 µl protein extraction buffer, stand for 1 h, sonicate 20 s, rotate 1 h, sonicate 20 s. Centrifuge for 20 min at 13,000 × g. The supernatant is the extracted protein.
2. Bio-Rad Mini PROTEAN® Electrophoresis system is used; easily adaptable to other formats. The glass plates for gel is cleaned with the detergent; rinsed extensively with tap water, ethanol, distilled water, and ethanol; dried in a clean plastic rack for use. Install the long and short glass plates in the gel cassette (avoid the bottom leaking).
3. Preparation of a 1.5 mm thick, 12% resolving-gel: 4 ml of 30% acrylamide/0.8% bisacrylamide, 3.34 ml deionized water, 2.5 ml of 1.5 *M* Tris-HCl pH 8.8, and 100 µl of 10% SDS are mixed in a clean 50-ml tube. Add 50 µl of 10% ammonium persulfate and mix quickly, add 5 µl of TEMED, and mix quickly and fully. Pour the resolving gel solution into the assembled gel cassette (avoid generating

bubbles), leave 1.0–1.5 cm space for a stacking gel. Overlay the resolving gel with 1 ml of 50% isobutanol-water solution. Stand (room temperature) and avoid moving the gel cassette. The gel will be polymerized in 30–40 min. Remove the isobutanol and rinse with distilled water 3 times, and absorb the redundant water with KimWipe paper.

4. Preparation of a 4% stacking gel: 0.8 ml of 30% acrylamide/0.8% Bis, 3.6 ml deionized water, 1.5 ml 0.5 M Tris-HCl pH 6.8, and 60 µl 10% SDS are mixed in a clean 50-ml tube. Add 30 µl of 10% ammonium persulfate and mix quickly. Add 6 µl TEMED and mix quickly and fully. Pour the stacking gel solution onto the polymerized resolving gel up to the top-end of short glass plate. Insert quickly 1.5-mm thick and 10-well comb into the resolving gel. The stacking gel will be polymerized in 30–40 min.
5. Preparation of electrophoresis running buffer: dilute 100 ml of 10 × running buffer with 900 ml distilled water in a 1000-ml measuring cylinder.
6. Assemble the prepared gel cassette into the Bio-Rad Mini PROTEAN® electrophoresis cell. Add the running buffer into the upper and lower chambers of the gel unit. Let the electrophoresis running buffer cover the top-end of prepared gel. Remove gently and carefully the comb, and the running buffer will automatically fill in each well.
7. Mix 10 µl of the extracted protein and 20 µl of sample loading buffer in a 0.5-ml tube, and boil in 100°C water. Cool to room temperature. Load 30 µl of the prepared sample in a well. Meanwhile, load 5 µl of prestained molecular weight markers into another well.
8. Complete the assembly of the gel unit by covering the lid and connect to the power supply. The gel is run at constant 80 V for 10 min, then at constant 120 V. Stop electrophoresis when the dye front is 0.5 cm from the bottom of glass plate. After electrophoresis, the separated protein is visualized with development reagent, such as Gel-code blue (*see* **step 9**) and silver stain (*see* **step 21** in **Subheading 3.4**), or is transferred to PVDF membrane for Western blot analysis (*see* **step 10** and forward).
9. Disassemble the mini-gel unit. Remove the gel carefully, and avoid breaking the gel. Put gel in the clean flat tank, wash with distilled water (shake, 5 min). Replace with 100 ml Pierce Gel-Code blue reagent and shake gently for 1–2 h. Destain with distilled water until the gel band is clearly visible and the gel background is very low.
10. Disconnect the power supply and disassemble the mini-gel unit. Remove the gel, cut a small corner for labeling, and gently shake in transfer buffer for 10 min.
11. Preparation of PVDF membrane: cut a piece of PVDF membrane (6 × 9 cm) and put it in the 100% methanol and shake for 10 min. Replace methanol with distilled water to check quickly its hydrophilic side (water moves slowly on the hydrophilic side and fast on the hydrophobic side). Use pencil to write the date for label on the margin of the hydrophilic side. Replace water with transfer buffer and shake for at least 10 min.
12. Wet two Mini Tans-blot Filter papers (6 × 9 cm) and two clean fiber pads in the transfer buffer.

13. Assemble the transfer cassette: Put the black-side of the clean plastic transfer cassette down and open the cassette. Lay on one wet fiber pad onto the blackside. Lay on one sheet of wet filter paper on the wet fiber pad, and remove any bubbles. Put the gel on the filter paper and remove any bubbles. Put the PVDF membrane (the hydrophilic side down) on the gel and remove any bubbles. Put one sheet of wet filter paper on the PVDF and remove bubbles. Put one wet fiber pad on the filter paper. Close the transfer cassette.
14. The assembled transfer cassette is placed into the transfer tank with sufficient transfer buffer and a magnetic stir bar. The black side of the transfer cassette is toward the black side (cathode, -). Put into a flat box of cooling ice. The lid is put on the transfer tank and connected to the power supply. The transfer tank is covered with ice. Transfer is carried out at 320 mA constant for 2 h or at 300 V constant for 1 h.
15. After transfer, disconnect the power supply, disassemble the transfer cassette (Position the gel up and PVDF down), and use a pencil to draw a line around the gel on the hydrophilic side of PVDF for labeling. Remove the gel. Place the PVDF membrane into a block solution.
16. The PVDF membrane (protein-side up) is blocked in 1% BSA-TBS solution (gently shake for 1 h) (*see* **Note 19**). After block, the PVDF is washed two times with deionized water.
17. Add the primary antibody solution 30 ml (15 µl mouse anti-nitrotyrosine monoclonal antibody is diluted in 30 ml of 3% BSA in TBS solution), and incubate for 1 h at room temperature. Pour out the primary antibody solution. Wash with 100 ml of 0.2% Tween-20 in TBS for 10 min for 6 times.
18. Add the secondary antibody solution (6.7 µl antimouse IgG conjugated with horse radish peroxidase diluted in 50 ml of 5% nonfat dry milk in TBS), and incubate at room temperature for 1 h with gentle shaking. Pour out the secondary antibody solution. Wash with 100 ml of 0.2% Tween-20 in TBS for 10 min for 3 times. Wash with 100 ml of TBS for 10 min for 3 times. Rinse with deionized water for 4 times (*see* **Note 20**).
19. ECL visualization of the blotted PVDF membrane: Absorb the redundant water on the PVDF membrane between two sheets of filter paper. Place PVDF membrane on a clean glass plate (protein-side up) and cover with pre-prepared ECL reagent (4 ml ECL reagent A is mixed fully with 4 ml ECL reagent B prior to use). Incubate for 3–5 min. Dry the PVDF membrane between two sheets of filter paper. The PVDF membrane is placed between two transparent plastic sheets, and fixed in an X-ray film cassette. The remaining following steps are carried out in a dark room under the safe red light conditions.
20. Put a sheet of film on the transparent plastic sheet that contains the PVDF membrane and close the X-ray film cassette for a suitable exposure time, typically a few minutes. If the detected protein is very low, then expose for several hours to overnight. If the detected protein is very high, then expose for 10 s to 1 min. Remove the film and place it into an automatic image instrument to obtain the Western blotting image.

3.4. 2DGE and Western Blot for Nitrotyrosine Immunoactivity

1. Protein extraction for 2DGE: Weigh sufficient lyophilized pituitary sample to mix with 250 µl of the protein extracting buffer. The mixture is vortexted for 5 min, sonicated for 5 min, and rotated for 50 min. Add 110 µl of rehydration buffer. The mixture is sonicated for 5 min, rotate for 50 min, vortexed for 5 min, and centrifuged for 20 min at 15,000 g. The supernatant is the "protein sample solution" ***(20)***.
2. Rehydration of IPG strip (*see* **Note 21**): add 350 µl of the "protein sample solution" into a slot of the rehydration tray. Remove the plastic cover from the Dry IPG strip (do not touch gel-side). Place slowly and carefully strip gel-side-down on the "protein sample solution" in the rehydration tray; and distribute the "protein sample solution" evenly along the whole strip length under the IPG strip; avoid bubbles. Overlay strip with 3–4 ml of mineral oil. Rehydrate the strip overnight (c.18 h; room temperature).
3. The first-dimension, isoelectric focusing (IEF) is performed on an Amersham Multiphor II Electrophoresis system (*see* **steps 4–10**).
4. Assemble the Amersham Multiphor II instrument, connect the red bridging cable, and set the Multitemp water circulator to 20°C.
5. Add 6–7 ml of mineral oil to the center of the cooling plate. Position the Drystrip tray onto the mineral oil on the cooling plate (the red wire towards the rear); distribute mineral oil evenly between the Drystrip tray and the cooling plate (no bubbles). Insert red electrode wire (anode, +) into the rear receptacle; connect black electrode to the pin in the front.
6. Add 12 ml of mineral oil into the Drystrip tray. Place immobiline strip aligner (plastic sheet with grooves up) on top of the oil in the Drystip tray; distribute evenly the mineral oil between plastic sheet and the Drystrip tray (avoid bubbles; avoid getting mineral oil on top of plastic sheet); and line up grooves with the pattern on the cooling plate.
7. Take the rehydrated IPG strip out of the rehydration tray, rinse fully with deionized distilled water (*see* **Note 22**), drain. Place the IPG strip (gel-side-up; pointed end (acidic/anode) towards the rear) into a groove in the strip aligner. An immobiline strip aligner can analyze up to 12 IPG strips at a time.
8. Cut two electrode paper strips (length = 110 mm), and moisten each electrode strip with 0.5 ml of distilled water. Blot the excess water on the electrode paper strips with paper tissue to make them slightly damp. Place the two moistened electrode paper strips on the gel surface of those aligned IPG strips (one across the cathode and one across the anode edges) (*see* **Note 23**). Position the electrodes onto the electrode paper strips (Red electrode goes to the rear right, black to the front left).
9. Pour 70–80 ml of mineral oil to completely cover the IPG strips. Place the lid onto the Multiphor II instrument, and connect to Amersham EPS3500XL power supply. The IEF parameters are: Step 1: 100 V, 2 mA, 5 W, 1 min gradient; Step 2: 100 V, 2 mA, 5 W, 2 h set; Step 3: 500 V, 2 mA, 5 W, 1 min gradient; Step 4: 3,500 V, 2 mA, 5 W, 1.5 h gradient; and Step 5: 3,500 V, 2 mA, 5 W, 8 h set. The total time is 11 h 32 min, Vh c.31,000.

10. After IEF, disassemble the unit, remove IPG strips, gently blot off mineral oil, wrap loosely in plastic wrap, and store at −80°C (*see* **Note 24**).
11. The second-dimension, SDS-PAGE is performed on a Bio-Rad PROTEAN plus® Dodeca™ cell vertical electrophoresis system (*see* **steps 12–19**).
12. Cast 12% PAGE resolving gel with a Bio-Rad PROTEN-plus Multicasting chamber: Assemble the PROTEIN-plus Multicasting chamber system. For 12 gels, mix 180 ml of 40% w/v acrylamide/bisacrylamide stock solution (29:1), 150 ml of 1.5 M Tris-HCl pH 8.8, 270 ml deionized distilled water; de-gas with vacuum pump for 10 min. Add 3 ml of 10% ammonium persulfate, and 150 µl TEMED to the mixture solution (mix gently and avoid any bubbles). Gently pour the solution into holding chamber, and connect the holding chamber to the inlet port on multi-casting chamber. Place a gel comb in the first gel cassette. Elevate the holding chamber above the level of multi-casting chamber to fill the gel solution up to the level of the comb. Remove the comb, and overlay the gels with deionized distilled water immediately. Allow the gels to polymerize for >1 h (*see* **Note 25**).
13. Connect Dodeca cell tank to carboy that holds 25 L electrophoresis buffer to allow electrophoresis buffer to flow into the Dodeca buffer tank. Set the circulating water bath temperature to 15°C, and turn on the circulator at least 1 h prior to the actual run.
14. Take out the frozen focused IPG strips, stand at room temperature for 3 min, and put them (one in each slot) in the equilibrium tray (gel-side-up). Add c.4 ml of reducing equilibrium buffer, and rock gently for 10 min. Replace immediately the reducing equilibrium buffer with c.4 ml of alkylation equilibrium buffer for each slot, and rock gently for 10 min.
15. During equilibrium, discard the Multi-casting chamber. Remove the prepared gel plate, and rinse the top surface of gel with deionized distilled water three times. Absorb excess water on the top surface of gel with a KimWipe paper. Position the prepared gel plate on the gel-stander.
16. Remove the equilibrated IPG strip, rinse once in the electrophoresis buffer in a 20-cm length of cylinder; remove the redundant electrophoresis buffer on the surface of IPG strip. Position the IPG strip over the top of resolving gel, gel-side facing front, plastic back contacting the glass plate, the pointed-end of IPG strip to the left and the square end to the right. Load quickly *ca*. 3 ml of 1% agarose solution (c.80°C) onto the top of the resolving gel, push quickly the IPG strip into the un-polymerized agarose solution, and align the up-side of IPG strip onto the top of the shorter glass plate. Polymerize in c.10 min.
17. Use two hands to insert the prepared gel plate hinge side down (PROTEIN plus hinged spacer plate) near the bottom of the tank; the IPG stip-end of gel is positioned next to the cathode (black electrode card; -) so that the sample migrates toward the anode (red electrode card; +); and make sure that the gasket is flared out toward the electrode. Adjust the level of electrophoresis buffer to the middle of the top spacer (*see* **Note 26**).
18. Place the lid on the tank, and connect the pump tubing to the top of the lid. Set the Buffer Recirculation Pump to 100 and turn it on. Connect the Dodeca Cell to

the PowerPac 200 power supply. Electrophoresis is run under the conditions of constant voltage 200 V for 370 min.

19. After the electrophoresis, disassemble the Dodeca cell, take out the PROTEAN plus hinged spacer plate on the benchtop, short plate facing upward and the hinge to the left. Insert the gel releaser between the short and the long plate at the top right corner. Pull the gel releaser up, lift the short plate until the gel cassette is opened completely (180°). Separate gently the gel from the plate, and prevent the gel from tearing (*see* **Note 27**).
20. The separated protein on the 2DGE gel can be visualized with development reagent, such as silver stain (*see* **step 21**) and Gel-code blue (*see* **step 9** in **Subheading 3.3**), or transfer to PVDF membrane for Western blot analysis (*see* **step 22** and forward).
21. After electrophoresis, the gel is taken out, followed by silver staining: (1) Fix gel in 250 ml of (50% v/v methanol and 5% v/v acetic acid) (20 min); wash in 250 ml of 50% v/v methanol (10 min); wash in deionized water (10 min). (2) Sensitize the gel in 250 ml of 0.02% w/v sodium thiosulfate (1 min); wash with deionized water (1 min, 2 times). (3) Silver reaction (20 min) in 250 ml of the solution (0.1% w/v silver nitrate plus 200 µl 37% v/v formaldehyde prior to use); wash with deionized water (1 min, 2 times). (4) Develop in 250 ml of 3%w/v sodium carbonate with 100 µl 37% v/v formaldehyde (add prior to use) until the desired intensity of staining occurs (usually c.3 min). (5) Stop the development within 250 ml of 5% v/v acetic acid (10 min); wash the gel in deionized water (5 min). (6) Store the gel in 250 ml of 8.8% glycerol.
22. After electrophoresis, remove the 2D gel and orientate the 2D gel by removing the left-upper corner (acidic end), and soak the 2D gel in the gel equilibration buffer for at least 10 min.
23. Preparation of PVDF membrane: Cut a sheet of PVDF membrane to match the gel size (20 × 17.2 cm), and place into 100% methanol for 10 min, wash with destilled water for 5 min, and check its hydrophilic side (*see* **Note 28**). Use pencil to write the date on the margin of hydrophilic side of PVDF membrane. Equilibrate in the PVDF membrane equilibration buffer for at least 10 min (*see* **Note 29**).
24. The transfer is performed on an Amersham Multiphor II semi-dry electrotransfer system. Assemble the electroblotting cassette: (1) saturate anode electrode plate with deionized destilled water, and remove excess water with paper. Put it onto the buffer tank. (2) Immerse 6 filter papers in anode transfer buffer R, and place them carefully onto the anode plate. (3) Soak 3 filter papers in anode transfer buffer S, and place them carefully on the top of the first 6 filter papers. (4) Wet PVDF membrane in anode transfer buffer S for 30 s, and place PVDF (hydrophilic side up) onto the layer of second 3 sheets of filter papers. (5) Put the 2D gel onto the PVDF membrane. (6) Immerse 9 filtering papers in cathode transfer buffer T, and place them carefully on the top of the gel. (7) Saturate the cathode electrode plate with deionized distilled water, and remove excess water with a filter paper, place it on the 9 filtering papers. (8) Connect all units of the transfer system (*see* **Note 30**).

25. Close the lid and connect to the power supply (Amersham EPS 3501XL). Electrotransfer is performed at a constant current of 0.8 mA/cm^2 for 1 h 40 min. After transfer, remove the top filtering papers and draw a line around the 2D gel on the margin of PVDF membrane.
26. PVDF membrane (protein side up) is blocked in 100 ml of 0.3% BSA/PBST at room temperature for 60 min with gentle shaking. After blocking, the PVDF membrane is rinsed twice with water.
27. Add 100 ml of diluted primary antibody (100 µl rabbit anti-nitrotyrosine anbibody is diluted with 100 ml of 0.3% BSA/PBST). Incubate for 1 h at room temperature with gentle shaking. Pour out the primary antibody solution. Wash with 200 ml PBST with shaking (15 min; 4 ×). Rinse twice with deionized distilled water.
28. Add 100 ml of diluted secondary antibody (20 µl goat antirabbit alkaline phosphase-conjugated IgG is diluted in 100 ml of 0.3% BSA/PBST). Incubate at room temperature for 1 h with gentle shaking. Pour out the secondary antibody solution. Washing with 200 ml of PBST with shaking (15 min; 3 ×). Wash with 200 ml of PBS with shaking (15 min; 3 ×). Rinse 4 times with water (*see* **Note 20**).
29. The blot proteins are visualized by adding 1-Step™ NBT/BCIP substrate to cover the PVDF membrane (protein-side up) with gentle shaking until the desired color is obtained. Wash in deionized destilled water for 10 min. Dry the PVDF in the air or between two sheet of filter papers. Store between two leaves of transparent plastic sheet.
30. Scan the visualized PVDF membrane and the corresponding silver-stained 2D gel into a digitized image. Import the digitized image into the Bio-Rad PDQuest 2D gel image analysis software to generate the 2D gel spots and the PVDF blot spots. Match the immunopositive Western blotting spot to the corresponding silver-stained 2D gel spot (*see* **Figure 1**) (*see* **Note 31**).

3.5. Immunoprecipitation of Nitrotyrosine-Containing Proteins

1. Protein extraction for immunoprecipitation: A portion (e.g., c.62 mg wet weight tumor tissue) of pituitary tissue in 1.5-ml Eppendof tube is rinsed 3 times with binding/washing buffer to remove blood from the tissue surface. Add 600 µl of Pierce M-PER® mammalian protein extraction buffer that is compatible with immunoprecipitation (10:1 = buffer:tissue), votex 5 min, homogenize 5 min, sonicate 20 s, rotate 2 h, sonicate 20 s, and centrifuge at 13,000 g for 30 min. The supernatant is the extracted protein sample, which is transferred to a new tube. The protein content is measured with the Bio-Rad Bradford Protein Assay reagent.
2. Immunoprecipitation of nitrotyrosine-containing proteins is carried out with a Pierce Seize X mammalian immunoprecipitation kit. Equilibrate Immobilized Protein G, Anti-nitrotyrosine antibody, and binding/washing buffer to room temperature.
3. Gently swirl the bottle of ImmunoPure Immobilized Protein G beads to resuspend fully the beads, and add 400 µl of beads into a 0.5-ml Handee spin-cup column that is placed inside a Handee microcentrifuge tube. Centrifuge at 3,000 g for 1 min. Discard the flow-through. Wash the beads with 400 µl of binding/washing buffer

(invert tube 10 times, centrifuge 3,000 g, 1 min) for 2 times. Put the spin-cub into a new microcentrifuge tube.

4. Add 300 µl binding/washing buffer and 100 µl (= 100 µg) anti-nitrotyrosine antibody, and invert quickly the spin-cup to mix the antibody and beads. Incubate at room temperature for 1 h with gently rotating to allow antibody to bind the protein G. Centrifuge at 3,000 g for 1 min and discard the flow-through. Wash with 500 µl binding/washing buffer (invert 10 times, centrifuge at 3,000 g for 1 min) for 3 times. Put the spin-cup into a new microcentrifuge tube.
5. Dissolve 2 mg disuccinimidyl suberate (DSS) in 80 µl dimethyl sulfoxide (DMSO). Dilute 25 µl DSS with 400 µl binding/washing buffer, and add 425 µl diluted DSS solution to the washed beads with immobilized protein G antibodies. Invert the tube quickly and incubate for 30 min with gently rotating to allow the antibodies to crosslink with the immobilized protein G (*see* **Note 14**). Centrifuge at 3,000 g for 1 min, and discard the flow-through.
6. Wash the beads with crosslinked protein G-antibodies with 500 µl of elution buffer (pH 2.8) (invert 10 times, centrifuge at 3,000 g for 1 min) for 5 times. Put the spin-cup into a new microcentrifuge tube.
7. Wash the antibody-protein G-beads with 500 µl binding/washing buffeer (invert tube 10 times, centrifuge 3,000 g for 1 min) for 4 times.
8. Dilute the extracted pituitary protein samples with binding/washing buffer (at least 1:1 dilution). Add 500 µl of diluted sample to the prepared antibody-protein G-beads, mix quickly by inverting the tube. Incubate overnight (gently rocking, 19 h, 4°C) to bind nitrotyrosine-containing proteins with anti-nitrotyrosine antibodies. Centrifuge at 3,000 g for 1 min, and discard the flow-through.
9. Wash the beads with nitroprotein with 400 µl binding/washing buffer (invert tube 10 times, centrifuge 3,000 g for 1 min) for 3 times to remove any nonbound proteins.
10. Elute the bound nitroproteins with 200 µl elution buffer (pH 2.8) that contains a primary amine (gently mix well, centrifuge 3,000 g, 1 min) for 3 times. The eluates that contain nitroproteins are collected, add 10 µl of the pH-neutralized solution per 200 µl eluate. If necessary, the eluate may be dried partially to elevate the concentration of nitroprotein.

3.6. Tandem Mass Spectrometry Characterization of Nitrotyrosine-Containg Proteins

1. Trypsin digestion of immunoprecipitated nitroprotein: The immunoprecipitated protein is digested with trypsin (*see* **Note 32**). The procedure ***(14)*** is:
   (a) To a vial of sequencing grade-modified trypsin (20 µg, Promega, Madison, WI), add 5µl trypsin resuspension buffer that contains 50 m*M* acetic acid (pH 2.8) and 95 µl of 200 m*M* NH_4HCO_3 (pH 8.2), and mix fully.
   (b) Add 20 µl of the eluate that contains nitroproteins into a 0.5-ml siliconized tube (*see* **Note 33**).
   (c) Add 1µl of solution that contains 1 *M* Tris (pH 9.5), 100 m*M* dithiothreitol, and 100 m*M* iodoacetamide.

(d) Add 25 µl trypsin solution and 54 µl ddH_2O, mix fully to form the enzyme digestion reaction system (100 µl, final concentration of NH_4HCO_3 = 50 m*M*, pH 8.1). Incubate overnight (37°C, 23 h).

2. Trypsin digestion of in-gel nitroprotein: Excise the protein spot that corresponded to the nitrotyrosine immunopositive spot from the 2-D gels, and digest with trypsin (*see* **Note 32**). The procedure ***(20)*** is:

   (a) Cut the silver-stained gel spots and place into a 1.5 mL siliconized tube (*see* **Note 33**). Wash 6 times with 500 µl of deionized water. Transfer the gel into another 1.5-mL siliconized tube, and mince it into several pieces (c.0.5–1 mm^3) with a pipette tip.
   (b) Pior to use, prepare the destaining solution by mixing 30 m*M* potassium ferricyanide with 100 m*M* sodium thiosulfate (1:1 v/v). Add 20 µl of fresh destaining solution to destain the gel pieces until the brownish color disappears (c.1–2 min). Remove the destaining solution, and wash 5–6 times the gel pieces with 20 µl water until the yellow color disappears.
   (c) Incubate the gel pieces for 20 min in 20 µl of 200 m*M* ammonium bicarbonate. Discard the buffer, and wash once the gel pieces with 20 µl water.
   (d) Dehydrate the gel pieces with 30 µl acetonitrile for 2 times until the gel pieces turn an opaque white. Dry in a vacuum centrifuge for 30 min at 30°C.
   (e) Add 100 µl of trypsin resuspension buffer to a vial of lyophilized trypsin powder (20 µg, 833 pmol) (Promega V5111), and mix fully. Dilute the trypsin solution (20 µl, 200 ng/µl) to 16 ng/µl with 230 µl of 50 mM ammonium bicarbonate.
   (f) Add 20–30 µl (0.32–0.48 µg) of the diluted trypsin solution to each dried gel piece. The gel piece should be covered by the digestion solution. Incubate (37°C, c.18–20 h), cool (4°C, 30 min).
   (g) Gently centrifuge for 10 s, sonicate in a water bath (30°C) for 5–6 min, and centrifuge at 12,000 g for 2 min. Transfer carefully the supernatant into a 0.5-ml siliconized tube.
   (h) Add 10–15 µl of 50 mM ammonium bicarbonate to the gel pieces to repeatedly extract (2 ×) tryptic peptides **(step 7)**. Combine all supernatants (the tryptic peptide mixture).

3. The tryptic peptide mixture from a 2-D gel spot or 20–40 µl tryptic peptide mixture from immunoprecipitated proteins is purified with a ZipTipC18 beads microcolumn (Millipore ZTC18S096, Bedford, MA). Set up the pipette to the 10-µl scale. Wash 5 times the beads with 10 µl acetonitrile, and 5 times with 10 µl of 50% acetonitrile. Equilibrate 5 times with 10 µl of 0.1% TFA. Bind the tryptic peptides by pipetting the sample up and down 15 times. Wash twice with 10 µl of 0.1% TFA.
4. Elute the purified tryptic peptide mixture with 6 µl of 85% v/v acetonitrile/0.1% v/v TFA by pipetting up and down for 10 times. The eluate is air-dried. Prior to MS analysis, redissolve the dried tryptic peptide mixture with 6 µl of 2% actonitrile/0.5% acetic acid.
5. The tandem mass spectrometry analysis of the purified tryptic peptide mixture is carried out with a capillary liquid chromatography (LC)- electrospray

ionization (ESI)-quadropole ion-trap (Q-IT) mass spectrometer system (LCQ^{Deca}; ThermoFinnigan, San Jose, CA).

6. Set the LCQ^{Deca} instrument parameters as follows: ESI voltage 2.0 kV, capillary probe temperature 110°C, and electron multiplier −900 V. Use a solution (1 pmol/ul) of synthetic des-arg bradykinin to determine the instrument sensitivity and mass accuracy. In the MS mode, the $(M + 2H)^{2+}$ ion of des-arg bradykinin at *m/z* 452.7 should have a signal intensity of 1×10^7 (arbitrary units) at a flow-rate of 0.5 µl/min. In the MS/MS mode, the precursor ion at *m/z* 452.7 should produce *m/z* 404.2, 710.4, and 807.4. Acquire the MS/MS data in the "triple-play" data-dependent scan mode that includes four scan events: a full-range MS scan, and three MS/MS scans that depend on the "triple-play" data scan mode.
7. Inject manually 6 µl tryptic peptide mixture into the LC system. Separate the peptide mixture on a capillary column: New Objective PicoFrit 360 µm (OD), 75 µm (ID), 15 µm tip pores (ID) packing an 8 cm length Magic C18AQ material material (5 µm beads, 200 Å pores) (Michrom Bioresources, Auburn, CA). Elute (35 µl/min flowrate) peptides with the following five gradients (Solution A = water + 0.1% v/v formic acid; Solution B = 90% v/v acetonitrile + 0.1% v/v formic acid): (1) 100% solution A and 0% solution B (5 min); (2) linear gradient up to 35% solution A and 65% solution B within 30 min; (3) maintain 35% solution A and 65% solution B (15 min); (4) linear gradient down to 100% solution A and 0% solution B within 5 min; and (5) maintain 100% solution A and 0% solution B. The peptides elute directly into the ESI source. All MS/MS data are acquired and managed with the ThermoFinnigan Xcalibur software.
8. Identification of a nitrotyrosine-containing protein. Use amino acid sequence to identify the protein by searching the SWISS-PROT and NCBInr databases with the SEQUEST software that is a part of the LCQDeca software package. Mass modifications of +45 kDa (+ NO_2–H) at Tyr, of +57 kDa (+NH_2COCH_2–H) at Cys, and of +18 kDa at Met are considered in the search. Each positive search result – nitration of a Tyr residue – is confirmed with a manual check of the original LC, MS, and MS/MS data to determine each nitration site. During the analysis of those nitrated proteins, the following experimental criteria are applied: K or R at the C-terminus; K, R, or D ***(1)*** preceding the N-terminus; 0 or 1 missed trypsin cleavage sites; singly charged product b- and y-ions, and Homo sapiens. *De novo* sequencing is used to independently and accurately determine each amino acid sequence. The amino acid sequence from *de novo* sequencing is used to search the human SWISS-PROT protein database with the SIB BLAST search engine (http://us.expasy.org/tools/blast/). An example **(Fig. 2)** demonstrates the identification of a nitrotyrosine-containing protein.

4. Notes

1. The water that is used to make all buffers/solutions and to wash gels should be deionized distilled (dd) water that has a resistivity of 18.2 MΩ^{-cm}. We often use Millipore water.

2. Tetranitromethane is an oxidizing reagent; very toxic; irritating to the eyes, respiratory system, and skin with very serious irreversible effects. Experimental gloves should be worn, and one should operate in the hood.
3. Butylated hydroxytoluene (BHT) is an effective antioxidant to protect a sample from oxidation.
4. Acrylamide and bisacrylamide in the monomeric form are neurotoxins. Avoid inhaling and exposing to skin. Dispose ecologically of the remains by polymerizing the remains with an excess of ammonium persulfate ***(21,22)***.
5. Use fresh ammonium persulfate solution. Fresh ammonium persulfate "crackles" when water is added. It it does not, replace it with fresh stock.
6. High temperature will decompose urea. Work at < to 30°C.
7. For "protein extraction buffer" and "rehydration buffer", generally a stock solution (7 *M* urea, 2 *M* thiourea, 4% (w/v) CHAPS, and trace bromophenol blue) is made, and stored in 1 ml aliquots at −80°C. Prior to use, the protein extracting buffer is made by adding 15.4 mg DTT (final concentration = 100 m*M*) and 20 µl pharmalyte (final concentration = 0.5%) to 1 ml of rehydration stock solution, and mix well. The rehydration buffer is made by adding 9.2 mg DTT (final concentration = 60 mM) and 5 µl Pharmacia IPG buffer (final concentration = 0.5%) to 1 ml of rehydration stock solution, and mix well. Thus, DTT, pharmalyte, and IPG buffer will be fresh.
8. For "reducing equilibration buffer" and "alkylation equilibration buffer," generally an SDS equilibration stock buffer (375 m*M* Tris-HCl pH 8.8, 6 *M* urea, 2% (w/v) SDS, 20% (v/v) glycerol, and trace bromophenol blue) is made, and stored in aliquots of 50 ml at −80°C. Prior to use, the reducing equilibration buffer is made by adding 1 g DTT (final concentration = 2% w/v) to 50 ml of SDS equilibration stock buffer, and mixed well. The alkylation equilibration buffer is made by adding 1.25 g iodoacetamide (final concentration = 2.5% w/v) to 50 ml of SDS equibration stock buffer, and mix well. Thus, DTT and iodoacetamide will be fresh.
9. SDS is a strong detergent that irriates the respiratory system. Avoid inhaling the SDS powder when SDS is weigh.
10. The Agarose solution should not be boiled over. If the solution turns light yellow, it should be replaced with a fresh agarose solution.
11. There are commonly two type of Immobilon-P transfer membrane: 0.45 µm and 0.2 µm. The 0.45-µm PVDF membrane is often used to transfer the protein, whereas the 0.2-µm PVDF membrane is often used to transfer small molecular weight proteins or peptides. If a 0.2-µm PVDF membrane is used to transfer protein, then there will be more resistance that decreases the transfer efficiency.
12. The anti-nitrotyrosine antibody is currently a commercial product that can be obtained from Upstate Biotechnology, International Chemicomn, and

Sigma, etc. A polycolonal or monocolonal antinitrotyrosine antibody can be obtained.

13. Pierce Immobilized protein G plus cross-linked 6% beaded agarose supplied as a 50% slurry (for example, 400 µl of settled gel is equivalent to 200 µl of 50% slurry) that contains 0.02% sodium azide. Binding capacity is > 20 mg human IgG per ml of settled gel.
14. Disuccinimidyl suberate (DSS) is a very strong crosslinker, whose activity is much stronger than DMP, another commonly used crosslinker. DSS is water-insoluble and should be first dissolved in an organic solvent such as DMSO or DMF, and added to the aqueous reaction mixture. DSS is moisture-sensitive. Store at 4–8°C in a desiccator. To avoid moisture condensation onto the product, the vial that contains DSS must be equilibrated to room temperature before opening. Prepare DSS solution just prior to use because DSS is readily hydrolyzed and becomes non-reactive. Overcrosslinking proteins with biological activity (e.g., enzymes, antibodies, etc.) could result in loss of activity possibly because of a conformational changes of the molecule. Activity loss also may occur when DSS modifies lysine groups that are involved in binding substrate or antigen. Adjusting the molar ratios of reagent to the target may overcome activity loss. Alternatively, use a cross-linker that targets a different functional group. Hydrolysis of DSS is a competing reaction and increases with increasing pH. Hydrolysis occurs more readily in dilute protein or peptide solutions. In concentrated protein solutions, the acylation reaction is favored.
15. Promega's Sequencing Grade Modified Trypsin is porcine trypsin modified by reductive methylation. Its resistance to proteolytic digestion is two times greater activity than unmodified trypsin. Sequencing Grade modified trypsin is further treated with TPCK followed by affinity purification to yield a highly active and stable molecule. Modified trypsin has maximal activity at pH 7–9, and is reversibly inactivated at pH 4. It is resistant to mild denaturing conditions: 0.1% SDS, 1 *M* urea, or 10% acetonitrile. Modified trypsin retains 48% activity in 2 *M* guanidine HCl.
16. It is important to wash the blood from the tissue surface. Care should be taken with small tissue samples because of loss of tissue.
17. In order to obtain consistent results among different samples when comparing gels, a lyophyilized pituitary is redissolved in a solution of 8 *M* urea and 4% CHAPS for BCA protein concentration analysis because BCA reagent is not compatible with thiourea, DTT, IPG buffer, and bromophenol blue. For different experiment, each time use the protein concentration of a fixed sample to verify the protein concentration of other samples.
18. The standard curve is an inverted "S"-like curve. The sample points that correspond to the linear section of the inverted "S"-like curve are used to determine the nitrotyrosine concentration of sample.

19. PVDF membrane with protein can be kept in blocking solution for 2–3 days at 4°C with gently shaking.
20. After blocking, incubation with primary antibody, and incubation with secondary antibody, wash fully because salt and Tween-20 could result in particles on the visualized PVDF that would increase the background.
21. The size of the commercially Amersham immobilized pH gradient dry strip is 0.5-mm thick and 3-mm wide with different length (7, 11, 13, 18, and 24 cm). The pH range is 3–10, 4–7, 6–9, 4–5, etc., with a linear pH gradient or non-linear pH gradient. The pH range of the IPG buffer should be consistent with the pH range of the IPG strip; for example, IPG buffer pH 3–10 NL matches the IPG stip pH 3–10 NL, IPG buffer pH 3–10 matches the IPG strip pH 3–10 (22).
22. It is necessary for a rehydrated IPG strip to be rinsed fully with ddH_2O to remove excess mineral oil and undissolved components.
23. The 110-cm long electrode paper strips not only conduct but also remove the salt from samples. The latter significantly improves the IEF effect because tissue samples all contain salts that will affect the IEF. If the salt is too high, during the IEF, the electrode paper strips may be replaced once with a new electrode strip.
24. After IEF, use only water and liquinox detergent (hot water works nicely to remove mineral oil) to clean electrodes, Dry strip tray, and strip aligner. Use paper towel to clean the cooling plate.
25. The cast gels can be used within a week when they are covered with moist filter paper and stored at 4°C. Moreover, for our 2-D gel studies, the reproducibility of a single-concentration gel is better than a gradient gel ***(23,24)***.
26. If the gel plate is completely immersed in buffer, then there will be a significant current leak that negatively affects the electrophoresis results. If the buffer level is not high enough to cover the entire gel area, then the end of the gel will show no separation.
27. After electophoresis, use only water to wash the Dodeca tank, gaskets, electrode cards, and lid. For long-term storage, flush all parts thoroughly with water to completely remove any residual buffer.
28. A PVDF membrane has two different sides: hydrophobic and hydrophilic. The water moves slowly on the hydrophilic side, and fast on the hydrophobic side. The protein should be transferred to the hydrophilic side of PVDF.
29. A PVDF membrane must always be kept wet; if it dries, then re-wet in methanol and water.
30. More attention should be paid to avoid any air bubbles in **steps 1** to **7**) because they severely affect the semi-dry electrotransfer.
31. Our studies ***(23,24)*** have demonstrated the high levels of reproducibility and resolution of 2DGE. For the first dimension IEF, a high reproducibility

can be obtained with commercially available IPGstrips. For the second-dimensional SDS-PAGE, different types of gel system are available: vertical versus horizontal gel systems; constant-percentage versus gradient gels. Compared to the horizontal Multiphor gel system (pre-cast gradient SDS gel = 180 × 245 × 0.5 mm; analyzes a gel at a time), the vertical Dodeca gel system (single-concentration gel = 190 × 205 × 1 mm; analyze up to 12 gels at a time) demonstrates a better spatial and quantitative reproducibility ***(23)***, and a wider linear dynamic range to measure the change in the protein abundance in a complex proteome ***(24)***. Moreover, for between-gel comparison, the same experiment conditions (including the loading amount of protein, sample-dissolving solution, IEF, IPGstrip equilibration solution, SDS-PAGE, and gel image process) should be used to conduct two-dimensional gel electrophoresis experiments and image analysis for each experiment ***(25)***.

32. In these experiments, especially for digestion with trypsin, gloves and a head cap are always used to avoid any keratin from skin and hair contamination of the protein sample ***(20)***.
33. All tubes and pipette tips that contact protein sample or peptides should be siliconized (or low-retention) to avoid any loss of protein or peptide.

Mass Spectrometric Determination of Protein Ubiquitination

Carol E. Parker, Maria Warren Hines, Viorel Mocanu, Susanna F. Greer, and Christoph H. Borchers

1. Introduction

Cellular homeostasis requires a delicate balance of protein synthesis and degradation, a balance which is maintained by the actions of regulatory proteins. In turn, proteins which are no longer required must be degraded in a rapid and selective manner. The selective degradation of proteins involved in diverse regulatory mechanisms such as signal transduction ***(1)***, transcriptional regulation ***(2)***, cell cycle regulation ***(3)***, and stress response ***(4)*** have been linked to the covalent attachment of ubiquitin to proteins. Ubiquitin is a 76-residue polypeptide, which attaches via its carboxy-terminus to lysine ε amino groups of the target protein. Ubiquitin-protein conjugates are short lived, primarily because of proteolysis by the 26S proteosome or, in some cases, dissociation of the complex with removal of the ubiquitin by ubiquitin isopeptidases ***(5)***. Other roles for monoubiquitination have recently been uncovered, including acting as a signal for protein trafficking, cell division, targeting proteins to subnuclear structures, endocytosis, signal transduction, and kinase activation ***(6–11)***. Both the dynamic nature of these important regulatory proteins, and the low protein levels *in vivo,* make analysis of protein ubiquitination inherently difficult.

The use of mass spectrometry to identify sites of ubiquitination within target proteins *in vivo* will allow greater understanding of the ways in which ubiquitination alters protein function. Therefore, the development of broadly applicable identification approaches is critical. The importance of ubiquitination and the role of mass spectrometry in the study of ubiquitination has recently been reviewed by Kirkpatrick, Denison, and Gygi ***(12,13)***, Xu and Peng ***(14)***, and Drews, Zong, and Ping ***(15)***.

2. Materials

2.1. MALDI Analysis of Intact Proteins

1. Bruker Reflex III or a Bruker Ultraflex matrix-assisted laser desorption (MALDI-MS, (Bruker Daltonics, Billerica, MA).
2. α-cyano 2-hydroxycinnamic acid (Aldrich; St. Louis, MO).
3. Ethanol.
4. Water, HPLC-grade.
5. Formic acid.

2.2. LC/MS/MS

1. Waters/Micromass Q-TOF (Waters/Micromass Corp., Milford, MA).
2. PepMap C_{18} 15 cm × 75 µm id capillary column (Dionex; Sunnyvale, CA).
3. Trapping column 5 mm × 800 Å id C_{18} P3 (Dionex).
4. Water, HPLC-grade (Pierce).
5. Acetonitrile, HPLC-grade (Pierce).
6. Formic acid.

2.3. Affinity Purification

1. Anti-HA antibody beads (Sigma, St. Louis, MO).
2. Anti-FLAG antibody beads (Sigma).
3. Ammonium bicarbonate.
4. Ethanol.
5. Water (Pierce).
6. Formic acid (Fisher).

2.4. In-Solution Digestion

1. Water, deionized or HPLC-grade (Pierce).
2. Trypsin, sequencing-grade (Promega; Madison, WI).
3. GluC (Sigma).
4. Ammonium bicarbonate.
5. Low-retention Eppendorf tubes (Axygen; Union City, CA).
6. Thermomixer (Eppendorf; Hamburg, Germany).

2.5. Lyophilization and Reconstitution

1. Freeze dryer (Labconco; Kansas City, MO).
2. Water (Pierce).

3. Methods

3.1. Evidence from Gels.

Most direct evidence for ubiquitination comes from gel electrophoresis (**Fig. 1**), where a series of higher molecular weight bands are observed above the molecular weight of the protein, or from Western blot analysis using anti-ubiquitin antibodies (**Fig. 2**).

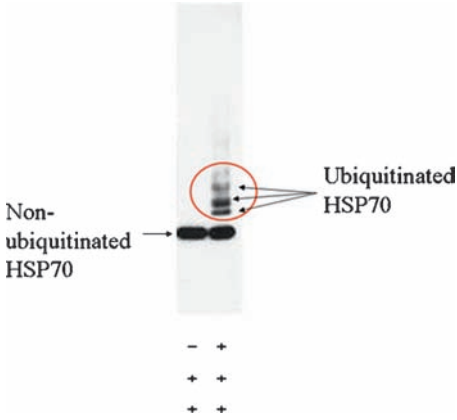

Fig. 1. Ubiquitination evidence from Gels. PAGE gel showing a series of bands above the molecular weight of the non-ubiquitinated protein. (Collaborator: W. C. Patterson).

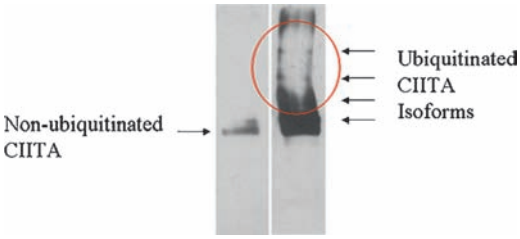

Fig. 2. Ubiquitination evidence from Western blot analyses. PAGE gel showing a series of bands above the molecular weight of the non-ubiquitinated protein: Western blot analysis of CIITA, showing ubiquitination.

3.2. Mass Spectrometric Evidence for Protein Ubiquitination

While ubiquitination is clearly important for protein degradation, most mass spectrometric studies on ubiquitination have focused on protein phosphorylation, rather than direct mass spectrometric studies of protein ubiquitination. There are three types of mass spectrometric evidence for ubiquitination: the first is ubiquitination of the intact protein, the second is co-electrophoretic migration of the target protein and the attached ubiquitin and, and the third is the mass shift of a ubiquitinated peptide relative to the nonubiquitinated peptide.

3.2.1. Evidence from MS of the Intact Protein

Direct mass spectrometric evidence of intact ubiquitinated HSP70 is shown in **Fig. 3**. This spectrum was obtained by direct MALDI-MS analysis of ubiquitinated HSP70, affinity-bound to anti-HSP70 beads.

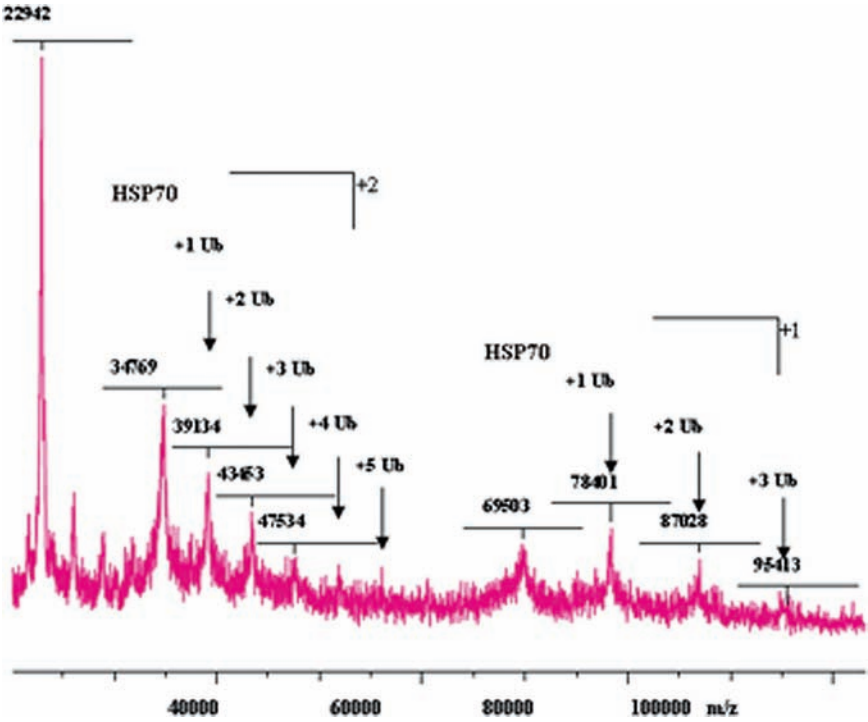

Fig. 3. Ubiquitination evidence from MALDI of intact proteins. MALDI-MS of HSP70 with a series of ubiquitin attached moieties.

3.2.1.1. Direct MALDI Analysis of Proteins Bound to Affinity Beads (*see* **Note 1**)

1. Use antibodies *covalently* bound to the affinity beads (*see* **Note 2**).
2. Bind the antibody according to the bead manufacturers' instructions (*see* **Notes 3** and **4**).
3. Rinse beads 3 times with 2–3 bead volumes of 100 mM ammonium bicarbonate (*see* **Note 5**).

3.2.1.2. Spotting the MALDI Target

1. Prepare the MALDI matrix solution – a saturated solution of recrystallized (*see* **Note 6**) α-cyano 2-hydroxycinnamic acid in 45:45:10 ethanol:water:formic acid. (*see* **Note 7**).
2. Pipet 0.5 µL of settled beads onto the MALDI target, followed by 0.5 µL of MALDI matrix solution.

3.2.2. Evidence from MS and MS/MS of Peptides

The second type of mass spectrometric evidence for ubiquitination comes from in-gel digestion and protein identification studies. In-gel digestion of the higher molecular weight bands followed by protein identification by MALDI-MS

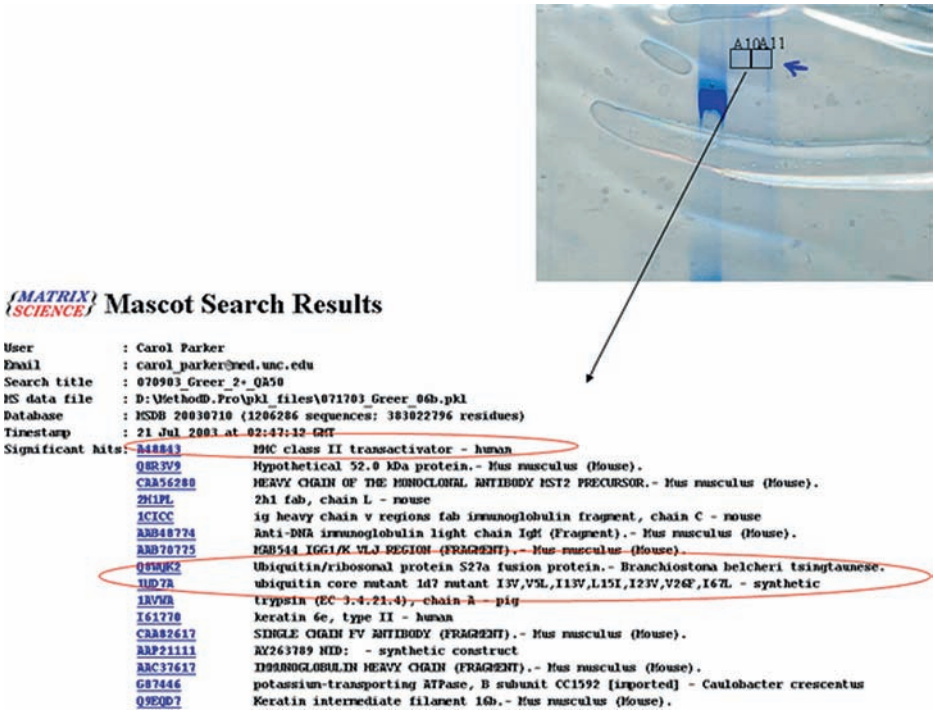

Fig. 4. Peptides from the target protein CIITA and peptides from ubiquitin from a gel band at mw ~200 KDa.

or LC/MS/MS on a gel can sometimes provide evidence for ubiquitination – evidence comes from peptides rather than proteins. In the example shown in **Fig. 4**, peptides from the target protein CIITA and peptides from ubiquitin were found in a gel band of approximately 200 Kda, clearly higher than the unmodified 150 kDa CIITA or the 8.7 kDa unbound modified monoubiquitin (*see* **Subheading 3.1.2.4**).

3.2.3. MS and MS/MS Spectra of Ubiquitinated Peptides

The third type of mass spectrometric evidence comes from the modified peptide itself, either from a shift in peptide molecular weight, or from MS/MS data. Ubiquitin is a 76-amino acid protein. An E3 ligase attaches ubiquitin to the ε amino group of a lysine residue in the target protein. This covalent linkage is formed at C-terminal glycine residue of the ubiquitin, with loss of the elements of water. Cleavage with trypsin or gluC (*see* **Note 8**) leaves characteristic "tails" on the modified lysine. These "tails" cause a shift in the molecular weight of the peptide, which can be used to distinguish these modified peptides from the unmodified peptides (**Fig. 5**). The actual site of ubiquitination can then be determined by MS/MS sequencing.

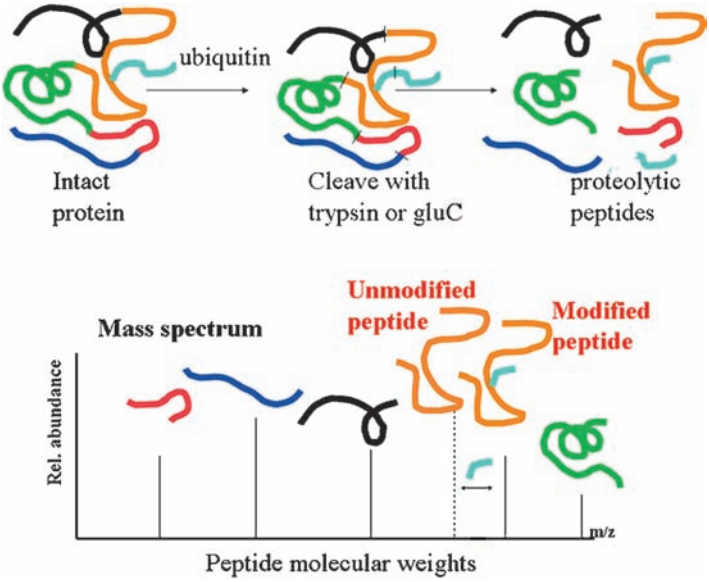

Fig. 5. Schematic showing the expected peptide molecular weight shift caused by ubiquitination.

These peptide mass shifts can be used to find and sequence ubiquitinated peptides. Mascot, for example, allows the user to create a modification of a particular mass, which can then be used to search the peptide data from a given digest. Due to their transient nature and low natural abundances, ubiquitinated peptides are difficult to detect. A study by Gururaja et al ***(16)*** on Hela cell lysates, used a 6 × his-tagged ubiquitin, IMAC purification, digested by Lys-C and trypsin, and protein identification by 2D-LC/MS/MS using strong cation exchange and C18 reversed phase media. Ubiquitination was confirmed by anti-his tag and anti-ubiquitin Western blotting on the undigested lysates. A total of 244 proteins were found, which the authors categorized into functional groups, but determination of the exact ubiquitination sites was not the focus of this study.

Very few ubiquitinated peptides were found by mass spectrometry from a single preparation until the work by the Gygi group in 2003 ***(17)***. As in the studies described above, a 6 × his-tagged ubiquitin was also used, and ubiquitinated proteins from yeast were purified by IMAC. The ubiquitin-enriched fraction (0.2 mg out of each original 100 mg of yeast cell lysate) was then digested with trypsin, fractionated into 80 fractions on a SCX column, and the 80 fractions were analyzed by capillary LC/MS/MS. Peptide MS/MS data was searched using Sequest software, allowing for a ubiquitin-modified lysine with a mass shift of +114 Da. In this manner, 110 ubiquitination sites were determined. In another study using 6 × his-myc-Ub, also from the Gygi group, 211 proteins were identified. Ubiqui-

tination sites were identified on 15 of these proteins ***(18)***. A detailed description of this method has been reported by Peng and Cheng ***(19)***.

Using a similar approach, Kirkpatrick et al ***(20)*** also studied the "ubiquitinome" of human cells, this time HEK293 cells. As in the above studies, 6 × his-tagged ubiquitin was used, followed by Ni-IMAC purification. Lysates from as many as 80 plates were pooled, and the eluted proteins were digested with trypsin, followed by LC/MS/MS. Twenty-two ubiquitinated proteins were identified, along with 19 additional proteins non-specifically-bound to the IMAC beads. An attempt was made to find the ubiquitinated peptides, but only branched peptides from polyubiquitin were identified in this study – by the presence of the GG modification on lysine. No consistent fragmentation (i.e., no loss of 114 Da) was observed in these GGK-modified peptides. Confirmatory evidence of the ubiquitination at these specific sites was the lack of tryptic cleavage at the modified K.

An alternative, but still "shotgun" approach is to use an anti-ubiquitin antibody to accomplish the enrichment. This approach was used by Figeys' group, and the digestion of 30 bands resulted in the identification of 70 proteins ***(21)***. Several GGK-containing "signature" peptides were located by their mass shifts, using a Mascot database search. An interesting and useful improvement on the anti-ubiquitin affinity purification approach was the use of the anti-*poly*ubiquitin antibodies which had been developed in 1994 by Fujimuro et al ***(22).*** The use of one of these antibodies (FK2) instead of a conventional anti-ubiquitin antibody has been shown to work even in denaturing conditions and improves the selectivity of ubiquitinated protein enrichment by avoiding the capture of free ubiquitin ***(23,24)***.

3.2.3.1. MS/MS Fragmentation of Ubiquitinated Peptides

When the work described in this book chapter was initiated (2004), we could only find two reports of ubiquitination site determination which showed detailed MS/MS spectra of ubiquitinated peptides. These were on specifically-targeted proteins of interest – the first was the work of Laub et al ***(25)***, who used gluC for proteolytic digestion of the protein, and the second was the work of Dohlman's group ***(26)***, who used trypsin. Both of these papers showed MS/MS spectra of the ubiquitinated peptides, and we decided to use these peptides as the starting point for a detailed study of the fragmentation of ubiquitinated peptides with the goal of finding specific diagnostic fragment ions to aid in detecting low levels of ubiquitinated peptides at lower levels in biological materials ***(27)***.

When a ubiquitinated protein is enzymatically digested, a portion of the ubiquitin side chain remains attached to the modified lysine (**Fig. 6**). A ubiquitinated peptide therefore has 2 N-termini – one from the original peptide and one from the ubiquitin side chain. Thus, it is possible to have two series of *b* ions and *y*

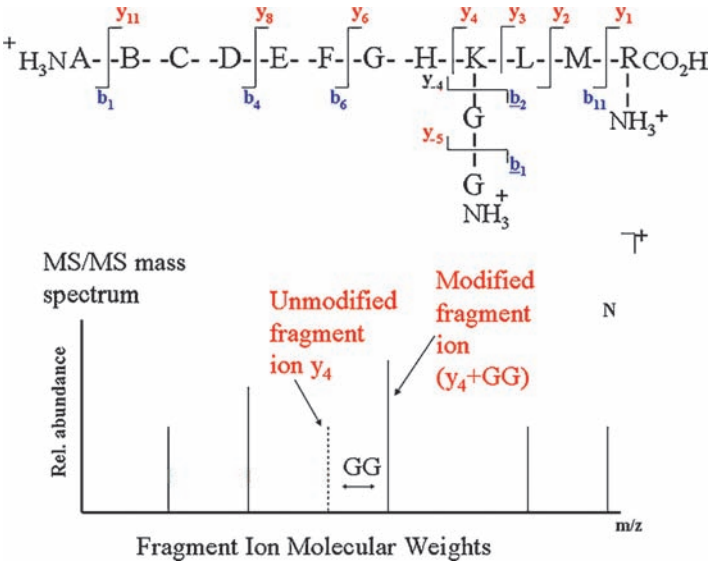

Fig. 6. Schematic showing fragmentation of ubiquitinated peptides.

ions. For the sake of clarity, we have chosen to refer to those *b* and *y* ions involving the ubiquitin side chain as *b* and *y* ions. Obviously, diagnostic ions for the modification must come from fragmentation of this side chain. Fragment ions involving any part of the "normal" peptide will vary in mass according to the peptide being modified and will therefore not be of general diagnostic use.

3.2.3.2. Examination of the Literature Tryptic Peptide Spectra

MS/MS spectra of GG-tagged tryptic peptides are shown in both the paper from Dohmann's group, and that of the Gygi group. Examination of these spectra show that *b* and *y* ions are produced by dissociation of the peptide from the target protein, but there do not appear to be any *b* ions from the GG side chain, or the GGK portion of the peptide.

3.2.3.3. Examination of the Literature gluC Peptide Spectra

The MS/MS spectrum of the gluC ubiquitinated peptide from rXL-calmodulin which was shown in the Laub et al paper ***(25)***, reveals b and y ions from the calmodulin portion of the peptide (**Fig. 7**). Interestingly, it also shows doubly-charged $(b_7\text{-}H_2O)^{2+}$, $(b_{14}\text{-}H_2O)^{2+}$, and $(b_{12}\text{-}H_2O)^{2+}$ ions which contain both of the N-termini (one from the calmodulin peptide and one from the ubiquitin side chain) of the original branched peptide. These two ions (athough of low relative abundance) can be seen in the MS/MS spectrum of the ubiquitinated peptide from natural BT-calmodulin. Careful examination of the both spectra

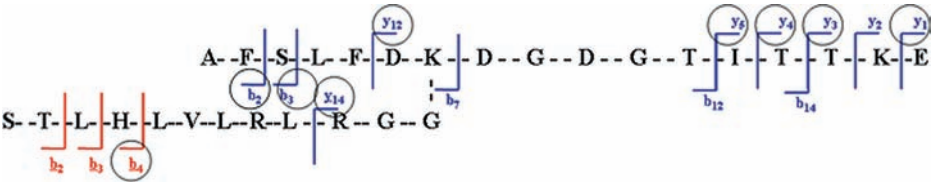

Fig. 7. Calmodulin ubiquitinated peptide structure after cleavage with gluC. Circled peptide fragments were not noted in the original publication by Laub et al ***(25)***, but appear to have the appropriate masses.

reveals ions which might be from the ubiquitin side chain, and therefore of possible diagnostic utility. The y_{14} ion includes ions from both the side chain and the C-terminus of the calmodulin-portion of the peptide, so it cannot be used as a ubiquitination marker ion. However, there are also ions from the side chain, b_4 at m/z 478.4 (obs) and, possibly, b_2, at m/z ~191.2 (obs), which appear to be diagnostic ions of ubiquitination, after digestion with gluC.

3.2.3.4. Preparation of Model Ubiquitinated Peptides

In order to further study the fragmentation of ubiquitinated peptides, we had a model peptide synthesized. A peptide was synthesized with the structure shown in **Fig. 7**. These modified peptides should show a characteristic mass shift from their unmodified analogues: in the case of trypsin, a mass shift of 114.0428 Da from the GG "tag" left on the modified lysine. In the case of gluC, a mass shift of 1302.7883 Da, a much larger mass shift resulting from the much longer "tail" (STLHLVLRLRGG-) on the modified lysine, is expected. Unfortunately, the model peptide was synthesized with an amide at the C-terminus, and an acetyl group at the N-terminus, so it is not an exact model of the peptide found by Laub et al ***(25)***. Fortunately, the acetyl group was in the "calmodulin" portion of the peptide, so we expected that diagnostic fragments from the ubiquitin side chain would still be present in the MS/MS spectrum.

ESI-MS/MS spectra of the model peptides were obtained by LC/MS/MS analysis using a Waters/Micromass Q-tof API US, equipped with a Waters capLC system. An aliquot of the sample was injected first onto a Dionex trapping column, which was then switched so that it was connected on-line to a 75 µm Dionex Pep-map analytical column and the ESI source. The original synthetic peptide, the model gluC peptide, was dissolved in water, and injected without further purification. It proved to be a mixture of acetylated and methylated forms, whose MS/MS spectra could be analyzed separately after separation by LC/MS/MS. The actual methylation sites can be deduced from the MS/MS spectrum: one is on the S in the calmodulin part of the peptide, the other is on one of the first two residues (S or T) of the ubiquitin tail.

The model ubiquitinated peptide was prepared from the synthetic peptide by means of an in-solution tryptic digest (see **Subheading 3.1.2.5.3**), using 2 µg of trypsin and 1 µg of the original peptide in 100 µL of 100 mM ammonium bicarbonate. As stated earlier, an aliquot of the digest was injected into the LC/MS/MS system, and went first onto a Dionex trapping column, which was then switched so that the column was connected on-line to a 75 µm i.d. Dionex Pepmap analytical column and the ESI source.

Two main products were formed: a peptide with the expected "GG" tail on the ubiquitinated lysine, and a second peptide with an "LRGG" tail, resulting from a missed cleavage. Even though this was an in-solution tryptic digest with a large amount of trypsin, a significant amount of a peptide was produced with a missed cleavage site on the side chain. Although this missed cleavage was unexpected, it is not unreasonable, since this cleave site is close to the branch point so cleavage at this site is likely to be sterically hindered. MS/MS spectra were obtained for both of these products. The formation of this peptide is of significant analytical interest as it provides a second characteristic molecular weight shift for ubiquitinated peptides after tryptic digestion.

3.2.3.5. Fragmentation of Model gluC Ubiquitinated Peptide

Because of the various possible dimethylated isoforms, the first model gluC peptide examined was the dimethylated version. The resulting spectrum is shown in **Fig. 8**. Both *b* and *y* fragment ions are found from the "normal" part of the peptide. Most interestingly, several fragments are found which only involve the side chain. As were observed in the literature spectrum, three characteristic ions were detected from the "ubiquitin" side chain: these are b_2, b_3, and b_4. These ions, in their un-methylated forms, (m/z 189.088, 302.172, 439.231, 555.315, and 651.383) should thus be diagnostic ions for peptides with ubiquitin side chains that have been cleaved with gluC.

3.2.3.6. Fragmentation of Model Tryptic Peptides

Cleavage of the synthetic model peptide with trypsin resulted in a GG-tagged peptide whose MS/MS spectrum is shown in **Fig. 9**. Unfortunately, as in the literature spectra, no characteristic fragment ions could be found which were diagnostic of the critical GGK portion of the molecule.

The MS/MS spectrum of the model tryptic peptide which had the LRGG tag (resulting from a missed cleavage) was more analytically useful (**Fig. 10**). Diagnostic ions of the ubiquitin tag were found. These include b_2, b_4, and the internal fragment ion (LRGGK-28). There is also a LRGGKD ion fragment ion, but since this includes the "D" from the calmodulin peptide, it cannot be used as a diagnostic ion for modification by ubiquitin. The assignment of these peptide fragments is confirmed by the MS/MS spectrum of the S-methylated calmodulin

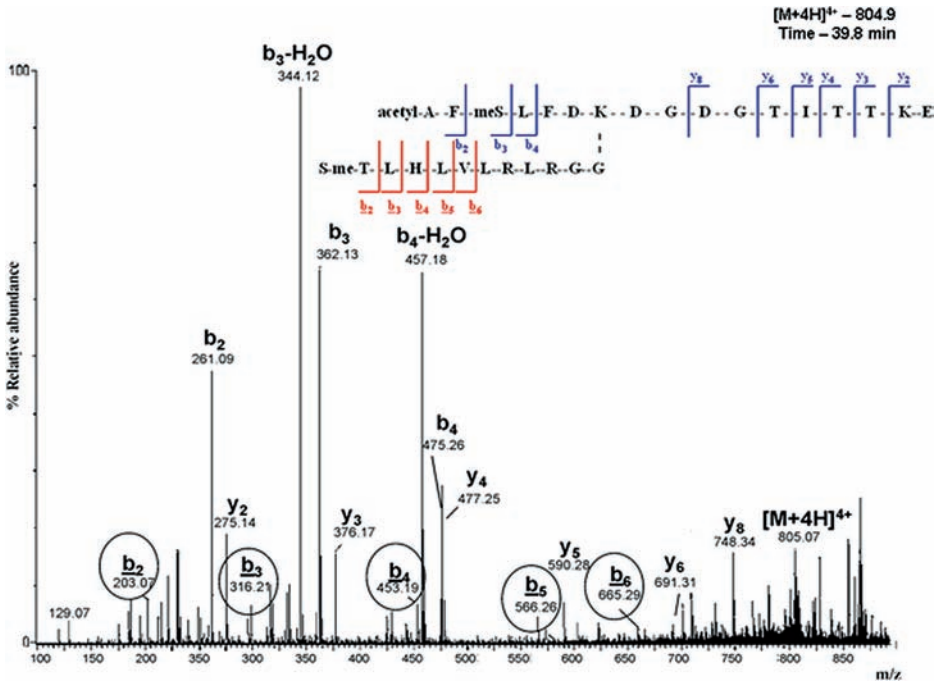

Fig. 8. MS/MS Fragmentation of synthetic model calmodulin gluC peptide, dimethyl form. (Reproduced with permission from ***ref. 27,*** copyright John Wiley & Sons, Limited).

peptide is shown in **Fig. 11**. The same diagnostic ions b_2, b_4, (LRGGK-28) ions are observed in this spectrum.

3.2.4. Enrichment of Samples for Specific Ubiquitin-Modified Proteins and/or Proteins That Interact with Them

As described above (**Subheading 3.2.3**), the work of Gururaja ***(16)***, Kirkpatrick ***(20)***, and Peng ***(17)*** depended upon enriching the sample in ubiquitinated peptides. Their goals were to find as many ubiquitination sites as possible in *any* protein, so their approach was to use a 6 × his-tagged ubiquitin, and enrich the sample in ubiquitinated proteins through the use of IMAC or 6 × his –myc-Ub ***(18)***. Other researchers have used antiubiquitin ***(21)*** or anti-polyubiquitin ***(23,24)*** for "shotgun" enrichment.

To find ubiquitination sites in a *particular* target protein requires a different approach. One method is the use of a GST-tagged substrate, and anti-GSH affinity beads. This method was used by the Marshall group for an FT-MS study of polyubiquitinated GST-Ubc5, ubiquitinated in vitro ***(28)***. FT-MS identified fifteen ubiquitination sites in GST-Ubc5, and four sites in ubiquitin, although large quantities of material were used (e.g., 700 µg GST-Ubc5).

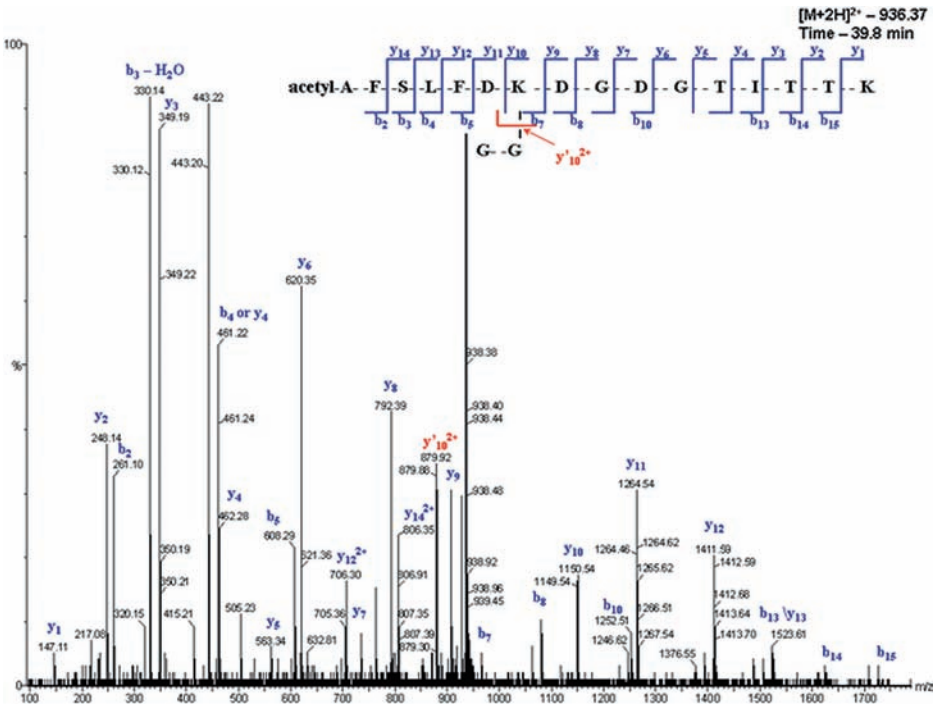

Fig. 9. Fragmentation of model "GG-" ubiquitinated tryptic peptide. Reproduced with permission from ***ref. 27,*** copyright John Wiley & Sons Limited.

If an antibody is available against the target protein, then it can be used to affinity purify the target protein from the cell lysate. If an antibody against the protein of interest is *not* available, an affinity tag can be incorporated into the target protein sequence. In our case, we used a FLAG tag added to the amino-terminus of the CIITA target protein so that it could be immunoprecipitated with anti-FLAG antibody beads.

As a second strategy for increasing the proportion of ubiquinated vs. non-ubiquitinated protein, a plasmid was used which coded for a modified ubiquitin which had all of the lysines modified to arginines and a HA tag on the C-terminus. This construct was designed to prevent the formation of polyubiquitin chains and thus to inhibit degradation of the target protein ***(29)***. The HA tag allows a second affinity purification step, either before or after proteolysis, this time on anti-HA beads. To avoid proteolysis of the ubiquitin (and loss of the HA tag), LysC was used for the initial digestion of the protein, instead of trypsin.

The affinity-bound protein can then be digested overnight with trypsin or with gluC (*see* **Note 8**) while still attached to the beads, using the protocols described in the next subheading. Alternatively, the protein can be eluted from the affinity beads with 1:1:8 ethanol:formic acid:water, lyophilized and digested in solution.

3.2.5. Elution and Enzymatic Digestion Procedures

3.2.5.1. Elution of Proteins from Beads

1. Place ~50–100 µL of beads in an Eppendorf tube.
2. Wash beads 3 × with 200 µL of 100 m*M* ammonium bicarbonate, and discard wash solutions.
3. Add 100 µL 1:1:8 Ethanol:formic acid:water.
4. Vortex, let settle.
5. Remove and save eluates.
6. Repeat extraction 2 more times.
7. Save and combine eluates.
8. Lyophilize.
9. Store at −80°C.

3.2.5.2. On-Bead Digestion Tryptic Procedure (30) (see **Note 9**)

1. Place ~50–100 µL of antibody beads (with the attached affinity-bound protein) in an Eppendorf tube.
2. Wash 3 × with 200 µL of 100 m*M* ammonium bicarbonate.
3. Add 100 µL of 100 m*M* ammonium bicarbonate.

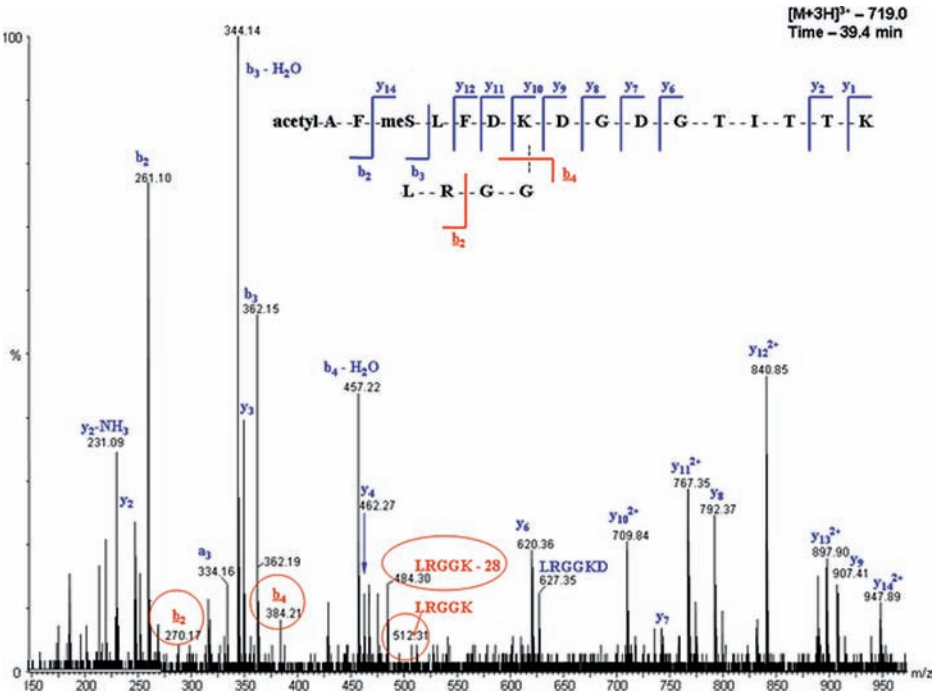

Fig. 11. Fragmentation of model "LRGG-" ubiquitinated tryptic peptide, methylated form. (Reproduced with permission from ***ref. 27,*** copyright John Wiley & Sons Limited).

4. Reconstitute Promega trypsin in 20 µL Promega resuspension buffer (0.015 *M* acetic acid) (Promega trypsin comes in aliquots of 20 µg per vial).
5. Add 2 µL trypsin solution to each sample (*see* **Note 10**).
6. Vortex/spin down at <1000 rpm to avoid breaking the beads.
7. Incubate overnight in sealed Eppendorf tubes, at 35°C with rotation (~400 rpm) (*see* **Note 11**).
8. Remove supernatant from beads.
9. Lyophilize to reduce volume (if sample is concentrated enough, supernatant can be injected directly).
10. Store at −80°C.

3.2.5.3. In-Solution Tryptic Digestion Procedure

1. Calculate what a 1:50 Enzyme:Substrate ratio would be (*see* **Note 12**).
2. Reconstitute Promega trypsin in 20 µL Promega resuspension buffer (0.015 *M* acetic acid) (Promega trypsin comes in aliquots of 20 µg per vial.)
3. Dissolve sample in ~20 µL of 100 m*M* ammonium bicarbonate solution (*see* **Note 13**).
4. Add calculated amount of trypsin solution to each sample.
5. Vortex/spin down.

6. Incubate for at least 4 hrs for a digest in solution, or overnight for beads, in sealed Eppendorf tubes, at 35°C with rotation (~400 rpm).

3.2.5.4. In-Solution Digestion with gluC (*see* **Note 14**)

1. Dissolve the enzyme (which comes lyophilized, 25 µg per ampule) in 25 µL sample in water.
2. Dissolve sample in 100 µL of 100 m*M* ammonium bicarbonate buffer.
3. Add 2 µL enzyme solution.
4. Incubate overnight at 35°C, at 35°C with rotation (~400 rpm).
5. Freeze at −80°C.

3.2.5.5. On-Bead Digestion with gluC (*see* **Note 14**)

1. Dissolve the enzyme (which comes lyophilized, 25 µg per ampule) in 25 µL sample in water.
2. Rinse ~50 µL of affinity beads 3 × with 100 µL of 100 m*M* ammonium bicarbonate buffer.
3. Add 100 µL of 100 m*M* ammonium bicarbonate to the beads.
3. Add 2 µL enzyme solution to the beads.
4. Incubate overnight at 35°C, at 35°C with rotation (~400 rpm).
5. Remove supernatant, and freeze at −80°C.

3.2.5. Mass Spectrometric Approaches for Detection of Ubiquitinated Peptides and Determination of Ubiquitination Sites

The first step is to simply perform LC/MS/MS on the peptide digest. Long runs with long linear gradients (>200 min) are preferred for separating complex mixtures of peptides in order to reduce suppression effects and to reduce the number of coeluting peptides, since selection of the precursor ions is done based on ion abundances. For an unknown modification site in a protein containing many potential sites, where the peptide molecular weight is therefore not known, automatic data-dependent triggering of MS/MS data collection (called "survey scan" mode in the Micromass MassLynx software) is the only feasible automatic scanning option.

The resulting MS/MS spectra are then analyzed by commercially-available software packages (such as Mascot or SEQUEST) which can be programmed (*see* **Notes 15** and **16**) to consider a lysine modified with a GG or, as we have learned from the above experiments on our model peptides, LRGG, for a tryptic digest, or with STLHLVLRLRGG for a gluC digest). Ideally, the ubiquitination will be found from this automated search routine (*see* **Notes 17** and **18**). **Fig. 12** shows an example of a database search of MALDI-MS data from a tryptic digest of a ubiquitinated protein. Here, a ubiquitinated peptide has been identified. Although promising, these results simply mean that there is a peak in the mass spectrum which has the mass of an expected tryptic peptide where a lysine has been modified with a GG tag. Since a peak at this mass could

Fig. 12. Mascot database search results from a tryptic digest of ubiquitinated CIITA, showing a “hit” for a potential ubiquitinated peptide. This potential ubiquitination site has not yet been confirmed by MS/MS data.

have come from another peptide in the mixture, this ubiquitination site cannot be confirmed without MS/MS sequence data of this peptide.

If MS/MS data has been acquired and searched, as is the case when LC/MS/MS has been used, the identity of the peptide can be confirmed and site of ubiquitination found from the database search results (*see* **Note 19**). This was the method used to find the ubiquitination sites in the Peng, *et al*. paper ***(17)***. Unfortunately, this approach often fails where lower amounts of biological material are available. Very low levels of the modified peptide mean that there may not be sufficient intensity of the modified peptide to trigger this automatic data-dependent MS/MS sequencing.

In this case, another much more time-consuming option is to examine the MS spectra to search for a peptide shifted by the masses corresponding these possible modifications. This can be done manually by creating a list of expected "normal" peptide masses, calculating the modified masses, and examining the MS spectra obtained during the LC/MS/MS run. Obviously, at 1 s per scan, thousands of spectra are obtained throughout the course of an extended LC/MS/MS run. Current software systems allow the combination of groups of spectra, and these groups of combined spectra can be examined. Most current software packages also allow the deconvolution of the spectra to singly-charged species, which reduces the complexity of the manual data analysis, since multiple charge states of the possible peptides are deconvoluted to singly-charged species. A semi-automated approach to this task is to combine all of the spectra, perform a deconvolution on the MS data to generate a pseudo-singly charged spectrum (*see* **Note 20**), and then submitting this data to the database search software for searching as an MS data file. As above, the MS data can then be searched for modified peptides (*see* **Note 21**).

If a possible modified peptide is identified in this manner, it is useful to examine the original MS data to see if the calculated +2 and +3 charge states for this peptide co-chromatograph. Now that the masses are known, it is possible to perform a different type of MS scanning, where the precursor ion is specified – in Micromass software, it is called "include only" MS/MS. In this scan mode, MS/MS is only performed on the preselected precursor ions. In a previous study ***(31)***, we have found that this can lead to an increase in sensitivity of a factor of 50–100 for these ions.

Although this scanning mode is dependent on intensity-based triggering, and thus has the same sensitivity limitations as the "survey scan" mode, knowing these characteristic fragment ions also allows the possibility of "precursor ion scanning". Here, when a preset characteristic ion is detected, the data system switches to the MS mode, detects the precursor, and collects the MS/MS data. Similar approaches are already commonly used, for example, in order to find peptides containing acetylated lysine from the acetylated lysine immonium

ion ***(32)*** or to find phosphotyrosine-containing peptides from its characteristic immonium ion ***(33,34)***.

The identification of the specific and characteristic fragment ions which we have described above, provides a powerful new approach for finding ubiquitinated peptides. Searching the MS/MS chromatograms (*see* **Note 21**) for these characteristic ions (which should cochromatograph because they are fragment ions from the same peptide) should allow one to find peptides containing ubiquitin side chains.

Since we first suggested the use of extended ubiquitin tags to improve the detection of ubiquitinated peptides in 2005 ***(35)***, two other groups have used the LRGG tag and have demonstrated the improvement resulting from inclusion of this second mass shift. Jeon, et al. ***(36)*** used GG and LRGG mass shifts resulting from GG and LRGG tags to search LC/MS/MS data in a mouse heart digest. The use of the GG tag resulted in the identification of 27 ubiquitination sites on 21 proteins. The use of the LRGG tag resulted in the identification of an additional 6 sites. These two tags were also used to identify the polyubiquitination sites on ubiquitin itself (in this case, Lys 48 and Lys 63). One important observation by this group is that the ubiquitinated proteins from mouse heart were insoluble in detergent-free buffer – CNBr cleavage resulted in smaller more soluble proteins, while preserving the ubiquitination.

Recently the Figey group used both GG and LRGG tags to increase the detection of ubiquitinated peptides from a human MCF7 breast cancer cell culture ***(37)***. This group found a total of 96 ubiquitination sites. Of these sites, 53% were found using internal GGK residue, an additional 8% from the internal LRGGK residue, and 39% from C-terminal GGK peptides (which were cleaved by trypsin at the modified residue). These C-terminal peptides (with the standard tryptic cleavage after K) would, of course, have been detected by the database searches, since at least the 1 missed cleavage expected from blocked tryptic would have been allowed. However, the authors noted that no C-terminal LRGG peptides were detected, only C-terminal GGK peptides. This provides support for the hypothesis that the missed cleavage of the LR-GGK bond results from steric hindrance of the trypsin.

A “two-stage” affinity purification strategy was used by the Figeys group for the study of the ubiquitination of proteins co-purifying with valosin-containing protein (VCP), a ubiquitin-dependent chaperone ***(38)***. In this study, first immobilized anti-VSP and then anti-ubiquitin beads were used. Using this strategy, along with a high-pressure device to improve tryptic digestion efficiencies, 27 ubiquitination sites were mapped on 21 proteins, and 58 additional “probably-ubiquitinated” proteins were also identified by LC/MS/MS, using the 114 or 383-Da mass shift associated with the GG- or LRGG-modified lysine residues.

3.2.6. Determination of Ubiquitin Branched Structure

Polyubiquitinated chains can be thought of as multiple ubiquitinations of ubiquitin. Tryptic cleavage of these linked ubiquitins results in GGK and LRGGK-tagged peptides from ubiquitin. A detailed strategy for determining this branching structure has been reported by Kaiser and Wohlschlegel ***(39)***, who used the GGK tagged peptides. They reported that they preferred to perform LC/MS/MS or LC/LC/MS/MS on digests of gel-separated proteins because if a mixture of proteins was present, it could not be determined which *protein* these polyubiquitin fragments came from. Also, without separation of the ubiquitinated peptides from the protein (prior to digestion of the polyubiquitin tail), the "average" branch structure would be determined if there were more than one ubiquitin site on each protein. This, or course, would be difficult to accomplish because enzymes that would separate the ubiquitination sites on the protein would also cleave the polyubiquitin chains.

3.2.7. Quantitation of Ubiquitination

Several recent papers have reported different methods of quantifying the ubiquitination at various sites in the protein, as well as quantitation of the various polyubiquitin isoforms. Cripps et al ***(40)*** used targeted detection of ubiquitinated peptides from a targeted protein, and also performed quantitation determination of the ubiquitinated peptides. *Relative* quantitation using selected reaction monitoring (*see* **Note 22**) was performed on GGK-modified tryptic peptides from Tau protein, immunoprecipitated from Alzheimers brain tissue, using unmodified Tau peptides as internal standards. From this MRM data, the authors determined the relative ubiquitination levels of the 3 sites found in this protein. Although the possible formation of the LRGG tag waas not considered in this studym, or any of the quantitation studies described below, it probably would not significantly affect the results.

Gygi and coworkers have recently published two ubiquitination studies with *absolute* quantitation (AQUA ***(42)***; *see* **Note 23**), the first on the epidermal growth factor receptor (EGFR) ***(41)***, and the second on cyclin B1 ***(43)***. In the EGFR study, recombinant EGFR receptor was purified, and LC/MS/MS was performed. Six ubiquitination sites (GGK) were identified, and quantitative determination of the "average" branch structure of the polyubiquitin chain at each site was performed by comparison of the selected reaction monitoring peak areas of each peptide with those from stable-isotope labeled peptides (the "ub-AQUA" method ***(42)***).

This "ub-AQUA" method was also used by the Gygi group to determine the branch structure of ubiquitinated cyclin B1 ***(43)***. The absolute amounts of each of the 10 possible polyubiquitin cleavage products (7 branched and 3 unbranched)

were determined by comparison with the amounts of 10 synthetic isotopically-labeled analogues. (For example, the heavy leucine in one of the reference peptide contained six ^{13}C's and one ^{15}N). As in the study by Kaiser and Wohlshlegel described above ***(39)***, ubiquitinated cyclin B1 was first separated by gel electrophoresis, and the quantitation was performed on the extract containing the in-gel digested peptides. Calculations were performed to determine the amount of ubiquitin in long chains vs. short chains.

To determine the relative quantitation of the branch structures in a set of 5 ubiquitin-conjugating enzymes and ubiquitin ligases, the Gygi group used a different strategy, utilizing a set of mutant ubiquitins, each having all but one of the 7 lysines replaced by alanines ***(44)***. The relative amounts of each type of linkage was based on spectral counting ***(45)*** of the resulting GGK-containing peptides, *i.e*. the number of spectra observed in a data-dependent LC/MS/MS acquisition, rather than the abundance of the spectra.

3.2.8. Emerging Strategies

In addition to new quantitative studies, there have been several interesting studies designed to improve detection of ubiquitinated peptides which is still extremely challenging when the amount of biological material is limited. As mentioned above (*see* **Subheading 3.1.2.3.1**), ubiquitinated peptides differ from "standard" peptides in that they have 2 N-termini.

Recently, Cotter and his group have developed a new method which uses this feature ***(46,47)***. This method is based on a derivatization procedure, similar to the chemistry behind Edman sequencing ***(48)***. This reagent attaches an SPITC (4-sulfophenyl isothiocyanate) moiety to the N-termini – to *both* N-termini for ubiquitinated peptides. Under MS/MS conditions, ubiquitinated peptides can then be distinguished from nonubiquitinated peptides by the loss of *two* SPITC groups forming a set of "signature" ions resulting from complete or partial loss of one or two of these tags ("normal" peptides can only have *one* loss of SPITC) (**Fig. 13**). This derivatization procedure, first developed by Keough et al ***(49)***, produces a y series from a derivatized peptide, while reducing the b series (ions which contain the N-terminus). The Cotter group first modified this reagent for more efficient use in aqueous media ***(50)***, and then used it to derivatize tryptic peptides prior to MALDI-MS and MALDI-MS/MS. They used this method for determination of ubiquitination sites in a synthetic peptide containing a GGK tag, and to tetraubiquitin ***(46)***. In a subsequent paper ***(47)***, the Cotter group used this procedure to find the ubiquitination sites on His-tagged CHIP (*C*-terminal *H*SP70-interacting protein), which was affinity purified using Cobalt beads, and IMAC. Three peptides were identified as doubly-tagged based on their MS/MS spectra, which produced "signature" ions from the SPITC moieties and

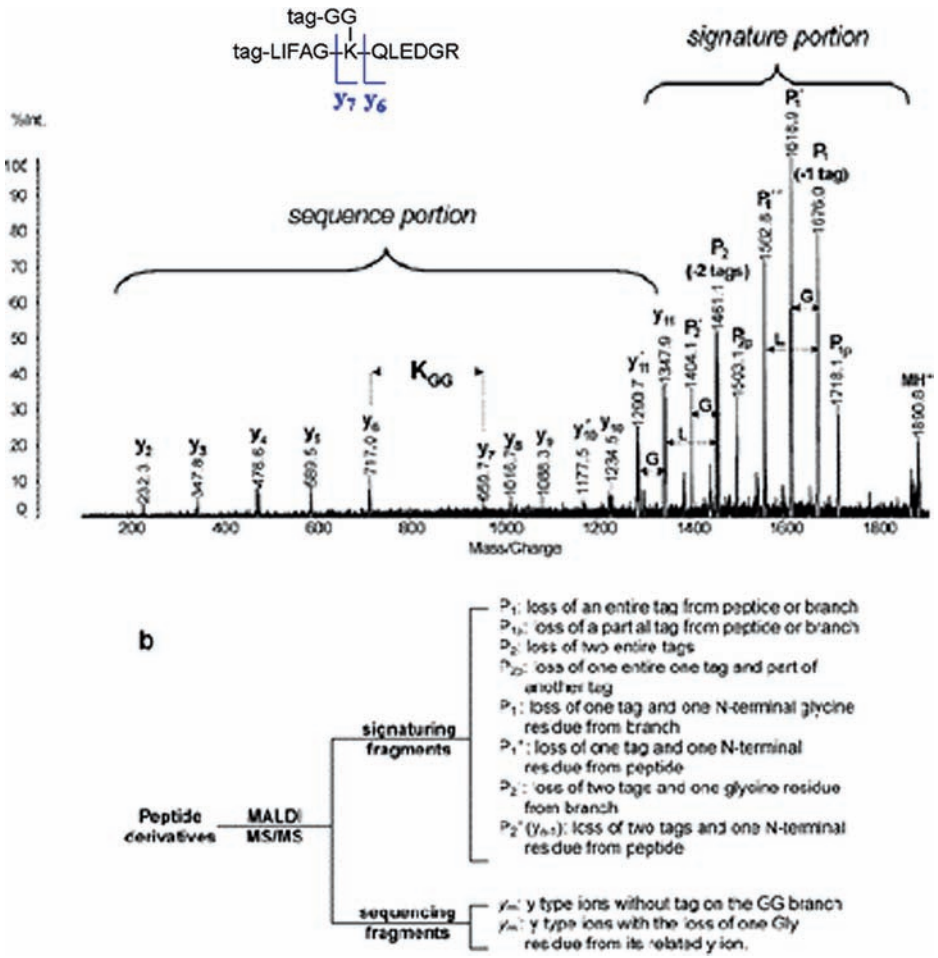

Fig. 13. Fragmentation of an SPITC-labeled ubiquitinated peptide. (Reprinted from ***ref. 46,*** with permission)

sequence ions which were used to identify the site of ubiquitination. In a recent report, the Perales group ***(51)*** used the SPITC approach, and reported improved quality of the resulting MS/MS sequencing, which is another advantage of this approach.

A different method for N-terminal derivatization was recently suggested by the Gebler group ***(52)***. Like the SPITC method, this is a new look at an older derivatization technique for mass spectrometry ***(53)***. This method relies on derivatization of the N-terminal peptides with tris(2,4,6-trimethoxyphenyl)

phosphonium acetic acid N-hydroxysuccinimide ester (TMPP-Ac-OSu), which introduces a fixed charge on the N-terminus and simplifies MALDI-.MS/MS sequencing. This method also has potential for improving the detection of "double N-terminal" ubiquitinated peptides.

These N-terminal labeling approaches should be very useful for identifying ubiquitinated peptides from a mixture, especially if the label could be combined with an affinity capture moiety such as biotin. This approach is proving extremely useful for the identification of crosslinked peptides ***(54)***, and it would seem that a similar strategy could be developed for the labeling and recovery of ubiquitinated peptides.

4. Notes

1. We call this "direct" analysis because the affinity beads are placed directly on the target, in contrast to methods were the affinity-bound proteins are eluted first, and the eluate is spotted on the target.
2. If binding has to be done through protein A, or the antibody is dissolved in ascites, the antibody can be crosslinked to the beads ***(55)*** before the target protein is affinity-bound.
3. Since only a small number of beads will be placed on the MALDI target, it is important to get much protein as possible on each bead, so use a small amount (~20 μL) of settled affinity bead slurry.
4. To avoid releasing parts of the antibody into the solution, try to avoid reducing agents such as β-mercaptoethanol or dithiothreitol (DTT) in the binding buffer.
5. Most salts will be removed during the wash steps. Other components not compatible with mass spectrometric analysis (such as glycerol or detergents) should be avoided or minimized. Although Zwittergent is thought to be compatible with mass spectrometry, it seems to make agarose beads turn "gummy," so it should not be used.
6. To recrystallize α-cyano 2-hydroxycinnamic acid, make a saturated solution of α-cyano 2-hydroxycinnamic acid in boiling methanol. Pour off the solution and discard it. Add more methanol, and again make a saturated solution in boiling methanol. This time, pour off the methanol and save it. Evaporate the methanol to dryness in a hood, while protecting the solution and the crystals from light with aluminum foil. Store in the dark or in a vial wrapped with aluminum foil.
7. The matrix solvent must contain both organic and acid so that it dissociates the affinity bound protein from the antibody on the MALDI target.
8. Also known as *Staphloccus aureus* V-8 protease.
9. The antibody used should be covalently attached to the beads, and DTT should not be used (or used in a very low concentration ***(56)***) in the purification step. If the disulfide bridges in the antibody are reduced, the

antibody can be enzymatically digested along with the attached protein. This will lead to a high background of IgG peptides along with the peptides from the target protein, and will make finding the modified peptide more difficult.

10. For proteins affinity-bound to antibody beads, much higher ratios of enzyme (e.g., 5:1) to substrate should be used than for proteins in solution ***(30)***.
11. Be sure to add enough digestion buffer so that the beads can "slosh around" in the Eppendorf tube and don't dry out during the overnight digestion.
12. If you do not know the protein concentration, use ~2 µL of a 1 µg/µL solution.
13. If the sample to be digested is already dissolved in water or a buffer such as PBS, add enough ammonium bicarbonate to the solution to ensure that the pH will be ~7–8.
14. The specificity of gluC depends on buffer used and pH of the solution. Cleavage can be either C-terminal to glutamic acid (in ammonium acetate at pH 4.0) or (ammonium bicarbonate at pH 7.8), or to *both* glutamic and aspartic acid (in PBS, pH 7.8). For a solution digest, you can add a second buffer to the original buffer in order to adjust the pH, but be sure to take both enzymes into account when calculating the expected of the peptide molecular weights.
15. This requires a site license for Mascot, although the company says that if there is sufficient interest, they will add new modifications to their on-line website (www.matrixscience.com).
16. Programming in these modification means, in effect, telling the software that there are three additional types of lysines, with new masses: 242.1374 for GGK, 511.6294 for LRGGK, and 1430.8824 for STLHLVLRLRGGK.
17. In searching using Mascot, first search with no variable modifications, *then* select the target protein and search in the error tolerant mode, specifying the appropriate ubiquitination modifications you have previously entered.
18. Be sure to specify at least two missed cleavages. Cleavage is not expected to occur at the modified lysine.
19. The database search can also be "forced" to consider a specific target program. In MASCOT, this is done by adding the accession number from the appropriate database as the first line of the peak list being searched. (e.g., accession=XXXXX, followed by a blank line).
20. For Micromass MassLynx software, this is MaxEnt 3, under "Tools".
21. If multiple levels of MS/MS spectra are produced, as in the Micromass MassLynx software, *all* of the MS/MS functions must be searched.
22. Multiple reaction monitoring (or selected reaction monitoring) is a technique performed on a tandem mass spectrometer. In this technique, a both the precursor and the product ion (formed in a collision cell) are selected, which makes it a very selective technique for quantitation.

23. This is a confusing term, partly because the AQUA acronym is used by two groups (both from Harvard) for different things, *a*utomated *qua*ntitation ***(57)*** and absolute quantitation ***(42)***. AQUA as used now in mass spectrometry ***(42)*** is a new name for a mass spectrometric technique dating back at least to the early 1970s ***(58, 59)*** where a stable-labeled form of the target analyte is introduced into the sample to act as an internal standard. This isotopically labeled molecule has properties nearly identical to the target analyte, but has a different mass (because of the isotopic label). This allows it to be distinguished from the native form by mass spectrometric analysis.

Acknowledgments

This study was funded by a gift from an anonymous donor to support research in proteomics and cystic fibrosis, and grants from the Cystic Fibrosis Foundation (CFFTI STUTTS01U0) and from NIH (ES11997, 5U54HD035041-07, and P30 CA 16086-25).

Detection of Sumoylated Proteins

Ok-Kyong Park-Sarge and Kevin D. Sarge

1. Introduction

Small ubiquitin–related modifier (SUMO) was discovered as a modifier of mammalian proteins in 1997 ***(1–2)***. SUMO has since been demonstrated to be a modifier of many important proteins, giving this modification a vital role in modulating a large number of important cellular processes ***(3–5)***. SUMO proteins are very similar to ubiquitin structurally, but sumoylation does not promote degradation of proteins and instead regulates key functional properties of target proteins. These properties include subcellular localization, protein partnering, and transactivation functions of transcription factors, among others ***(3–5)***. Protein sumoylation plays a particularly vital role in regulating many important processes occurring in the nucleus, and although sumoylation can be found on proteins that exist in a number of cellular compartments, most of the sumoylation characterized to date occurs on nuclear proteins ***(3–5)***. Indeed, proteins of the SUMO conjugation machinery have been found to be localized to nuclear pore complexes, in addition to other locations in the nucleus.

SUMO proteins are covalently attached to lysine residues of proteins, which are generally found within the consensus motif ΨKXE where Ψ is a hydrophobic amino acid and X is any residue. Like ubiquitination, the covalent attachment of SUMO to other proteins involves a series of enzymatic steps (*see* **Fig. 1**), but the proteins involved are distinct from those in the ubiquitin conjugation pathway. First, the SUMO proteins have to undergo proteolytic processing near their C-terminal end to form the mature proteins, a step which is performed by SUMO proteases (Ulps). These proteases are dual-functional, as they are also responsible for cleaving SUMO groups from substrate proteins by cleaving the isopeptide bonds by which they are joined ***(3–5)***. The mature processed SUMO protein is covalently attached via a thioester bond to the Uba2 subunit of the heterodimeric SUMO E1 activating enzyme in an ATP-dependent reaction ***(6–9)***.

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

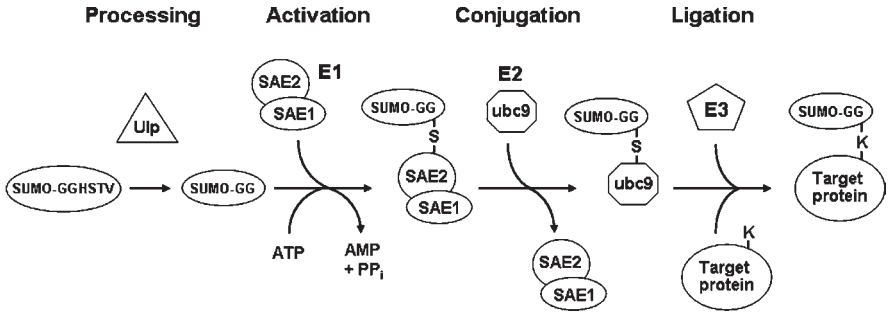

Fig. 1. The SUMO conjugation pathway. After they are translated, SUMO proteins must first be processed by a SUMO protease such as Ulp1, which removes four C-terminal residues so that the mature form ends with a glycine. These SUMO proteases are also responsible for removing SUMO groups from proteins. This mature form is then activated in an ATP-dependent manner by forming a thioester bond with a cysteine residue in the SAE2 subunit of the heterodimeric E1 activating enzyme. Following this activation step, the SUMO moiety is transferred to the E2 conjugating enzyme ubc9. In the final step SUMO is transferred in a ligation reaction from ubc9 to substrate proteins, forming an isopeptide bond between the terminal glycine on SUMO and the ε-amino group of a lysine in the target protein. The efficiency of sumoylation of some proteins is enhanced by SUMO ligase E3 proteins, via their ability to bind both ubc9 and the target protein, thereby increasing the kinetics of the SUMO transfer.

The SUMO moiety is transferred from the E1 to ubc9, the SUMO E2 enzyme, which then binds to the ΨKXE consensus sequence in target proteins and forms an isopeptide bond between the ε-amino group of the lysine within this sequence and the carboxyl group of the C-terminal glycine of the SUMO polypeptide ***(10–13)***. SUMO E3 proteins have been identified that enhance the efficiency of SUMO attachment by interacting with both ubc9 (the E2 enzyme) and the substrate, thereby acting as bridging factors ***(3–5)***. Vertebrate cells contain three SUMO paralogs. SUMO-2 and SUMO-3 are very similar to each other in sequence, and have approximately 50% sequence identity with SUMO-1, which is the best characterized of the three vertebrate SUMO proteins.

In this chapter we describe two different experimental approaches for determining whether a specific protein is sumoylated. One method employs immunoprecipitation of the protein of interest, either endogenous or transfected epitope-tagged protein, followed by Western blot with SUMO antibodies. The sond method involves incubating the protein, either as a ^{35}S-labeled in vitro translation product or purified recombinant protein, with a reconstituted in vitro sumoylation enzymatic reaction, followed by SDS-PAGE and autoradiography or Western blot, respectively, to look for the appearance of higher molecular

weight bands indicative of sumoylation. By comparing wild type protein constructs with those containing non-sumoylatable arginine substitutions of candidate target lysine residues, these protocols can also allow identification of those lysine residues where SUMO attachment actually occurs in a given protein. This information then provides the critical reagents for testing the functional consequences of blocking sumoylation of that particular protein. To illustrate the types of data that can be obtained using these methodologies we present figures showing the results of immunoprecipitation and in vitro sumoylation analyses of a transcription factor we study called HSF2.

2. Materials

2.1. Detection of Sumoylated Proteins by Immunoprecipitation Analysis

1. Cells expressing the protein of interest.
2. Phosphate Buffered Saline (PBS).
3. Lysis solution: 0.15 *M* Tris-HCl (pH 6.7), 5% SDS, & 30% glycerol.
4. N-ethylmaleimide.
5. Complete protease inhibitor (Roche; Indianapolis, IN).
6. Protein G-sepharose or protein A-sepharose.
7. Primary antibody capable of immunoprecipitating protein of interest (or against epitope tag if analyzing a transfected tagged protein), species-matched nonspecific IgG, and antibodies against SUMO-1, SUMO-2, or SUMO-3 (Invitrogen).
8. SDS loading buffer
9. Polyacrylamide gel electrophoresis equipment and SDS-PAGE solutions.
10. Reagents for immunoblotting and detection (nonfat dried milk for blocking, and ECL or other detection system).

2.2. Detection of Sumoylated Proteins by In Vitro Sumoylation Analysis

1. Plasmid containing open reading frame of protein of interest oriented to be expressed from a T7 promoter in the vector.
2. pGEX-SUMO-1, pQE30-SUMO-1, pGEX-Ubc9, and pGEX-SAE2/SAE1 bicistronic expression construct, or purified SUMO, ubc9, SAE1/SAE2 available commercially (e.g., LAE Biotech International).
3. Ampicillin and LB media.
4. Isopropyl-β-D-thio-galactopyranoside (IPTG).
5. Phenylmethylsulfonyl fluoride (PMSF).
6. Glutathione-agarose and Ni-NTA-agarose.
7. In vitro translation kit (e.g., Promega TNT T7 Quick for PCR DNA kit).
8. Polyacrylamide gel electrophoresis equipment and SDS-PAGE solutions.
9. Whatman paper, X-ray film, and cassettes for detection of ^{35}S-labeled proteins in sumoylation reaction.

3. Methods

3.1. Detection of Sumoylated Proteins by Immunoprecipitation Analysis

In this protocol, proteins to be tested for sumoylation are immunoprecipitated using lysis buffers designed to block the action of desumoylating enzymes (*see* **Note 1**) and then subjected to Western blot analysis using anti-SUMO antibodies to look for the appearance of a band with a size consistent with a sumoylated form of the protein. Although the theoretical molecular weight of the SUMO proteins is approximately 11 kDa, the size increase for each SUMO added on SDS-PAGE is typically in the range of 15–17 kDa. In the case of a protein with multiple sumoylation sites, or where SUMO chains form on a lysine target site (*see* **Note 2**), multiples of this size increase are expected, sometimes yielding very large shifts in mobility. Multiple bands representing different sumoylation states of the protein are also possible. This approach can be used to analyze endogenous proteins, or transfected proteins containing an epitope tag (FLAG, myc, etc.) (*see* **Note 3**). The transfection approach can also be used to determine the lysine residue(s) to which the SUMO group is attached, by comparing the sumoylation of wildtype constructs to ones in which candidate lysines have been changed to non-sumoylatable arginines. Two different lysis conditions are described, one using SDS to inhibit desumoylase enzymes and the other containing N-ethylmaleimide, a chemical inhibitor of these enzymes.

1. Tissue culture cells are grown in media appropriate for that cell line or primary cell type, and typically at least 1×10^6 cells are needed for each immunoprecipitation.
2. For harvesting place the plate of cells on ice, remove media by aspiration and add 1 ml of ice-cold PBS to the plate. Scrape cells off plates with a cell scraper, transfer to a 1.5 ml microcentrifuge tube.
3. Collect cells by centrifugation at 13,000 ×g for 30 sonds at room temperature, and remove supernatant by aspiration.
4. Lyse cells in 150 µl of lysis solution which is then diluted 1:10 in PBS/0.5% NP40 plus complete protease inhibitor (Roche) and centrifuged (16,000 g, 10 min, 4°C) to remove cellular debris. Sonication can be done prior to the centrifugation step if the lysate is highly viscous. Alternatively, the cells can be lysed in any of the standard immunoprecipitation lysis buffers (e.g., RIPA, etc.) known to extract the protein of interest, providing the lysis solution is supplemented with 20 m*M* N-ethylmaleimide (desumoylase inhbitor, freshly dissolved).
5. While the cell lysate is being centrifuged prepare 30 µl of 50% protein G-Sepharose (or protein A-sepharose if that is preferential for the particular antibody) as per manufacturer's instructions. After protein G-Sepharose has been prepared add the above cell lysate to the protein G-Sepharose and rotate at 4°C for a half hour to preclear the lysate.
6. Pellet the protein G-Sepharose by centrifugation (16,000 g, 20 s, 4°C) and transfer the supernatant to a new tube. At this point take 30 µl of cell lysate, place in a separate tube with 10 µl 4×SDS load buffer and label "input."

7. Divide the remainder of each treatment lysate into 2 equal amounts in separate 1.5 ml centrifuge tubes. To one of the tubes add a sufficient amount of primary antibody and to the other tube add a species-matched nonspecific IgG. Place samples on rotator at 4°C for 1 hr after which add 20 µl of PBS washed protein G-Sepharose and rotate at 4°C for 3 h.
8. Collect beads by centrifugation (16,000 g, 10 sonds, 4°C) and discard supernatant.
9. Wash the beads 4 times with PBS/0.5% NP40 plus complete protease inhibitor, or other lysis buffer if another was chosen, collecting the beads by centrifugation after each wash (16,000 g, 10 s, 4°C). Add 30 µl 2×SDS-PAGE loading buffer to beads after removing supernatant from final wash.
10. Separate immunoprecipitated proteins by SDS-polyacrylamide gel electrophoresis.
11. Transfer proteins to nitrocellulose or nylon membrane and subject to Western blotting using antibodies against SUMO-1, SUMO-2, or SUMO-3 (commercially available). This methodology can also be used to examine the sumoylation state of an epitope-tagged version of the protein of interest being expressed in transfected cells (*see* **Note 3**). The results of immunoprecipitation analysis to examine sumoylation of the HSF2 protein is shown in **Fig. 2**.

3.2. In vitro Sumoylation Assay

In this protocol the protein of interest is in vitro translated (typically with ^{35}S-methionine incorporation) and then incubated in a reaction containing the SUMO E1 and E2 enzymes and SUMO-1, followed by SDS-PAGE and autoradiography to determine whether a lower mobility band appears that would be consistent with a sumoylated form of the target protein. Because of the high concentrations of SUMO E1 and E2 enzymes used in this in vitro sumoylation reaction, the need for SUMO E3 proteins is diminished and thus sumoylation can be detected without their addition. Performing the in vitro sumoylation reaction using mutants of the protein in which candidate sumoylation site lysine

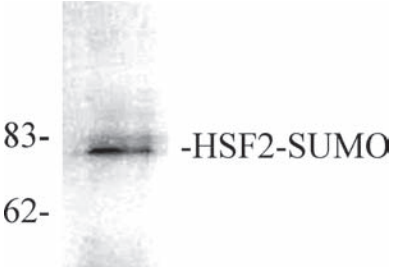

Fig. 2. Detection of sumoylation by immunoprecipitation/SUMO-1 Western blot. HSF2 protein was immunoprecipitated from extracts of HeLa cells followed by Western blot using anti-SUMO-1 antibodies. The positions of molecular weight standards are indicated on the left side of the panel. (Reprinted with permission from ***ref. 15***).

residues are changed to nonsumoylatable arginines can be used to determine the site(s) at which SUMO attachment is occurring (e.g., *see* **Fig. 4**). The expression and purification of the recombinant proteins required for the in vitro sumoylation assay is described in **Subheading 3.2.1**, and the protocol for performing assay itself is described in **Subheading 3.2.3**.

3.2.1. Expression If Recombinant SUMO, ubc9 (SUMO E2), and SAE1/SAE2 (SUMO E1) Heterodimer

The SUMO proteins are expressed and purified as fusion proteins with GST or 6xHis at the N-terminal end of the SUMO proteins, and these affinity tags do not need to be removed prior to using these SUMO proteins for the sumoylation reaction. The size difference of GST-SUMO vs. 6xHis-SUMO can also provide a useful control for the sumoylation reaction as it yields a predictable size difference between the sizes of the sumoylation products (e.g., *see* **Fig. 3**). The SUMO E1 is a heterodimer of SAE1/SAE2, and is active when expressed in E. coli from a bicistronic contruct of GST-SAE2 and untagged SAE1; the two proteins complex and can be purified using glutathione-agarose affinity chromatography ***(14)***. The SUMO E2 can be expressed which appears to be more active, at least in our hands when the GST tag is removed by thrombin cleavage. The following is the general protocol for expressing and purifying these recombinant proteins needed for the *in vitro* sumoylation assay. Once purified these recombinant proteins can be stored at −80°C for extended periods of time.

1. Transform expression construct into DH10B E. coli cells using standard molecular biology methods.
2. Plate cells on LB plates containing ampicillin and incubate overnight at 37°C.
3. Select single colonies and grow overnight at 37°C in LB media containing ampicillin.
4. Inoculate individual liters of LB containing ampicillin with aliquots (5 mL) of overnight culture and grow cells to an $O.D._{600\,nm}$ 0.6–0.8.
5. Induce the cells with IPTG (1 m*M*) for 3 hs.
6. After 3 hr induction harvest cells by centrifugation (4,000 g; 5 min; 4°C) and resuspend pellet in PBS (4°C) then repellet cells. At this point the cell pellet can be extracted or stored at −80°C.
7. To extract protein from the cells they are resuspended in PBS (4°C) with PMSF (phenylmethylsulfonyl fluoride) to a final concentration of 1 m*M*.
8. Pass cells through a French press at 10,000 to 14,000 psi, and repeat to ensure complete lysis.
9. Centrifuge the cell lysate (30,000 g;1 h; 4°C) and retain the supernatant.
10. Purify proteins using standard nondenaturing affinity chromatography techniques suitable for their fusion tags (glutathione agarose affinity chromatography for GST-fusion proteins and Ni-NTA-agarose affinity chromatography for 6 × His-fusionprote ins).

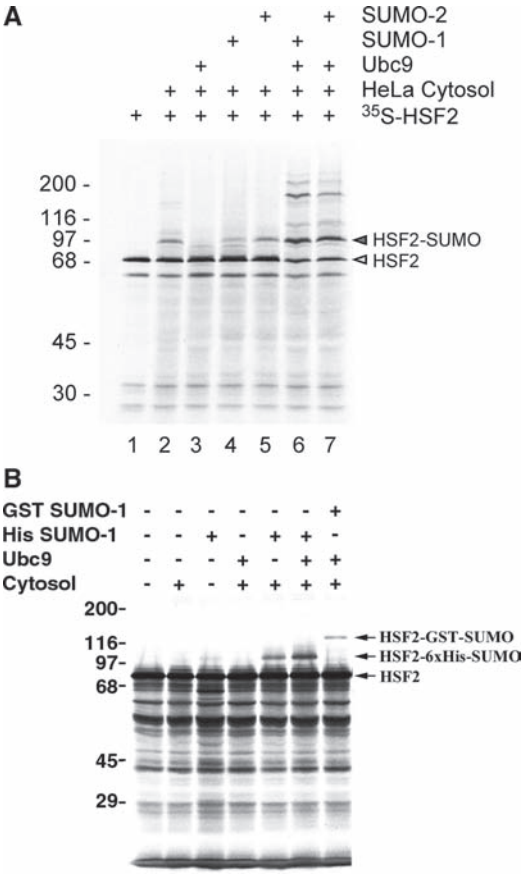

Fig. 3. Analysis of SUMO-1 modification by reconstituted in vitro sumoylation reaction. **(A)** In vitro translated ^{35}S-labeled HSF2 protein was incubated with HeLa cytosol (as a source of E1), Ubc9, SUMO-1, SUMO-2 or with various combinations of each of these, and then subjected to SDS-PAGE followed by autoradiography. The positions of unmodified and SUMO-modified HSF2 are indicated to the right of the panel. **(B)** In vitro translated ^{35}S-labeled HSF2 protein was subjected to the in vitro SUMO-1 modification assay using either 6xHis-SUMO-1 or GST-SUMO-1 as the SUMO-1 substrate for the reaction. (Reprinted with permission from ***ref. 15***).

11. Check purified proteins by Coomassie blue staining of a SDS-PAGE gel (GST-SUMO1 = 38 kDa, GST-Ubc9 = 44 kDa, and 6His-SUMO1 = 14 kDa).
12. For the *in vitro* sumoylation assay the GST-Ubc9 needs to be thrombin cleaved to remove the GST-tag. This can be done following standard protocols. Check thrombin cleavage of GST-Ubc9 by Coomassie staining of a SDS-PAGE gel (Ubc9 = 18 kDa).

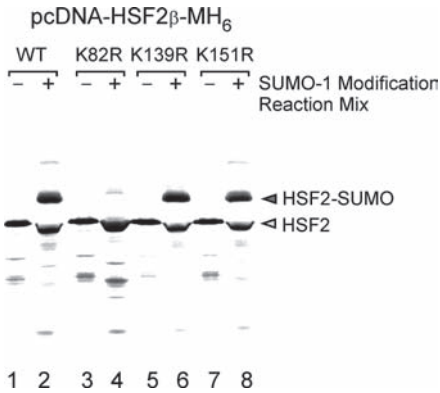

Fig. 4. In vitro translated ^{35}S-labeled wildtype HSF2 protein and the HSF2 SUMO-1 consensus site mutants K82R, K139R, and K151R were used as substrates in *in vitro* SUMO-1 modification reactions. The positions of unmodified and SUMO-modified HSF2 proteins are indicated to the right of the panel. (Reprinted with permission from ***ref. 15***).

3.2.2. In Vitro Sumoylation of Rabbit Reticulocyte System Translated Proteins

The in vitro sumoylation assay uses ^{35}S-methionine radiolabelled protein as the substrate. We generate radiolabelled protein using the TNT T7 Quick for PCR DNA kit (Promega, Madison WI) following the manufacturers instructions. Described below is the SUMO modification procedure to be utilized with radiolabelled translated proteins.

1. Translate target protein fresh before each sumoylation assay following the manufacturer's instructions. Place freshly translated protein on ice until **step 3**.
2. For each sumoylation reaction prepare a mixture containing the following (on ice): 1 µl 10× sumoylation buffer, 0.4 units creatine phosphokinase, 10 m*M* creatine phosphate, 0.6 units inorganic pyrophosphatase, 100 ng purified SAE1/SAE2 heterodimer (E1), 400 ng purified ubc9 (E2), 1 µg purified 6 × His-SUMO-1, and H_2O to 10 µl. 10× sumoylation buffer contains 500 m*M* Tris-HCl (pH 7.6), 500 m*M* KCl, 50 m*M* $MgCl_2$, 10 m*M* DTT, and 10 m*M* ATP. As a negative control, make another mix identical to the one above except that it lacks SUMO protein. If desired a third mix can be made in which GST-SUMO-1 is added instead of 6 × His-SUMO.
3. Set up the reactions (no SUMO control, +6 × His-SUMO, and +GST-SUMO) by adding 2 µl in vitro translated protein to the 10 µl reaction mixes, and then incubate at 37°C for 1 hr.
4. Terminate the reaction by adding 12 µl 2×SDS-PAGE load buffer. Store at −20°C until gel electrophoresis.
5. Boil the samples for 5 min and separate on SDS-PAGE gel. After electrophoresis the gel is fixed for 10 min in SDS-PAGE fixing solution (50% methanol/10% acetic

acid), then dried on Whatman paper, and finally placed on x-ray film.^{35}S emissions are low energy and so it is advisable not to leave plastic wrap between the dried gel and the X-ray film if possible, as this can increase required exposure times.

6. One important experiment to do to give confidence in the in vitro sumoylation assay is to do a reconstitution test where each of the components required for sumoylation (E1, ubc9, SUMO-1) are individually left out of the reaction and compared to a reaction where all components are present (**Fig. 3A**). As shown in this figure, such an experiment can also reveal the relative efficiency of sumoylation of your target protein by different SUMO proteins (e.g., SUMO-1 vs. SUMO-2). Another experiment which increases confidence that your protein is indeed being sumoylated vs. being targeted by some other modification is to compare the effect of using of 6×His-SUMO vs. GST-SUMO as the donor SUMO, because this gives a predictable size shift between the sumoylated reactions (**Fig. 3B**).
7. To identify the sumoylation site in the protein of interest site directed mutagenesis is done to change candidate lysine (changed to arginine) in the sumoylation consensus sequence (ΨKXE) to non-sumoylatable arginine residues utilizing protocols such as the Quickchange Site Directed Mutagenesis Kit (Stratagene). The extent of sumoylation of the wild type vs. lysine-to-arginine mutant can then be compared using either the transfection/immunoprecipitation approach or the in vitro sumoylation assay. Results of such an experiment using the in vitro sumoylation assay are shown in **Fig. 4**.

4. Notes

1. SUMO-modified proteins are highly susceptible to SUMO proteases. The SDS in the lysis buffer described in this protocol inactivates the SUMO proteases allowing for easier detection of sumoylated proteins. However, a common complication with the SDS-lysis method is that the cell lysates tend to be very viscous and sticky due to genomic DNA in the lysate. This problem is remedied by brief sonication which shears the DNA and makes the samples easier to manipulate. SUMO proteases can also be inhibited by the addition isopeptidase inhibitor N-ethylmaleimide (20 mM) to standard lysis buffers such as NP-40 lysis buffer (50 m*M* Tris-HCl (pH 8.0), 150 m*M* NaCl, 1% NP-40) if another lysis buffer besides the SDS-lysis is more desirable.
2. The size of putative sumoylated forms of a protein on SDS-PAGE will depend on how many different SUMO attachment sites the protein has. In addition, SUMO-2 and SUMO-3 have been reported to form polymeric chains reminiscent of ubiquitin, which could result in large increases in size for a sumoylated protein on SDS-PAGE compared to the non-sumoylated form ***(14)***. Thus, it is possible to observe bands that are multiples of the approximate 15–17 kDa size of each SUMO unit, as well as multiple bands representing different sumoylation states.

3. Investigating sumoylation may also be done using cells transfected with fusion-tagged plasmid constructs of the protein thought to be sumoylated with immunoprecipitation utilizing fusion tag antibodies which are available from commercial sources (e.g., GFP, FLAG, Myc, and 6×His tags). In these types of experiments it is advisable to co-transfect the cells with a SUMO expression construct (often this is epitope-tagged) to ensure that sufficient SUMO protein is present in the transfected cells to allow for efficient sumoylation of the transfected target protein being tested.

Acknowledgments

We are very grateful to Mike Matunis (Johns Hopkins), Ron Hay (University of St. Andrews), and Chris Lima (Sloan Kettering Institute) for providing constructs and reagents.

Efficient Enrichment of Intact Phosphorylated Proteins by Modified Immobilized Metal-Affinity Chromatography

Anna Dubrovska

1. Introduction

The lack of an efficient technique to enrich for phosphorylated proteins is limiting of phosphoproteomes studies. Enrichment with antiphospho serine, antiphospho threonine, or anti-phospho tyrosine antibodies depends on the affinity and specificity of antibodies that limit comprehensiveness of the analysis ***(1–3)***. Metabolic labeling of cells with inorganic (^{32}P) phosphate, followed by an analysis of the whole proteome, requires efficient separation to exclude comigration with nonphosphorylated proteins ***(4,5)***. Chemical modifications of phosphorylated residues in the peptides, followed by MS, allow identification of phosphorylation sites ***(1,5–8)***. However, these techniques do not provide information about full length proteins, e.g., molecular mass of intact proteins. Immobilized metal-affinity chromatography (IMAC) has been successfully used for enrichment of phosphopeptides ***(1,5,9,10)***, but the efficiency of purification of phosphoproteins has been low, indicating significant losses of phosphoproteins ***(5,9,10)***. Another important limitation of available IMAC methods is that bound proteins are eluted into a solution which is incompatible with further separation by 2-DE. A modified IMAC technique developed in our laboratory makes possible efficient and comprehensive analysis of phosphoproteins, and is compatible with 2-DE ***(11)***.

2. Materials

2.1. Cell Culture and Lysis

1. Clonetics® Normal Human Mammary Epithelial Cell Systems (Lonza Walkersville, Inc.).
2. Cell lysis buffer: 1% (v/v) Triton X100, 150 mM NaCl, 10 mM Tris-HCl, pH 8.0, protease inhibitors (Roche Diagnostics; complete inhibitor cocktail tablets EDTA-free) (*see* **Note 1**). Store at 4°C. Add protease inhibitors just prior to use.
3. Transforming growth factor-β1 (TGFβ1, Peprotech) is reconstituted with sterile 4 mM HCl containing 1 mg/mL BSA to a final concentration 50 μg/mL and stored in single use aliquots at −80°C, and then added to tissue culture dishes at the concentration5 ng/mL.
4. Radioactive orthophosphate ((^{33}P) or (^{32}P) orthophosphate) (GE Healthcare Uppsala, Sweden).

2.2. Preparation of Fe-NTA Agarose

1. NTA agarose (Qiagen, VWR International AB).
2. 6 *M* guanidine-HCl in 0.2 *M* acetic acid. Store at room temperature.
3. Water solution of 2% (w/v) sodium dodecyl sulfate (SDS). Store at room temperature.
4. 25%, 50%, 75% and 100% (v/v) ethanol-water solutions.
5. Aqueous solution of 100 mM ethylenediamine tetraacetic acid (EDTA), pH 8.0
6. Solution of 0.1 *M* $FeCl_3$ in 0.1 *M* acetic acid. Prepare just prior to use.
7. Aqueous solution of 0.1 *M* acetic acid.
8. Rotor shaker.
9. Empty econo-pac chromatography columns (Bio-Rad, Hercules, CA).

2.3. Phosphoprotein Enrichment Procedure

1. Washing buffer: 5 m*M* Tris-HCl, pH 6.3, 150 m*M* NaCl. Store at 4°C.
2. Elution buffer: 100 m*M* dithiotriethol (DTT), 2% (w/v) SDS, 50 m*M* Tris-HCl, pH 6.8. Prepare just prior to use.
3. Methanol 100%.
4. Glacial acetic acid.
5. Aqueous solution of 25% (v/v) methanol, 10% (v/v) acetic acid.
6. Quick Start Bradford Protein Assay Kit (Bio-Rad, Hercules, CA).

2.4. 2-DE Electrophoresis

1. Rehydration solution: 8 *M* urea, 2.5% (w/v) CHAPS, 0.28% (w/v) DTT, 0.5% (v/v) IPG buffer, pH 3–10 (GE Healthcare), 0.002% bromophenol blue. Store at −80°C. Add DTT just prior to use.
2. DTT or iodoacetamide-containing equilibration buffer: 2% SDS, 50 m*M* Tris-HCl pH 8.8, 6 *M* urea, 30% (v/v) glycerol, 0.002% bromophenol blue. Store in 10 ml aliquots at −80°C. Add DTT to 1% or iodoacetamide to 2.5% just prior to use.

3. SDS electrophoresis buffer: 25 m*M* Tris, 192 m*M* glycine, 0.1% SDS, pH 8.3. Store at room temperature.
4. Agarose sealing solution: 0.5% agarose, 0.002% bromophenol blue in SDS electrophoresis buffer.
5. 4× resolving gel buffer: 1.5 *M* TrisHCl, pH 8.8. Filter solution through a 0.45 µm filter. Store at 4°C.
6. 10% ammonium persulfate.
7. 10% SDS.
8. Acrylamide/bis acrylamide solution (37.5:1; T = 40%, C = 2.6%).
9. N,N,N,N'- Tetramethyl-ethylenediamine (TEMED) (GE Heralthcare, Uppsala, Sweden).
10. Water-saturated isobutanol. Shake equal volumes of water and isobutanol in a glass bottle and allow to separate. Use a top layer. Store at room temperature.
11. Prestained molecular weight markers (New England BioLabs, Ipswich, MA).
12. IPGDry strips with immobilized pH gradient, pH range 3–10, 18 cm, linear (GE Healthcare, Uppsala, Sweden).
13. Ettan IPGphor first-dimension isoelectric focusing system (GE Healthcare, Uppsala, Sweden).
14. Ettan DALT*six* Electrophoresis System (GE Healthcare, Uppsala, Sweden).
15. ImagePlatinum software (GE Healthcare, Uppsala, Sweden).

2.5. Silver Staining Procedure

1. Fixing solution: 20% (v/v) methanol, 10% (v/v) acetic acid.
2. Sensitizing solution 30% (v/v) ethanol, 0.2% (w/v) sodium thiosulphate ($Na_2S_2O_3$), 6.8% (w/v) sodium acetate (CH_3COONa).
3. Silver solution: 0.25% silver nitrate, $AgNO_3$.
4. Developing solution: 2.5% (w/v) sodium carbonate (Na_2CO_3), 0.015% (v/v) formaldehyde. Add formaldehyde immediately before use.
5. Gel drying solution: 30% (v/v) methanol, 5% (v/v) glycerol.
6. Cellophane sheets.
7. Rocking platform.
8. Fuji ImageReader software (Fuji).
9. FujiX2000 PhosphorImager (Fuji).
10. AIDA 2D Densitometry software (Bio Imaging).

2.6. Western Blotting for Phosphorylated Proteins

1. Criterion precast gel system (Bio-Rad, Hercules, CA).
2. Criterion TrisHCl Gels, 12.5% (Bio-Rad, Hercules, CA).
3. Criterion electrophoresis cell (Bio-Rad, Hercules, CA).
4. Criterion blotter cell (Bio-Rad, Hercules, CA).
5. Hybond P membrane (Amersham Biosciences, Piscataway, NJ).
6. Tris-buffered saline with Tween (TBS-T): make 10× stock solution with 1.37 M NaCl, 27 m*M* KCl, 250 mM Tris-HCl, pH 7.4, 1% Tween-20. Dilute 100 mL with 900 mL water to use.

7. Blocking solution and antibody dilution buffer: 5% (w/v) BSA fraction V in TBS-T.
8. Primary antibody: antiphospho tyrosine; antiphospho threonine (Santa Cruz, CA); anti-phospho serine (Sigma-Aldrich).
9. Secondary antibody: Antimouse IgG conjugated to horse radish peroxidase (GE Healthcare).
10. Chemiluminescence Luminol Reagent (Santa Cruz, CA).
11. Kodak BioMax MR film (Sigma-Aldrich).

3. Methods

The described Fe-IMAC procedure permits significant enrichment of phosphoproteins, and allows generation of good quality 2-D gels. Combined with the simplicity of the procedure described here, it provides a tool for the efficient and comprehensive analysis of phosphoproteins. This technique may be applied to various types of biological material from cultured cells to tissues.

3.1. Preparation of Fe-NTA Agarose

NTA or Ni-NTA agaroses are commercially available from Qiagen and can be used for preparation of Fe-NTA resin using the following procedure:

1. Place the column on a stand above the capacious beaker for flow-through collection. Add 50% NTA agarose slurry in the column on the basis of 1 mL the beads per 1.5 mL of total cell lysate.
2. Wash the column with 2 volumes of 6 *M* guanidine-HCl in 0.2 *M* acetic acid.
3. Wash the column with 5 volumes of ddH2O.
4. Wash the column with 3 volumes of 2% SDS.
5. Wash the column with 1 volume of 25% ethanol.
6. Wash the column with 1 volume of 50% ethanol.
7. Wash the column with 1 volume of 75% ethanol.
8. Wash the column with 5 volumes of 100% ethanol.
9. Wash the column with 1 volume of 75% ethanol.
10. Wash the column with 1 volume of 50% ethanol.
11. Wash the column with 1 volume of 25% ethanol.
12. Wash the column with 1 volume of ddH_2O.
13. Wash the column with 5 volumes of 100 mM EDTA, pH 8.0.
14. Wash the column with 10 volumes of ddH_2O.
15. Wash the column with 5 volumes of 0.1 *M* acetic acid.
16. Wash the column with 5 volumes 0.1 *M* $FeCl_3$ in 0.1 *M* acetic acid.
17. Close the column tip and add 5 volumes 0.1 *M* $FeCl_3$ in 0.1 *M* acetic acid.
18. Close the upper side of column and incubate the NTA beads with 0.1 *M* $FeCl_3$ solution on rotor shaker for 16 h at room temperature.
19. Wash the column with 5 volumes of 0.1 *M* acetic acid. Beads can be stored in 0.1 *M* acetic acid at 4°C for 2 weeks.

20. Wash the column with 5 volumes of lysis buffer (1% Triton X100, 150 m*M* NaCl, 10 m*M* TrisHCl, pH 8.0, protease inhibitors). Washed Fe-NTA beads can be used for phosphoprotein enrichments procedure.

3.2. Metabolic Labeling

To monitor phosphorylated proteins, we performed metabolic labeling of MCF10A human breast epithelial cells with radioactive (^{33}P) orthophosphate or (^{32}P) orthophosphate. (^{33}P) isotope has lower energy, as compared to (^{32}P) isotope, which may be of importance for safety considerations (*see* **Note 2**).

1. The MCF10A cells were growing to confluence in mammary epithelial growth medium (MEGM) in 150 mm dishes.
2. The cells were metabolically labeled with serum free MEGM medium supplemented with 0.25 mCi/mL (^{32}P) inorganic phosphoate for 16 h to ensure an efficient incorporation of radioactive isotope into the proteins.
3. The cell were treated or not with 5 ng/ml TGFβ1 for 3 h to initiate TGFβ1-dependent protein phosphorylation.
4. The cells were washed 3 times with cold washing buffer (*see* **Note 3**).
5. Proteins were extracted from cells using lysis buffer (3 mL of lysis buffer for 15 cm dish). To provide complete protein extraction cell were incubated with lysis buffer on ice for 30 min with agitation and the material was scraped into the appropriate labeled tubes.

3.3. Phosphoprotein Enrichments Procedure for the Cell Culture

It is important to pick up a small amount of each chromatography fraction (30–60 mkl) for the next analysis. Make a note about total volume of each fraction taken for analysis as it might be helpful for estimation of phosphoprotein binding.

1. Cell extracts were clarified by centrifugation at 13000 g for 20 min at 4°C, and were incubated with washed Fe-IMAC beads for 12 h at 4°C on rotor shaker. We applied 3 mL of lysate with average concentration of total proteins 0.85 mg/ml for 2 mL of Fe-IMAC beads directly into the chromatography column (*see* **Note 4**).
2. After incubation with cell extract, Fe-IMAC beads were washed six times with washing buffer. Washing procedure was performed at room temperature. The bound proteins were eluted by incubation with a buffer containing 100 m*M* dithiotriethol (DTT), 2% SDS, 50 m*M* TrisHCl, pH 6.8 for 5 min at 95°C (*see* **Note 5**).
3. Eluted proteins were precipitated by adding of methanol to 25% and acetic acid to 10% directly to the samples followed by incubation on ice for 30 min (*see* **Note 6**).
4. Precipitated proteins were centrifuged at 13000 g for 30 min at 4°C.
5. The pellet was washed twice with 25% (v/v) methanol, 10% (v/v) acetic acid solution followed by centrifugation at 13000 g for 30 min at 4°C (1 mL of precipitation solution per 1.5 mL tube).

6. The result white protein-containing pellet was dried in vacuum centrifuge to remove traces of a precipitation solution (*see* **Note 7**).
7. The dried protein pellet was dissolved in rehydration solution.
8. Complete solubilization of proteins required 5–12 h vortexing at room temperature; prolonged drying in a vacuum centrifuge increased the time of solubilization.

3.4. Phosphoprotein Enrichments from Tissue

The Fe-IMAC technique described here is also suitable for enrichment of phosphoproteins from tissues.

1. Frozen tissue (0.5- 1 cm^3) was placed in Petry dish in 3 mL of ice-cold lysis buffer and cut into small pieces (1 mm^3) with scalpel.
2. Tissue pieces were transferred in 50 mL Falcon tube and sonicated on ice by performing 10 cycles at 30 s/cycle with 1 min interval between the cycles to cool down the tube content.
3. Tissue extract was clarified by centrifugation at 13000 g for 20 min at 4°C, and protein concentration was measured. 3 mL of the tissue lysate with protein concentration 0.85 mg/mL was incubated with 2 mL of Fe-IMAC beads for 12 h at 4°C on rotor shaker.
4. All the next stages of the procedure are the same as described above for the cell culture. Using this described technique we observed 81% recovery of phosphoproteins extracted from chicken liver, as evaluated by immunoblotting with anti-threonine antibodies (**Fig. 2E**). An example result for 2-DE of phosphoproteins enriched from chicken liver is shown in **Fig. 2F** and **2G**.

3.5. Evaluation the Efficiency of Phosphoprotein Enrichment

To evaluate the efficiency of phosphoprotein enrichment by Fe-IMAC, we performed 1-DE and 2-DE, followed by monitoring of phosphorylated proteins by Western blotting or authoradiography.

3.5.1. Silver Staining Procedure

1. To estimate the efficiency of phosphoprotein binding to and elution from Fe-IMAC beads all fraction of Fe-NTA based chromatography were taken for 1-DE (input, flow-through, washes, elution and combined elution fraction). Combined elution fraction is the resulted protein solution obtained after dissolving the washed protein pellet in rehydration solution.
2. Equal volume of each chromatography fraction (50 mkl) was taken for SDS-PAGE separation using Criterion electrophoresis system.
3. For silver staining the gel was placed in a tray containing fixing solution and agitated on a shaker for at least 2 h.
4. The fixing solution was drained from the tray and the gel was washed ddH_2O for 10 min.
5. The sensitizing solution was added and gel was agitated in sensitizing solution for 30 min.

6. The sensitizing solution was drained from the tray and the gel was washed with ddH_2O 4 times for 15 min.
7. The gel was incubated in silver solution for 30 min.
8. After 30 min, the silver nitrate solution was drained into an appropriate waste beaker and gel was washed with ddH_2O two times, 1 min each time.
9. The developing solution was added to the gel, and agitated until tiny yellow or brown precipitate appears. Then developer was poured off, add fresh developer was added. The developing step was continued until desired intensity of protein staining is achieved.
10. Adding the fixing solution terminated the staining.
11. The gel was then agitating in drying for 20 min.
12. The soaked gel was placed between the wet cellophane sheets and dried on the gel drier at 65°C for 1 h (*see* **Note 8**).

3.5.2. Estimation a Chromatography Efficiency Using 1-DE Gels

1. To monitor efficiency of phosphoprotein binding FE-NTA chromatography fractions were separated by 1-DE and the gels were exposed in a FujiX2000 PhosphorImager. Examples of the silver stained gel and autoradiography are shown in **Fig. 1A** and **1B**.
2. Quantification of radioactivity associated with proteins separated by SDS-PAGE was performed using Fuji ImageReader software, and was normalized to volumes of fraction using the formula $A_{ppf} = D/V$, where A_{ppf} is an amount of phosphoproteins in each fraction, D is densitometric intensity of this fraction and V is a fraction volume.
3. AIDA 2D Densitometry module (Bio Imaging) was used to evaluate the relative amount of total proteins in each chromatography fraction. Data obtained by densitometry of silver stainined gel and autoradiography were used to calculate an yield of phosphoproteins (Y_{pp}), concentration factor (C_{pp}) and and level of phosphoproteins in the elution fraction (E_{pp}) as shown in **Fig. 1C**.

3.5.3. Monitoring the Phosphoprotein Binding by Western Blotting for Phosphorylated Proteins

1. Criterion electrophoresis system was used for protein SDS-PAGE separation and blotting.
2. Once the transfer was completed, the nitrocellulose membrane was washed with 1× TBS-T with agitation 3 times for 15 min each wash.
3. After washing the membrane was blocked with 5% BSA in TBS-T for 1 h at room temperature on a rocking platform.
4. The blocking buffer was discarded and the membrane was incubated with primary antibody for antiphospho tyrosine (dilution 1:500), anti-phospho threonine (dilution 1:500), antiphospho serine (dilution 1:1000), anti-Smad2 and antiphospho Smad2 proteins. Anti-Smad2 and antiphospho Smad2 antibody were prepared in our institute and used with dilution 1:500. All antibodies were diluted in 5% BSA in TBS-T. The membrane was incubated with primary antibody solution overnight at 4°C on a rocking platform (*see* **Note 9**).

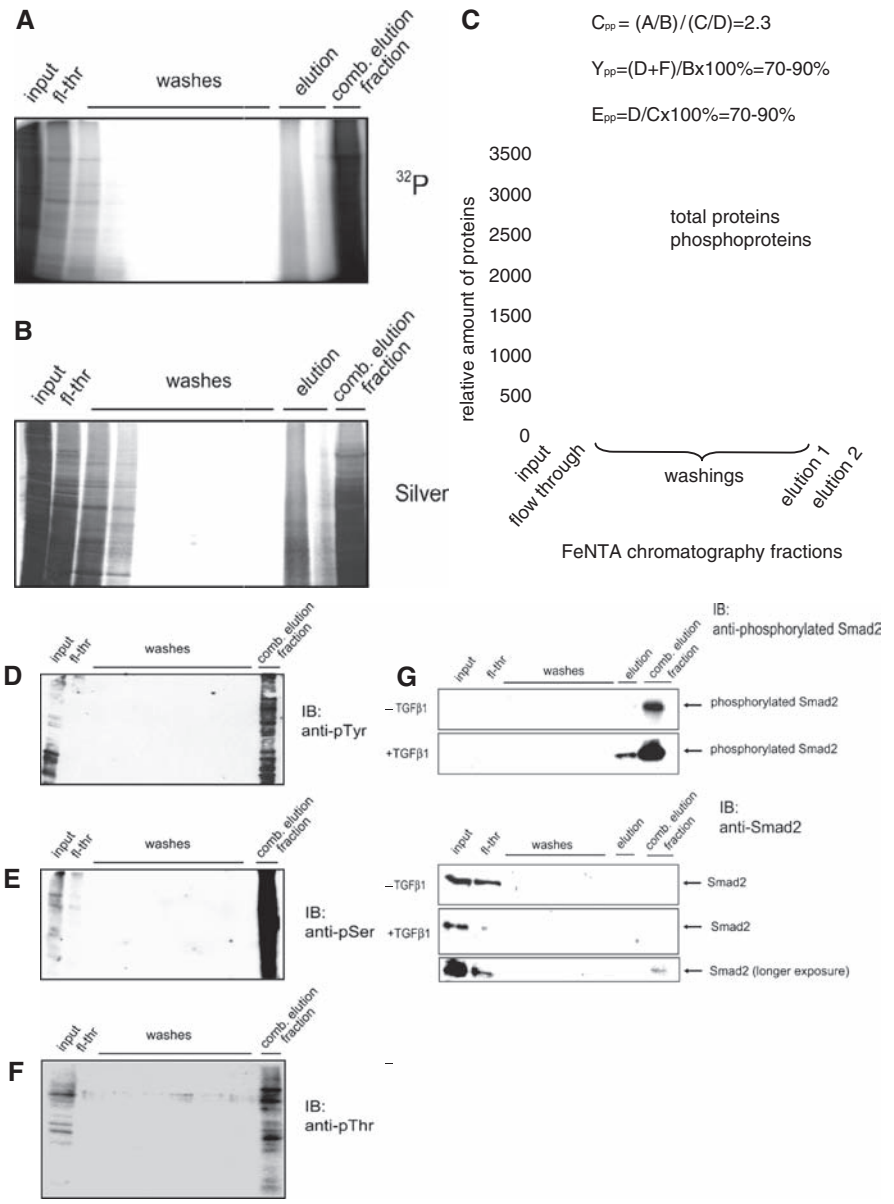

Fig. 1. Fe-IMAC allows efficient enrichment of phosphoproteins **(A**, **B)**. Aliquots of the whole cell lysate (input; 1/50 of the input), flow-through (fl-thr; 1/50 of the fraction), washes, elution fractions from Fe-IMAC beads (elution; 1/50 of the elution fraction), and elution sample prepared for 2-DE (comb. elution fraction; 1/50 of the sample) were subjected to SDS-PAGE, as indicated. Gels were dried and exposed in a phosphorimager. An image of 32P-labeled proteins **(A)** and an image of silver-stained gel **(B)** are shown.

5. The membrane was washed 3 times with TBS-T for 15 min each wash.
6. The membrane was incubated with secondary antibody 30 min at room temperature on the rocking platform. The secondary antibody was freshly prepared prior to use with dilution 1:10000 in 5%BSA in TBS-T.
7. The membrane was washed 3 times with TBS-T for 15 min each wash.
8. The membrane was then incubated with Chemiluminescence Luminol Reagent (Santa Cruz, CA), and proteins were visualized by a suitable exposure with Kodak BioMax MR film. An example result is shown in **Fig. 1D**, **1E**, **1F**, and **1G**.

3.5.4. Separation of Eluted Fraction with 2-DE

1. Prepared samples (eluted proteins solubilized in rehydration solution from **step 3.3)** were subjected to isoelectric focusing using IPGDry strips with immobilized pH gradient, pH range 3–10, 18 cm, linear (GE Healthcare, Uppsala, Sweden) according to the following protocol: rehydration 10 h; 50 V, 3 h; 1000 V, 1 h; 8000 V, 10 h or to 50,000 Vh.
2. 2-D SDS–PAGE was performed in 12% polyacrylamide gels. The Ettan DALT*six* gel caster was used to cast the gels 5–13 h prior to 2-D electrophoresis. Gels were stored at room temperature prior to use.
3. The 2-D gels were run during the day (about 7 h) at constant power 5W per gel through the sealing agarose and 60 W in total through the acrylamide gel.
4. After the electrophoresis, gels were fixed in 10% acetic acid and 20% methanols for 10–12 h. Proteins were detected by silver staining, as described above.
5. To monitor efficiency of phosphoprotein enrichment the gels were exposed in a FujiX2000 PhosphorImager for 18 h.

Fig. 1. (continued) Data obtained by densitometry of silver stainined gel and autoradiography were used to calculate an yield of phosphoproteins (Y_{pp}), concentration factor (C_{pp}) and level of phosphoproteins in the elution fraction (E_{pp}) as shown in panel **(C)**, where **A**, **C**, and **E** is densitometrical intensity of the input fraction, elution fraction 1 and elution fraction 2 correspondingly for silver stained gel; **B**, **D**, and **F** is densitometrical intensity of the input fraction, elution fraction 1 and elution fraction 2 correspondingly for autoradiography.

To monitor phosphorylated proteins, the gels were subjected to immunoblotting with antibodies specific to phosphotyrosine **(D)**, to phosphoserine **(E)**, or to phosphothreonine **(F)**. To monitor TGFb-induced phosphorylation of Smad2, MCF10A cells were treated or not with TGFb1 (5 ng/mL), as indicated, and phosphoproteins were enriched with Fe-IMAC procedure **(G)**. Collection of fractions and gel electrophoresis were performed as described in panels **A–E**. Immunoblotting was performed with antibodies specific to phosphorylated Smad2 (phosphorylated Smad2) or to total Smad2 (Smad2), as indicated. Lanes corresponding to the whole cell extract (input), flow-through (fl-thr), washing fractions (washes), and elution fractions (comb. elution fraction) are indicated. Combined elution fractions represent samples prepared for 2-DE (precipitated and solubilized elution fraction). Longer exposure with anti-Smad2 antibodies indicates presence of Smad2 in elution fractions. (Reproduced with permission from ***ref. 11***. Copyright Wiley-VCH Verlag GmbH & Co. KgaA.)

3.5.5. Estimation a Chromatography Efficiency Using 2-DE Gels

1. We performed 2-DE with eluted fractions, measured quantity-reflecting values of the silver-stained protein spots (quantitating volumes, as defined by the Image-Platinum software, GE Healthcare), and matched them with the radioactively labeled spots, which were detected in a phosphorimager.
2. Then, we compared the quantitating volume of proteins in silver-stained spots which corresponded to radioactively labeled proteins, to the total quantitating volume of silver-stained proteins in 2-D gels. We found that up to 90% of proteins of elution fractions, which were separated by 2-DE, were phosphorylated (**Fig. 2A** and **2B**).
3. The elution procedure allows the generation of good quality 2-D gel. In 2-D gels of proteins prepared with Fe-IMAC technique, we detected in average 500 ^{33}P- or ^{32}P-labeled proteins (**Fig. 2B**) and in average 700 silver-stained spots (**Fig. 2A**). For comparison, we identified in average only 240 ^{32}P-labeled proteins in 2-D gels of whole cell lysate from MCF10A cells (**Fig. 2D**). Silver staining revealed in average 1400 proteins spots in the same gel (**Fig. 2C**).
4. To make sure that Fe-IMAC technique described here is compartible with mass-spectrometry, we randomly selected and identified more than 50 proteins from 2-D gels, which are shown in **Fig. 2**, using MALDI-TOF MS (**Table 1** shows identification of six proteins, as example). Searches of PubMed and prediction of phosphorylation sites with NetPhos showed that the identified proteins were reported as phosphorylated in cells and/or have a number of well-defined phosphorylation sites (**Table 1**). Together with ^{33}P- and ^{32}P-metabolic labeling and immunoblottings with anti-phospho amino acids antibodies (**Figs. 1** and **2**), this confirms efficient enrichment of phosphoproteins with Fe-IMAC.

4. Notes

1. It is important to use EDTA-free inhibitor cocktail. Presence of EDTA in lysis buffer may prevent phosphoprotein binding.
2. Be sure that you have a permission to work with radioactive material, otherwise contact your lab coordinator.
3. Do not use 1×PBS (phosphate buffered saline) for cell washing. Nonorganic phosphates may interfere with phosphoprotein binding by Fe-NTA resin and cause significant losses of phosphoproteins.
4. Clarified cell lysate has been incubated with Fe-NTA beads directly into the chromatography column. Be sure that column tip is closed prior to add cell lysate.
5. The tubes content must change color from dark to white otherwise extend incubation time to 10 min to make sure that all bound phosphoproteins were eluted. In average 0.3–0.4 mg of proteins were eluted when 2.5 mg of cellular proteins were taken as the input. The composition of the elution buffer was optimized for the most efficient recovery of proteins, and to

be compatible with further 2-DE separation. Elution with EDTA, phosphate salts, or with a buffer containing only SDS were found to be incompatible with 2-DE.

6. Shake the sample immediately after adding of methanol and acetic acid. The flakes of precipitated proteins should appear after incubation the samples on ice. Acetone or ethanol precipitation resulted in formation of

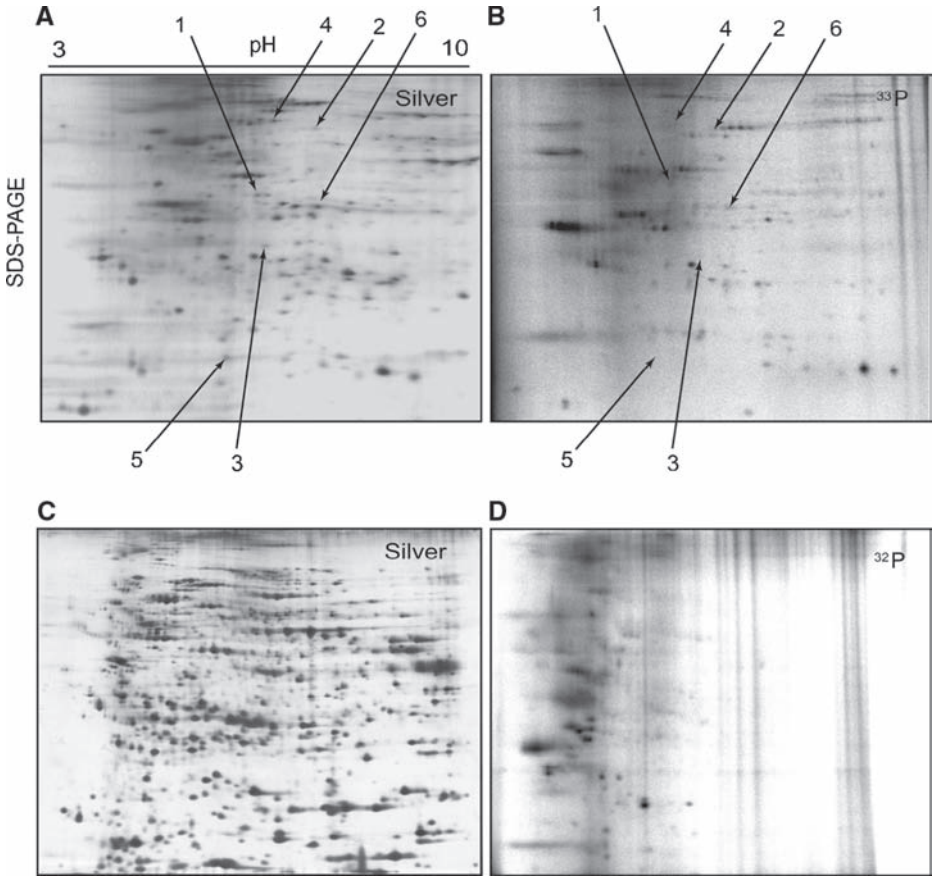

Fig. 2. Fe-IMAC protocol improves resolution of phosphorylated proteins in 2-DE. Images of 2-D gels obtained with samples of MCF10A cells prepared according to the Fe-IMAC protocol **(A**,**B)**, prepared from the whole MCF10A cell extract **(C**,**D)**, and prepared from chicken liver **(F**,**G)** are shown. Radioactive orthophosphate labeled proteins of MCF10A cells were detected after exposure gels in a phosphorimager, and images are shown in panels **B** and **D**. Images of the same gels after silver staining are shown in panels **A** and **C**. Arrows show migration positions of proteins listed in **Table 1**, as examples of identified proteins. Annotation of proteins (spot numbers) is as in **Table 1**.

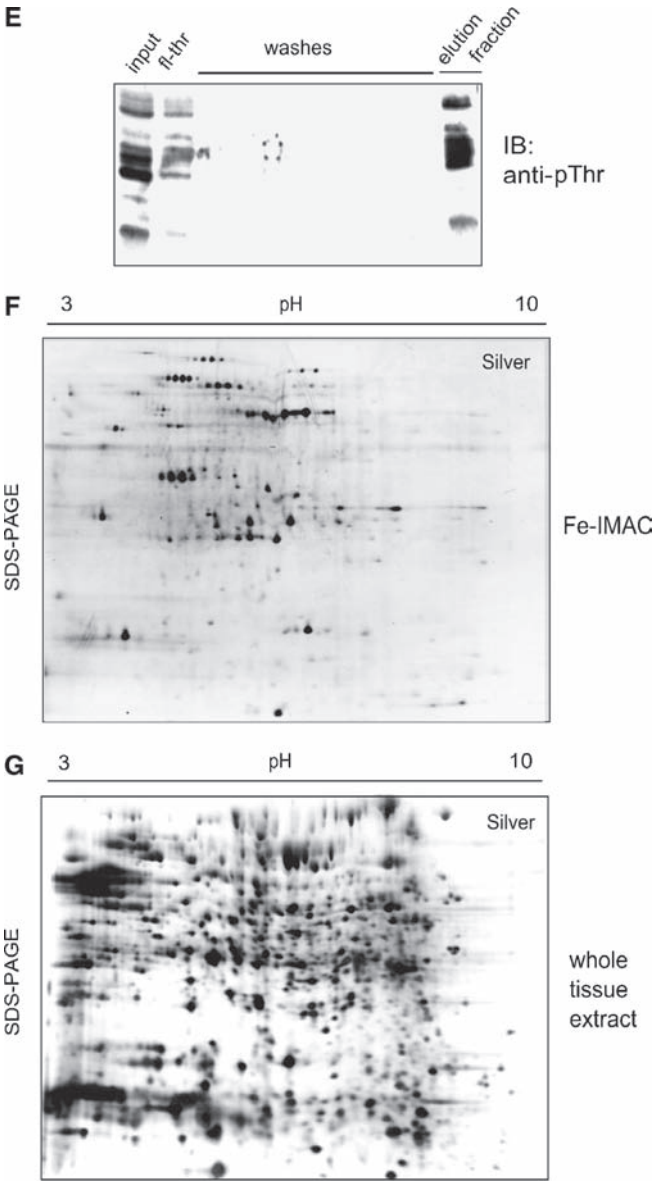

Fig. 2. (continued) Fe-IMAC-based enrichment of phosphoproteins from chicken liver was monitored by 1-DE, followed by immunoblotting with antiphosphothreonine antibodies **(E)**. Images of silverstained 2-D gels obtained with Fe-IMAC sample **(F)**, and with whole liver extract **(G)** are shown. 2-DE was performed as described by Kanamoto et al. **(13)**. Directions of isoelectrofocusing (pH) and SDS-PAGE are indicated (directions in panel **A** are also for gels in panels **A–D**). (Reproduced with permission from ***ref. 11***. d) Lower molecular masses of identified GTP-binding protein alpha *q* subunit and Grb14 may be due to the limited proteolysis of proteins.

precipitates which were not compatible with 2-DE. Dialysis of elution fraction did not eliminate completely the compounds interfering with 2-DE, or caused significant losses of phosphoproteins.

7. Be sure that no solution left in the tube prior to dissolve the pellet with rehydration solution.
8. Any bubbles trapped between the gel and the cellophane must be removed.
9. We monitored the phosphorylation of Smad2, which is a component of transforming growth factor-b (TGFb) signaling pathway, and which is phosphorylated at two C-terminal serine residues upon its activation (12). You can use anti-phospho- antibodies to any other proteins, which you can induce to be phosphorylated instead. It will provide you a good marker to check the phosphoprotein distribution between the chromatography fractions.

Analyzing Protein Phosphorylation

John Colyer

1. Introduction

Protein phosphorylation is a ubiquitous modification used by eukaryotic cells to alter the function of enzymes, ion channels, and other proteins in response to extracellular stimuli, or mechanical or metabolic change within the cell. In many instances, phosphorylation results in a change in the catalytic activity of the phosphoprotein, which influences one particular aspect of cellular physiology, thereby allowing the cell to respond to the initiating stimulus. A number of different residues within a protein can be modified by phosphorylation. Serine, threonine, and tyrosine residues can be phosphorylated on the side chain hydroxyl group (*o*-phosphoamino acids), whereas others become phosphorylated on nitrogen atoms (*N*-phosphoamino acids, lysine, histidine, and arginine). The former group are involved in dynamic "regulatory" functions and have been studied extensively ***(1)***, whereas the latter group may perform both structural/catalytic roles and signaling functions, the study of which has occurred more recently ***(2)***. The disparity in our understanding of the role of *o*- and *N*-phosphoamino acids is in part a consequence of the acid lability of *N*-phosphoamino acids, which leads to their destruction during the analysis of many phosphorylation experiments.

In terms of the process of studying an individual phosphoprotein, a number of key issues can be identified. First, one must demonstrate that phosphorylation of the protein takes place; then define the number of sites within the primary sequence that can be phosphorylated and by which protein kinase; identify the individual residue(s) phosphorylated; the functional implication of phosphorylation of each site; and describe the use of each site of phosphorylation in vivo. This chapter aims to describe the conduct of an experiment performed to identify a protein as a phosphoprotein. In the case of oligomeric enzymes, it will identify the subunit(s) phosphorylated by a particular kinase. The determination of

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

the stoichiometry of phosphorylation is also described, which provides the first information concerning the number of phosphorylation sites within a polypeptide. These procedures are most straightforward if one has access to the purified protein kinase of interest and the protein substrate. In the case of the kinase, this can be served in many instances by a number of commercial sources, but the approach may be limited by the availability of sufficient pure protein substrate. If this is the case, phosphorylation of a particular target as part of a complex mixture of proteins (e.g., whole-cell extract) can be performed. Under these conditions, identification of the protein of interest will require exploitation of a unique electrophoretic property of the protein ***(3)*** or require purification of the protein by immunoprecipitation or other comparable affinity-interaction means prior to electrophoresis. The identification of the protein as a phosphoprotein can thereby be achieved, although analysis of the stoichiometry of phosphorylation in this way is inadvisable. In each case, the experimental procedure has a common design: an in vitro phosphorylation reaction is followed by separation of the phosphoproteins by SDS-PAGE and subsequent identification by autoradiography. The incorporation of labeled phosphate can be determined by excising the phosphoprotein band from the dried gel, scintillation counting this gel piece, and converting ^{32}P cpm into molar terms from the knowledge of the specific activity of the initial ATP stock, and the amount of protein substrate analyzed.

2. Materials

1. Purified and partially purified multifunctional protein kinases can be obtained from several commercial sources. The availability of a number of enzymes is illustrated in **Table 1**. The list is not exhaustive, and inclusion in the table does not constitute endorsement of the product:

Table 1
Commercial Source of Multifunctional Protein Kinases

Kinase	Source
Protein kinase A	*a,c,d,e*
Protein kinase C	*a,b,c,d*
Calmodulin kinase II	*c*
Casein kinase II	*a,b,d*
CDC2 kinase	*d*
src kinase	*d*

[a]Boehringer Mannheim.
[b]Calbiochem-Novabiochem.
[c]Sigma Chemical Co.
[d]TCS Biologicals Ltd.

2. Phosphorylation buffer for the catalytic subunit of protein kinase A (c-PKA): 50 m*M* Histidine-KOH, pH 7.0, 5 m*M* $MgSO_4$, 5 m*M* NaF, 100 n*M* c-pKA, 100 µ*M* ATP.
   a. Histidine-KOH, pH 7.0 is prepared as a concentrated stock, 200 m*M* stored at 4°C for 1 mo, or −20°C for >12 mo. (Warm to 30°C for 30 min to dissolve histidine following storage at −20°C.)
   b. $MgSO_4$, EGTA, NaF: all prepared as 100-m*M* stock, stable at 4°C >12 mo.
   c. ATP, nonradioactive: 20- or 100-m*M* stock (pH corrected to 7.0 with KOH) stable at −20°C for >12 mo. Aliquot to avoid repeat freeze-thaw cycles.
   d. c-pKA, M_r 39,000 ***(4)***, sources **Table 1**: stable at −70°C for ~12 mo. Avoid dilute solutions—enzyme tends to aggregate and inactivate.
3. γ-^{32}P-ATP, ICN Pharmaceuticals: dispense into small aliquots and store −20°C. Avoid freeze to thaw cycles. $T_{1/2}$ ~14 d; discard 1 mo after reference date.
4. SDS-PAGE sample buffer, (double-strength): 125 m*M* Tris-HCl, pH 6.8, 20% glycerol, 2% SDS, 10% 2-mercaptoethanol, 0.01% bromophenol blue, stable at −20°C >12 mo. Aliquot and avoid freeze-thaw cycles.
5. Filter paper: Whatman 3MM.
6. X-ray film, X-ray cassettes, intensifying screens, developer and fixative: X-Ograph Ltd.; developer and fixative are stored at room temperature, are reusable, and are stable for approx 2 wk.
7. Scintillation fluid: Emulsifier-safe, Packard.

3. Method

3.1. Phosphorylation Reaction Using Purified Protein Substrates

1. In a designated radioactive area with appropriate acrylic screening prepare a stock of radioactive ATP. The addition of 50 µCi [γ-^{32}P]-ATP to a 0.5-mL solution of 1 m*M* ATP will produce a suitable experimental ATP stock of 220 cpm/pmol (*see* **Note 1**). Warm to 37°C.
2. Incubate the purified protein of interest (0.1–1.0 mg/mL) in the phosphorylation assay medium lacking ATP. Allow the sample to warm to 37°C for 2 min (*see* **Note 2**). A number of control samples should be set up in parallel. One control should contain target protein, but no exogenous kinase, and another, kinase but no target protein.
3. Start the phosphorylation reaction by the addition of ATP, containing [γ-^{32}P]-ATP (as defined in **step 1, Subheading 3**.). Cap the tube and vortex briefly. Follow the phosphorylation as a function of time by removing aliquots of the reaction at specific points in time, every 20 s for the first minute, and then at 60-s intervals for the next 4 min.
4. Terminate the reaction by mixing the sample with an equal volume of double-strength SDS-PAGE sample buffer at room temperature. Dispense the phosphorylation sample into an Eppendorf tube containing an equal volume of double-strength sample buffer, cap the tube, and vortex briefly. Store these samples at room temperature, behind appropriate screens, until all samples have been collected.

5. Incubate all samples for 30 min at 37°C. Perform SDS-PAGE in a gel of suitable acrylamide composition, loading a minimum of 5 µg pure target protein/lane (details of electrophoresis in Chapter 21). Allow the dye front to migrate off the bottom of the gel (depositing most of the radioactivity into the electrode buffer), stain with Coomassie brilliant blue, and destain the gel (*see* Chapter 21).
6. Mount the gel on filter paper and cover with clingfilm. The filter paper should be wet with unused destain solution prior to contact with the SDS-PAGE gel. Lower the gel onto the wet filter paper slowly, and flatten to remove air bubbles. Cover with clingfilm, and dry using a vacuum-assisted gel drier for 2 h at 90°C.
7. Once dry, an X-ray film should be placed in contact with the gel for a protracted period to image the location of phosphoproteins. **This procedure must be performed in the dark**, although light emitted by dark room safety lamps is permitted. An X-ray film is first exposed to a conditioning flash of light from a flash gun. Hold a single piece of X-ray film and the flash gun 75 cm apart. Set the flash gun to the minimum power output, and discharge a single flash directly onto the film (*see* **Note 3**). Place the film on top of a clean intensifying screen within an X-ray cassette. Take the dried SDS-PAGE gel, still sandwiched between filter paper and clingfilm, and place it gel side down onto the X-ray film. Do not allow the gel to move once in contact with the film, and use adhesive tape to secure the contact. With a permanent marker pen, draw distinctive markings from the filter paper backing of the gel onto the X-ray film to facilitate orientation of film and gel once autoradiography is complete (*see* **Note 4**). Close the X-ray cassette, label the cassette with experimental details, including the current date and time, and store at −70°C.
8. After 16 h of exposure, the autoradiograph can be developed. Remove the cassette from the −70°C freezer, and allow at least 30 min for it to thaw. Once in the dark room, with safety light illumination only, the cassette should be opened, and SDS-PAGE gel removed from the X-ray film. The film should be placed in 2 L developer and agitated for 4 min at room temperature, in the dark. Using plastic forceps, the film is removed from developer, rinsed in water, and then agitated for a further 90 s in 2 L of fixative (room temperature, dark). At the end of 90 s, the autoradiograph is no longer light-sensitive, and normal lighting can be resumed. Wash the autoradiograph extensively, for 10 min in a constant flow of water, and allow to air-dry.
9. Identification of phosphorylated polypeptides can be performed by superimposition of autoradiograph on the SDS-PAGE gel (*see* **Note 5**). A uniform, almost transparent background should be achieved, with phosphorylated proteins identified as black bands on the autoradiograph of variable intensities (depending on the level of phosphorylation), but regular width and shape (*see* **Note 6**). Exposure times can be altered in the light of results obtained, and repeated autoradiographs of various durations performed on a single gel (*see* **Note 7**).

3.2. Phosphorylation of Components in Complex Protein Mixtures

1. The phosphorylation experiment is performed largely as detailed in **Subheading 3.1**. with the following modifications. A protein concentration of 1–5 mg/mL is recommended supplemented with 100 n*M* purified c-pKA and 10 µ*M* adenosine

cyclic 3,5-monophosphate, and with 1 μ*M* microcystin-LR for additional Ser/Thr phosphatase control.

2. Perform a phosphorylation time-course experiment and process as described in **Subheading 3.1**. If the identity of a particular protein cannot be gauged from a peculiar electrophoretic feature (e.g., dissociation of oligomer to monomer on boiling; ***3***), then an affinity purification step must be introduced prior to electrophoresis.
3. In this case, phosphorylation will be terminated by placing the sample on ice. Immunoprecipitation of the protein of interest should be performed, taking care to solubilize membrane proteins effectively if they are of interest. Immunoprecipitates should be processed as described in **Subheading 3.1., step 5** onward (*see* **Note 8**).

3.3. Determination of Phosphorylation Stoichiometry

1. The specific activity of the ATP (cpm/pmol) needs to be determined empirically. At the time of the phosphorylation experiment, dilute a sample of the experimental ATP (1 m*M* containing 100 μCi/mL [γ-^{32}P]-ATP, as described in **Subheading 3.1., step 1**) to 1 μ*M* by serial dilution in water. Dispense triplicate 10-μL aliquots of the 1-μ*M* ATP (10 pmol) into separate scintillation vials, and add 4.6 mL scintillation fluid to each. Cap and label 10 pmol ATP (*see* **Note 9**).
2. Perform **steps 1–9** of **Subheading 3.1**. To excise the phosphorylated protein bands from the dry SDS-PAGE gel, identify the location by superimposition of gel and autoradiograph. With a marker pen, outline the autoradiographic limits of the phosphoprotein on the gel. Overlay again to confirm the accuracy of demarkation. Mark similar-sized areas of gel that do not contain phosphoproteins to determine background [^{32}P]. Excise these gel pieces with scissors, remove the clingfilm, and place the acrylamide piece and filter paper support in a scintillation vial. Add 4.6 mL scintillation fluid, and cap the vial.
3. Scintillation count each vial for 5 min or longer, using a program defined for ^{32}P radionucleotides. Minimal quenching of ^{32}P occurs under these conditions.
4. To calculate the pmol phosphate incorporated/μg protein, subtract the background radioactivity (cpm) from experimental data (cpm) to obtain phosphate incorporation into the protein sample (in units of cpm). Convert this to pmol incorporation/μg using the formula:

$$\text{Phosphorylation (pmol/μg protein)} = [\text{protein phosphorylation (cpm)}/\text{SA of ATP (cpm/pmol)} \times \text{μg protein}] \quad (1)$$

With a knowledge of the molecular weight of the polypeptide, a molar phosphorylation stoichiometry can be calculated from these data using the formula:

$$\text{Phosphorylation (mol/mol protein)} = [\text{phosphorylation (pmol/μg protein)} \times \text{molecular weight}/10^6] \quad (2)$$

5. Experimental conditions that result in maximal protein phosphorylation will have to be optimized. Parameters worth considering include alteration of the pH of the reaction, extension of the time-course of phosphorylation (up to several hours), addition of extra protein kinase during the phosphorylation process, and addition of extra ATP throughout the time-course.

4. Notes

1. The specific activity of ATP must be tailored to the experiment intended. Phosphorylation and autoradiography of proteins require ≥200 cpm/pmol, studies that require analysis beyond this point (e.g., phosphoamino acid identification) require ~2000 cpm/pmol, while phosphorylation of peptides requires ~ 20–50 cpm/pmol.
2. The stability of proteins at low concentration is sometimes an issue; inclusion of an irrelevant protein, but not a phosphoprotein (e.g., bovine serum albumin) at 1 mg/mL (final) is recommended. The phosphorylation example used to illustrate this method (c-pKA) displays catalytic activity in the absence of signaling molecules. In other instances this is not so. Therefore, relevant activators should be included as dictated by the kinase (e.g., Ca^{2+}, calmodulin, acidic phospholipids, and so forth).
3. Film developed at this stage will exhibit very slight discoloration compared to unexposed film.
4. Phosphorescent labels (Sigma-Techware) can be used to label an SDS-PAGE gel prior to autoradiography. It will also facilitate superimposition of gel and autoradiograph. These can also highlight the position of mol-wt markers, an image of which will be captured on the X-ray film.
5. Protein kinases invariably autophosphorylate. This can be identified clearly in control samples lacking phosphorylation target (**Subheading 3.1., step 2**).
6. Autoradiographs sometimes have a high background signal. Uniform black coloration over the whole film, extending beyond the area exposed to the gel is indicative of illumination of the X-ray film. Discoloration of part of the film is indicative of light entering the X-ray cassette. Examine the cassette carefully, particularly the corners that are prone to damage by rough handling.
7. Phosphoimage technology represents an alternative to autoradiography, it has the advantage of collecting the image quickly. Exposure times are reduced by an order of magnitude. However, in my experience, this benefit is at the expense of the quality of the image, which is granular.
8. The time required for immunoprecipitation or similar procedure should be kept to a minimum to limit the dephosphorylation of proteins by endogenous phosphatase enzymes. A cocktail of phosphatase inhibitors should be included for the same reason.

9. The hydrolysis of ATP to ADP and Pi occurs at a low rate in the absence of any enzyme. The extent of hydrolysis of [γ-^{32}P]-ATP can affect the determination of phosphorylation stoichiometry, since it will result in the overestimation of the specific activity of ATP if a correction is not made. Quantification of the purity of ATP is quoted in the product specification from suppliers. Only fresh [γ-^{32}P]-ATP should be used in these procedures or the degree of hydrolysis confirmed by thin-layer chromatography ***(6)***.

Mass Spectrometric Analysis of Protein Phosphorylation

Stefan Gander, Alessio Cremonesi, Johana Chicher, Suzette Moes, and Paul Jenö

1. Introduction

Phosphorylation is one the most frequently occurring posttranslational modifications in proteins, playing an essential role in transferring signals from the outside to the inside of a cell and in regulating many diverse cellular processes such as growth, metabolism, proliferation, motility and differentiation. It is estimated that up to one-third of all proteins in a typical mammalian cell are phosphorylated ***(1)***. Phosphorylation is carried out by a vast group of protein kinases which are thought to constitute 3% of the entire eukaryotic genome ***(1–3)***. To decipher the recognition signal of protein kinases and protein phosphatases acting on a given molecular target, and to understand how the activity of the target protein is regulated by phosphorylation, it is important to define the sites and the extent of phosphorylation at each specific site.

Earlier techniques of phosphoprotein analysis involves in vivo or in vitro labeling with [^{32}P]-phosphate ***(4–8)***. The radiolabelled protein is subsequently digested with a suitable protease and radiolabelled peptides are separated either by high-performance liquid chromatography (HPLC) ***(7,8)*** or by two-dimensional phosphopeptide mapping ***(4–8)***. The site of phosphorylation is then determined by solid-phase Edman sequencing ***(6)***. Identification of phosphorylation sites by Edman degradation of [^{32}P]-labelled proteins has been almost completely replaced by mass spectrometric techniques mainly because of speed, versatility and the availability of powerful computational tools ***(9–12)***. MS-based techniques have been steadily improved in the past so that the global analysis of protein phosphorylation, its dynamics and the elucidation of substrates phosphorylated

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

by protein kinases have become possible ***(13,14)***. These studies have provided remarkable insights into signaling cascades and their organization.

The basic elements of mass spectrometric phosphoprotein analysis consist of proteolytic digestion of the protein(s) of interest followed by measuring the masses of the resulting peptides. Individual phosphopeptides can be detected by a variety of techniques such as MALDI-mass mapping and phosphatase treatment ***(15)***, neutral loss scanning ***(16)***, and precursor ion scanning ***(17)***. The phosphorylation site in a given phosphopeptide can be identified by subjecting the peptide to fragmentation in the collision cell of the mass spectrometer. From the mass difference between the fragment ions, the sequence can be "read" and the site of phosphorylation can be identified when the mass difference is either 167, 181, or 243 Da, corresponding to the residue masses of P-Ser, P-Thr, or P-Tyr. Powerful search programs such as SEQUEST and MASCOT ***(18,19)*** exist to identify both, the phosphoprotein and the site at which the phosphate resides.

Phosphorylation at Ser, Thr, and Tyr residues may modulate the activity of a given protein. Thus, the determination of the extent to which a protein becomes phosphorylated is important for the understanding of the dynamics of how a protein responds to a particular stimulus. Recently, mass-spectrometry based techniques for relative quantification of protein phosphorylation have been developed, using either stable-isotope tagged amine-reactive labels (iTRAQ) ***(20)*** or stable isotope labeling by amino acids in cell culture (SILAC) ***(21)***. Alternatively, chemical ***(22)*** or enzymatic approaches ***(23)*** can be used to quantitate relative changes in phosphorylation.

One major obstacle in phosphoprotein analysis is the low relative level of phosphorylation, in particular tyrosine phosphorylation. To access phosphorylation events, enrichment strategies have been developed that allow selective isolation of serine/threonine phosphorylation by immobilized metal affinity chromatography (IMAC) ***(24)*** or tyrosine phosphorylation by immunoprecipitation with antiphosphotyrosine antibodies ***(25)***.

In this chapter, we will describe the basic steps of mass spectrometric phosphopeptide mapping, namely enzymatic digestion of phosphoproteins, reverse-phase high-performance liquid chromatography of peptides with mass spectral analysis (LC/MS), and determination of the site of phosphorylation by tandem mass spectrometry (MS/MS).

2. Materials

2.1. Equipment

1. HPLC system: For LC/MS coupling, a Rheos 2200 pump (Flux Instruments, Basel, Switzerland) was operated at a flow of 150 ml/min. A precolumn split was used to reduce the flow to approximately 500 nl/min.

2. Mass Spectrometers: LTQ Orbitrap mass spectrometer (Thermo Electron, San Jose, CA) equipped with a Finnigan Nanospray Probe (Thermo Electron, San Jose, CA) and Bruker Reflex III MALDI-TOF instrument (Bruker Daltonics GmbH, Switzerland).

2.2. Materials and Reagents

1. Fused silica capillaries (100 µm i.d., 280 µm o.d.) and PEEK sleeves (300 µm i.d.) (LC Packings, Dionex Switzerland AG, Olten, Switzerland). F120 PEEK Finger-tight fittings (Upchurch Scientific, ERCATECH AG, Berne, Switzerland).
2. C_{18} capillary columns for LC/MS: 300SB C-18 columns, 0.3×50 mm (Agilent Technologies, Basel, Switzerland). C_{18} ZipTips, P10 size, were from Millipore (Bedford, MA). PHOS-Select Iron affinity Gel was purchased from SIGMA-ALDRICH (Buchs, Switzerland).
3. Chemicals: TFA (Applied Biosystems, Rotkreuz, Switzerland) and acetonitrile (Lab-Scan, MACHEREY-NAGEL AG, Oensingen, Switzerland). DTT and ten times concentrated dephosphorylation buffer (0.5 *M* Tris-HCl, pH 8.5, 1 m*M* EDTA) (Roche Diagnostics, Mannheim, Germany). Iodoacetamide (Fluka Chemie AG, Buchs, Switzerland).
4. Enzymes: Proteases were obtained from the following suppliers: modified trypsin: (Promega, Madison, WI), endoproteinase LysC (Achromobacter protease) (Wako Pure Chemical Industries, Osaka, Japan), endoproteinase GluC, sequencing grade, and calf intestinal alkaline phosphatase (1000 U/ml) (Roche Diagnostics, Mannheim, Germany).
5. Isotopically labeled $H_2{}^{18}O$, >95% pure (CAMPRO Scientific GmbH, Berlin, Germany). α-cyano-4-hydroxycinnamic acid for MALDI-TOF (Sigma-Aldrich, Buchs, Switzerland).

3. Methods

3.1. Enzymatic Digestions of Phosphoproteins

To efficiently trace sites of phosphorylation in proteins, it is important to obtain an essentially complete proteolysis of the protein of interest (*see* **Note 1**). This is best achieved if the protein is fully denatured by reduction and alkylation with DTT and iodoacetamide. For reduction, the protein is dissolved in 10 µl 100 m*M* Tris-HCl, pH 8.0, 8 M urea (freshly prepared), 1.5 µl 75 m*M* DTT dissolved in water) is added and the protein is reduced for 1–2 h at 37°C. Alkylation is done by adding 1 µl of 625 m*M* iodoacetamide and incubating the protein for 15 min at room temperature.

To obtain an as complete a digest as possible, digestion with a combination of proteases is preferable. After reduction and alkylation the protein is first digested with the endoproteinase LysC. The residual iodoacetamide and urea (approximately 6 *M*) do not appreciably inhibit the enzymatic activity. The enzyme to substrate ratio is kept between 1:50 and 1:20 (w/w). Incubation with endoproteinase LysC is carried out at 37°C for 1 h. The reaction is stopped by the addition of 10% TFA

to a final concentration of 0.5% TFA. For subsequent trypsin digestion, the urea concentration has to be lowered to 2 M by dilution with 100 mM Tris-HCl, pH 8.0, whereas endoproteinase GluC is severely inhibited even by 2 M urea. When using this enzyme, it is best to remove urea completely. This can be achieved by reverse-phase chromatography. Digestion with trypsin or endoproteinase GluC is carried out at an enzyme to substrate ratio of 1:50 to 1:20 (w/w) for 18 h at 37°C.

3.2. Phosphorylation Analyzed by Liquid Chromatography-Mass Spectrometry

To find phosphopeptides in protein digests, reverse-phase chromatography in MS-compatible solvents such as formic acid or acetic acid is directly coupled to the mass spectrometer. The eluting peptides are measured in a data-dependent mode. First, full-range mass spectra are analyzed in real time, and then ions are collected for fragmentation to generate sequence-specific ions for data bank searching. For phosphopeptide detection we rely in most cases on neutral loss scanning. The neutral loss is the result of a gas-phase b-elimination reaction of phosphoric acid (–98 Da) from phosphoserine and phosphothreonine. Peptides phosphorylated on serines and threonines can be found by searching the LC/MS data for those peptides that had lost either 49, 32.6, or 24.5 Da for doubly, triply, or quadruply charged peptides. P-Tyr containing peptides do not tend to lose phosphoric acid and escape detection by neutral loss scanning. Individual MS/MS spectra are then compared against the known protein sequence using TurboSequest software *(26)*. **Fig. 1A** shows the LC/MS analysis of a tryptic digest of the yeast ribosomal protein RPL24A (systematic yeast gene annotation is YGL031C). In particular, we were interested in the peptide GDSKIFR surrounding Ser21 that had been reported to be phosphorylated in vivo *(21)*. The phosphorylated doubly charged peptide eluted at 30.49 min from the reverse phase column (**Fig. 1B**). Searching the LC/MS data for the neutral loss of phosphoric acid for doubly charged peptides (49 Da) revealed a strong candidate peptide whose elution coincides with the predicted phospho-GDS*KIFR peptide (**Fig. 1C**). Fragmentation of the phosphopeptide was triggered at scan 5208 (30.43 min). The primary fragmentation product is an intense ion (402.67 Da) 49 Da less than the precursor ion (**Fig. 2A**). While the doubly charged ion of 451.7 Da matches exactly the singly phosphorylated peptide GDSKIFR, positive identification by data bank searching with the TurboSEQUEST software was not possible due to the few fragment ions present in the spectrum. This is typical for phosphopeptides that tend to predominantly lose phosphoric acid via b-elimination and therefore suppress the formation of informative fragment ions. Therefore, the 402.67 ion that underwent neutral loss of phosphoric acid was brought to fragmentation in the subsequent scan. This resulted in a richer fragmentation spectrum from which the phosphopeptide and

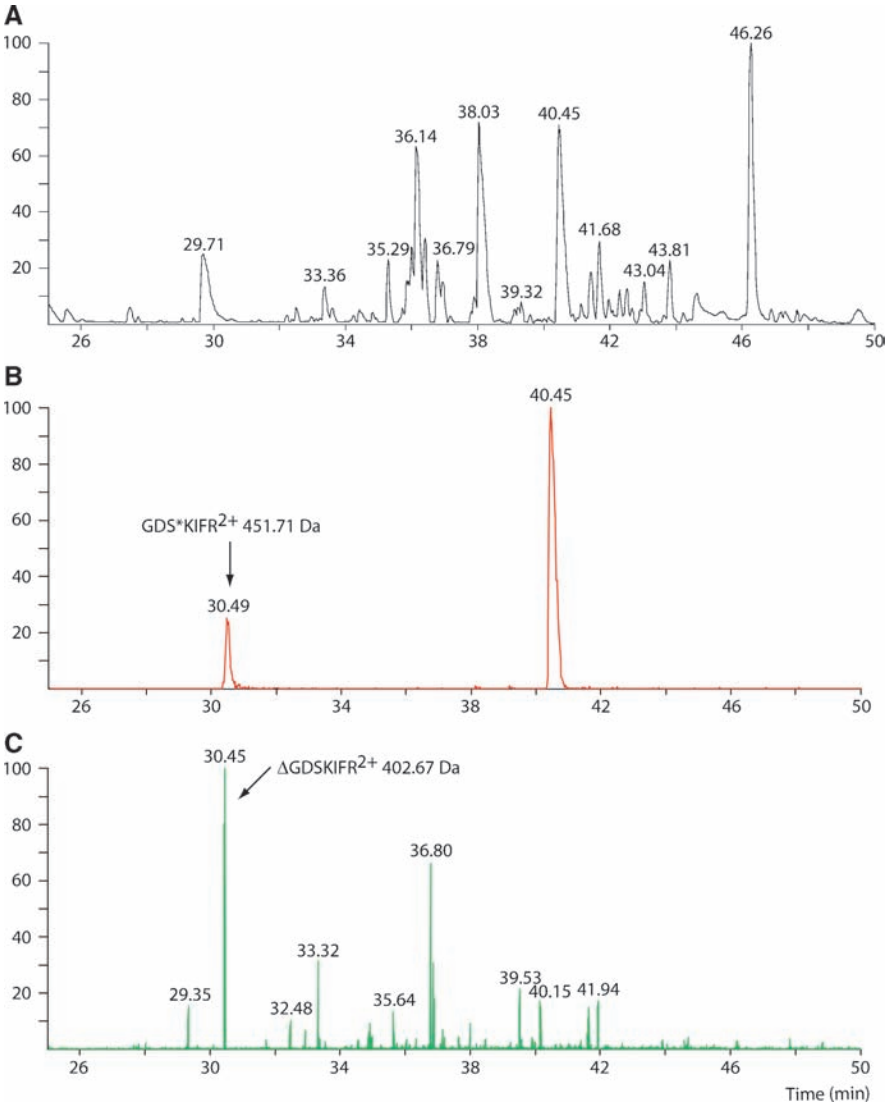

Fig. 1. **(A)** Ion chromatogram of an endoproteinase LysC/tryptic digest of yeast ribosomal proteins eluting from a capillary column into the mass spectrometer. **(B)** Selected ion tracing for the 451.71 Da ion that corresponds to the singly phosphorylated GDS*KIFR from ribosomal protein RPL24A (YGL031C). **(C)** Neutral loss scanning experiment showing the ion tracing for doubly charged peptides that underwent loss of phosphoric acid (49 Da). The asterisk indicates phosphorylation, and D marks the peptide that had lost phosphoric acid during collisional activation.

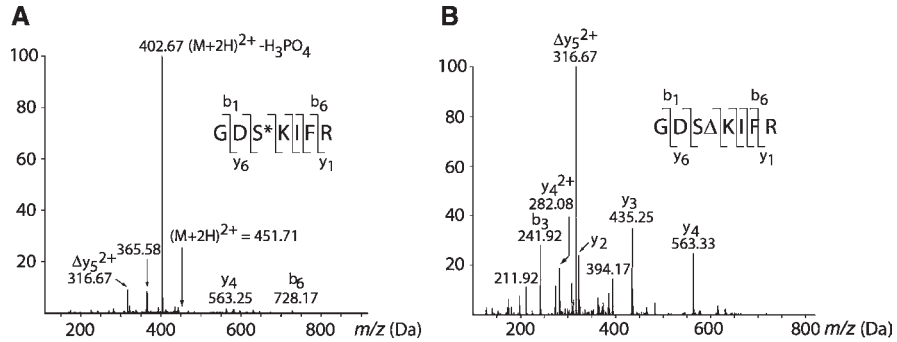

Fig. 2. Fragmentation spectrum of the doubly charged GDS*KIFR phosphopeptide. **(A)** The 451.71 Da precursor ion caused a prominent loss of phosphoric acid (402.67 Da) with little fragmentation of the peptide backbone. **(B)** Abundant peptide fragmentation occurs upon further fragmentation of the 402.67 Da neutral loss fragment ion (MS/MS/MS). The asterisk indicates phosphorylation, while D marks the serine that had lost phosphoric acid during collisional activation.

the site of phosphorylation could be unambiguously identified (**Fig. 2B**). The "phosphate-specific" MS scan takes advantage of the neutral loss of phosphoric acid from phosphopeptides in a fully automated fashion (see notes). Once all the data have been collected, data bank search is initiated with the following settings: variable modification of Ser, Thr, and Tyr set to 80 Da (the mass of a phosphate) and 57 Da static modification for Cys (alkylation by iodoacetamide).

3.3. Stoichiometry of Phosphorylation

Stoichiometries of phosphorylation by mass spectrometry can be quantified by dividing the sum of the peak areas of all intensities of a given phosphopeptide (all charge states must be included) by the sum of all intensities of the phosphorylated and its nonphosphorylated forms. However, this often results in underestimating the phosphorylation stoichiometriy, as phosphopeptides tend to ionize with lower efficiency than their corresponding unphosphorylated peptides ***(27)***. Quantitation in site-specific phosphorylation has been achieved by the use of stable isotope labeling ***(28)*** and most recently, by iTRAQ ***(29)***. For the quantification of relative changes in the extent of phosphorylation that occur upon drug treatment of yeast cells we rely on a simple method that involves the labeling of individual pools of differentially phosphorylated proteins by enzymatic digestion in isotopically labeled water, affinity selection of phosphopeptides followed by MALDI time-of-flight mass spectrometry ***(23)***. The method consists of three steps: (i) enzymatic digestion of a protein in $H_2{}^{16}O$ or isotopically enriched $H_2{}^{18}O$ to label individual pools of differentially phosphorylated proteins; (ii) affinity selection of phosphopeptides from combined digests by immobilized metal-affinity

chromatography; and (iii) dephosphorylation with alkaline phosphatase to allow for quantitation of changes of phosphorylation by MALDI-TOF.

We have successfully used ^{18}O labeling to trace relative changes in phosphorylation of the yeast protein kinase Npr1 (systematic yeast gene name YNL183C). Upon treatment of yeast cells with rapamycin or following nitrogen starvation, Npr1 becomes activated by dephosphorylation to support sorting of the general amino acid permease Gap1 to the plasma membrane ***(30)***. We mapped the global changes of phosphorylation in Npr1 following rapamycin treatment. Particularly sensitive phosphorylation sites to rapamycin treatment are found on Ser353 and Ser356. The 1227.4 Da MALDI-TOF signal corresponds to the doubly phosphorylated peptide SQHSSIGDLKR (comprising residues 353–363) from untreated cells while the 1231.4 Da signal derives from the same phosphopeptide of Npr1 that had been obtained from rapamycin-treated yeast cells (**Fig. 3A**). The same Npr1 phosphopeptide was isolated from a genomically deleted Sit4 mutant. In this case, no decrease in the extent of phosphorylation of

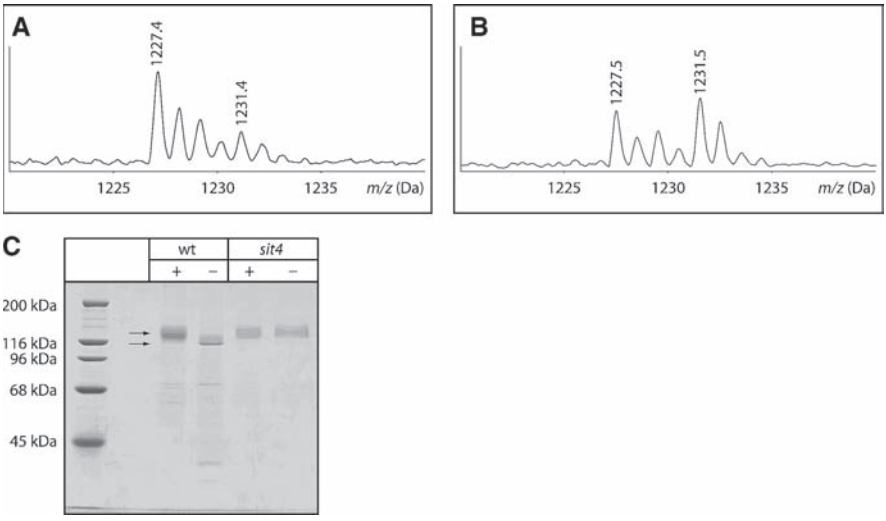

Fig. 3. (A) MALDI-TOF spectra of the doubly phosphorylated peptide (S*QHS*SIGDLKR) encompassing residues 353–363 of the yeast protein kinase Npr1 (YNL183C) that had been isolated from untreated (1227.4 Da) or from rapamycin-treated (1231.4 Da) cells. The 1231.4 Da signal indicates an approximately four-fold dephosphorylation. (B) The same phosphopeptide was obtained from a mutant in which the sit4 phosphatase responsible for Npr1 dephosphorylation was deleted. The 1231.5 Da signal indicates that no dephosphorylation occurred at these sites. (C) Coomassie-blue stained SDS gel of GST-Npr1 from wild-type cells (lane 1 and 2) or sit4 mutant cells, either untreated (–) or treated (+) with 200 nM rapamycin for 15 min. The arrows indicate phosphorylated (upper) and dephosphorylated (lower) GST-Npr1. (Modified from ***ref. 23***.)

the SQHSSIGDLKR phosphopeptide was detectable due to the lack of the Sit4 phosphatase responsible for dephosphorylation of Npr1 (**Fig. 3B**).

3.4. Procedure for ^{18}O Labeling of Peptides

1. Dry 20 µl of reduced and carboxamidomethylated phosphoprotein (in 100 m*M* Tris-HCl, pH 8.0, 150 m*M* NaCl, 0.2 µg/µl protein concentration) in a SpeedVac.
2. Dissolve one pool of phosphoprotein in 20 µl $H_2{}^{16}O$ (for example, phosphoprotein derived from non-treated or wild type cells) and the other pool (for example, phosphoprotein derived from treated or mutant cells) in 20 µl isotopically enriched $H_2{}^{18}O$.
3. Digest the two protein pools separately with trypsin at an enzyme/substrate ratio of 1:25 at 37°C for 2 h. During digestion in $H_2{}^{18}O$, two atoms of ^{18}O will be incorporated into every newly generated peptide C-terminus.
4. Stop the digestion by adding TFA to a final concentration of 0.1%. Mix the digest from normal and from $H_2{}^{18}O$ water and desalt them by adsorbing the peptides onto a C_{18} ZipTip. The peptides are washed with 0.1% TFA and desorbed with 5 µl 80% acetonitrile containing 0.1%TFA.
5. Select phosphopeptides by adding approximately 2 ml of a 50% suspension of PHOS-Select IMAC beads (in 0.1% acetic acid/30% acetonitrile) to the desalted peptide pool. Incubate the peptide-IMAC suspension in an Eppendorf Thermoshaker (set to 1,200 rpm) at room temperature for 1 h.
6. Wash the beads three times with 25 ml 0.1% acetic acid/30% acetonitrile.
7. Release the bound phosphopeptides with 10 ml 100 m*M* Tris-HCl, pH 8.0 containing 0.5 units of alkaline phosphatase by shaking the suspension at 37°C for 15 min.
8. For MALDI-TOF analysis desalt the peptides with ZipTips as above, except that peptide elution is done with 80% acetonitrile, 0.1% TFA, containing 1 mg/ml a-cyano-4-hydroxycinnamic acid.

4. Notes

1. For routine phosphopeptide mapping, we usually digest the proteins first with the endoproteinase LysC followed by a second digestion with trypsin. This digestion regime generates peptides with at least two positive charges on each peptide for efficient ionization. The C-terminal lysine or arginine favours fragmentation in the collision cell, which leads to a high sequence coverage, a prerequisite for unambiguous localization of the site of phosphorylation. Also, since the endoproteinase LysC is active in 6 *M* urea, highly insoluble phosphoproteins can be efficiently digested. Subsequent trypsin digestion also is possible after lowering the urea concentration to 2 *M*.
2. One major obstacle in phosphopeptide analysis is that they are often too hydrophilic to bind to reverse-phase supports used for LC/MS separation.

A simple solution to this problem has been suggested by combining graphite powder for retaining phosphopeptides that are otherwise lost in the flow through ***(31)***.

3. In cases where phosphorylation is suspected but could not be proven due to poor fragmentation, we dephosphorylate the digest with alkaline phosphatase and repeat the analysis. If the candidate peptide is phosphorylated, dephosphorylation leads to a reduction of its mass by 80 Da (or multiples thereof in the case of multiple phosphorylation). Enzymatic dephosphorylation with calf-intestinal alkaline phosphatase (CIP) can be directly carried out in the digestion mix, since CIP is completely resistant to proteolysis by enzymes such as trypsin, endoproteinase LysC or -GluC, although urea tends to inactivate the enzyme. For protein digests in the 1–500 picomole range, 1 U of CIP was found to be sufficient to lead to complete dephosphorylation of phosphopeptides.
4. For phosphopeptide identification of LC/MS/MS data we rely on the SEQUEST software (Thermo Finnigan, San Jose, CA). The routine search settings are as follows: Delta CN for peptides is 0.1; Xcorr versus charge state is set to 1.50 for singly, 2.0 for doubly, and 2.5 for triply charged peptides, respectively; minimal protein probability is 0.01.
5. In principle, phosphorylation stoichiometries can be quantified by comparing the integrated peak intensities of a phosphopeptide and its nonphosphorylated counterpart. In doing so, it is assumed that both forms of the peptide ionize with equal efficiencies. This estimation of stoichiometries is in many cases valid for singly and doubly phosphorylated peptides. However, with increasing clustering of phosphorylation sites we have found that extensively phosphorylated peptides tend to become poorly ionized. In such cases, we prefer $H_2{}^{18}O$-labelling and phosphatase treatment. This allows estimation of relative changes in the extent of phosphorylation because an isotopically labelled pair of peptides with equal ionization prope ties is generated. Also, for MALDI-TOF experiments, neutral loss of phosphate does not occur, while the relative extent of phosphorylation is preserved. Absolute quantitation of the extent of phosphorylation is possible with the recently introduced AQUA technology ***(32)***.
6. The search parameters for the identification vary, of course, with the software used for protein identification. With the SEQUEST protein/peptide identification, we set the search parameters variable for Ser/Thr/Tyr phosphorylation (+80 Da) and variable Ser/Thr modification to −18 Da for those peptides that underwent loss of phosphoric acid and that had been fragmented in an MS3 scan.

Protein Microarrays for Phosphorylation Studies

Birgit Kersten and Tanja Feilner

1. Introduction

Posttranslational modification of proteins by phosphorylation is the most abundant type of cellular regulation which affects essentially every intracellular process of eukaryotes. Phosphorylation of a protein can cause changes in its structure, stability, enzymatic activity, the ability to interact with other molecules, or its subcellular localization. Protein kinases are catalyzing the reversible phosphorylation of protein substrates at serine, threonine or tyrosine residues. In Arabidopsis, e.g., serin/threonine kinases represent about 4% of the proteome ***(1)***, but their biological function is not well understood. Therefore, high-throughput proteomics methods ***(2,3)*** for global analysis of protein kinase function are needed to identify downstream substrates. Various techniques for determining consensus phosphorylation site sequences, including peptide libraries ***(4)*** and peptide arrays ***(5,6)*** led to the identification of kinase substrates. Furthermore, a solid-phase phosphorylation screening of λ phage c-DNA expression libraries ***(7,8)*** as well as different protein-protein-interaction screening methods, such as overlay methods ***(9–11)*** and the yeast two hybrid system ***(12–14)*** have been applied in this respect. More recently protein kinases were engineered to accept unnatural adenosine triphosphate (cyclopentyl ATP) analogues and have been used to identify specific substrates ***(15–17)***. Furthermore, preliminary studies demonstrated the suitability of protein microarrays to study phosphorylation by kinases ***(18,19)***. To elucidate the sites of phosphorylation, antibodies against phosphorylated protein epitopes ***(6)*** may be used for detection on protein microarrays. Furthermore, peptide arrays ***(5,6)*** or MS-based methods ***(20,21)*** may be applied in this respect.

We here describe a protein microarray-based method for the phosphorylation screening of proteins and the identification of potential kinase substrates in a high-throughput manner. We successfully used this screening tool to

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

identify novel targets for the barley casein kinase 2α (CK2α) ***(22)*** as well as for different *Arabidopsis thaliana* mitogen activated kinases (MAP kinases) ***(23)***. Our method utilizes plant protein microarrays which have been generated as described in detail previously ***(22, 24)***. Then microarrays have to be incubated with the soluble and active kinase in the presence of radioactive [γ^{33}-P]ATP. Radioactive signals detected by phosphor imager or X-ray film were then evaluated for the selection of potential substrates. We verified the potential substrates by on blot-phosphorylation *in vitro*. As a whole, our approach allows to shortlist candidate substrates of plant protein kinases for further analysis. Follow-up *in vivo* experiments are essential to evaluate their physiological relevance ***(13,25,26)***.

2. Materials

2.1. Purification of Recombinant Kinases under Native Conditions

1. Medium for culturing cells: 2YT or LB containing 100 µg/ml ampicillin, 15 µg/ml kanamycin and 2% glucose.
2. Isopropyl-β-D-thiogalactopyranoside, IPTG.
3. Native lysis buffer: 300 m*M* NaCl, 50 m*M* NaH_2PO_4, 10 m*M* imidazole, pH 8.0.
4. Native wash buffer: 300 m*M* NaCl, 50 m*M* NaH_2PO_4, 20 m*M* imidazole, pH 8.0.
5. Native elution buffer: 300 m*M* NaCl, 50 m*M* NaH_2PO_4, 250 m*M* imidazole, pH 8.0.
6. Lysozyme.
7. PMSF.
8. Ultrasonic homogeniser (Branson Ultrasonic, Danbury, CT).
9. 1 ml polypropylen columns (Qiagen, Hilden, Germany).
10. Bradford reagent (Bio-Rad Labratories GmbH, Munich).

2.2. Kinase Assay on Protein Microarrays

1. TBS+Tween (TBST): 10 m*M* Tris-HCl pH 7.5, 150 m*M* NaCl, 0.1% (v/v) Tween.
2. Blocking solution: 2% bovine serum albumin, BSA (Sigma, St. Louis, MO) in TBST.
3. [γ^{33}-P]ATP, 250 µCi/ml (Amersham Pharmacia Biotech Europe GmbH, Freiburg, Germany).
4. CK2α buffer: 25 m*M* Tris–HCl pH 8.5, 10 m*M* $MgCl_2$, 1 m*M* DTT.
5. FAST™-slides (Whatman Schleicher & Schuell, Dassel, Germany).
6. Cover slide (Carl Roth GmbH, Karlsruhe, Germany).
7. X-ray cassette (Hypercassette, Amersham Pharmacia, Freiburg, Germany).
8. X-ray film (Kodak, Stuttgart, Germany).
9. Imaging screen (BAS-SR 2025, Fujifilm, Japan).
10. Phosphor imager (BAS-Reader-5000, Fujifilm, Japan).

3. Methods

3.1. Purification of Recombinant Kinases under Native Conditions

For the phosphorylation screening the kinase has to be soluble, active and pure, which means that no other kinase should be present. To achieve this a possibility would be a large scale production and purification of recombinant His-tagged protein kinases from cDNA expression libraries, e.g. a barley expression library constructed in the *E. coli* vector pQE30NST (accession number: AF074376; ***22***) or an Arabidopsis expression library in vector pQE30NASTattB (accession number: AY386205; ***23***) (*see also* ***24***). In order to express and purify protein kinases from these libraries we apply the following protocol:

For expression:

1. 50 ml falcon tubes were filled with 10 ml of medium for culturing cells.
2. Cultures were inoculated with bacteria from 384-well plates, which were stored at −80°C.
3. After overnight growth at 37°C with vigorous shaking the cultures were transferred into 300 ml Erlenmeyer flasks and 90 ml of prewarmed 2YT medium supplemented with 100 µg/ml of ampicillin, and 15 µg/ml of kanamycin were added. The incubation was continued until an OD of 0.7 was reached.
4. To induce protein expression, IPTG was added to a final concentration of 1 m*M*, and incubation was continued for 4 h at 37°C.
5. Cells were transferred into 50 ml falcon tubes (two for each culture), harvested by centrifugation at 1,900 × g for 10 min and stored immediately at −80°C.

For native protein purification (all of the following steps were performed at 0–4°C):

1. The frozen pellets were thawed on ice.
2. Cells were lysed in 0.5 ml of native lysis buffer supplemented with 0.25 mg/ml of lysozyme and 0.1 m*M* of PMSF.
3. Lysates were pooled and DNA was sheared with an ultrasonic homogeniser for 3 × 1 min at 50% power on ice.
4. Lysates were transferred into 1.5 ml Eppendorf-tubes and centrifugated at 20,000 × g, 4°C.
5. Supernatants were transferred into fresh Eppendorf-tubes.
6. Then 250 µl of NiNTA–agarose were added to bind the His-tagged proteins by shaking for 1 h at 300 rpm at 4°C.
7. The mixtures were transferred to 1 ml polypropylen columns.
8. The columns were washed with 10 bed volumes native wash buffer.
9. Proteins were eluted with 4 elution steps using 0.5 ml of native elution buffer each.
10. Proteins were mixed with glycerol (20% (v/v) end concentration) and stored at −80°C (*see* **Note 1**).

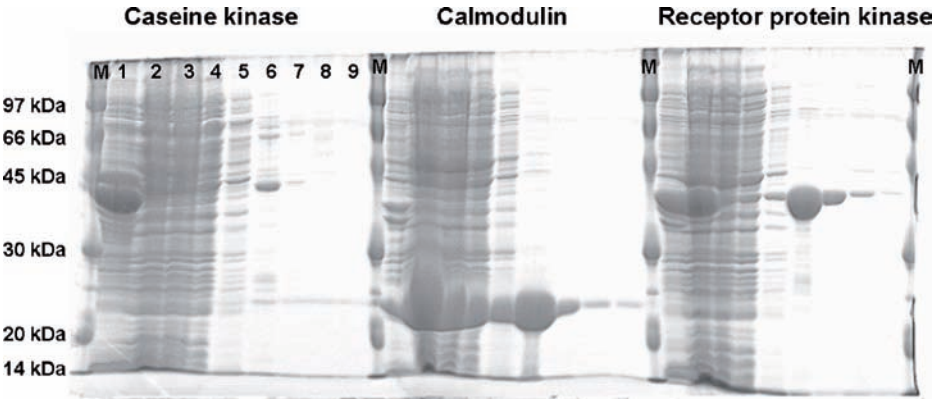

Fig. 1. 15% SDS-Page of two native purified kinases and calmodulin (Coomassie-stained). Nine samples of each purification step were separated: 1: pellet (insoluble fraction after centrifugation); 2: supernatant (soluble fraction after centrifugation); 3: first column flow-through; 4+5: first and second washing fraction; 6–9: eluates. M, molecular weight marker. Approximate size of the protein markers are shown at the left in kDa.

We would recommend collecting an aliquot from each centrifugation-, lysis-, wash- and elution step in order to control the efficiency of the purification steps using a polyacrylamide gel, e.g. 15% (*see* **Fig. 1**). Protein concentration was determined by Bradford assay ***(27)***.

3.2. Kinase Assay on Protein Microarrays

We recommend checking the activity of the kinase prior to microarray experiments (*see* **Note 2**) using a known substrate as a positive control (*see* **Note 3**). Furthermore, prior to microarray experiments, one has to exclude that the kinase will phosphorylate 3′- or 5′-tags of the recombinant proteins, such as His-tags (*see* **Note 4**).

We intended to perform a qualitative signal evaluation after kinase assay. Therefore we have spotted proteins and controls (*see* **Note 3**) in quadruplicates on FAST™-slides (*see* **Note 5**) using a 10 × 10 spotting pattern (*see* **Note 6**) as demonstrated in **Fig. 2** ***(22)***. Spotting pattern for further quantitative evaluation has been described recently ***(23)***.

For kinase assay:

1. Microarrays, which were spotted the day before and stored at 4°C in a closed slide holder, were washed for 1 h in TBST with vigorous shaking at room temperature (*see* **Note 7**).
2. Washed microarrays were blocked for 1 h at room temperature with 2% BSA/TBST.
3. Blocked microarrays were placed on Whatman paper soaked with TBST to avoid drying of the micorarrays during the subsequent kinase reaction.

4. Microarrays were incubated with 250 µl kinase solution containing 13 µg/ml of CK2α and 25 µCi/ml of radioactive labelled [γ^{33}-P]ATP in CK2α buffer for 1 h at room temperature (*see* **Note 1**). This incubation was performed underneath a cover slide.
5. Six wash steps of 30 min each were performed in TBST.
6. Finally, the microarrays were dried using a microtiter plate centrifuge (e.g., Eppendorf AG, Hamburg, Germany: 5810R) or by manual fanning and transferred into an X-ray cassette.
7. Signal detection was performed by means of an X-ray film. The film was laid on the microarrays and the cassette was stored for a suitable time at −80°C (*see* **Note 8**). Afterwards, the film was developed in a dark chamber. Alternatively, the microarrays were exposed to an imaging screen, which was screened afterwards by a phosphor imager for signal detection (*see* **Note 8**).

Fig. 2 (left) shows a typical result of a phosphorylation screening experiment with CK2α after exposure of the microarrays to X-ray film. Quadruples of several proteins gave distinct signals on the film.

In order to determine the immobilisation of the recombinant His-tagged proteins on the microarrays we screened them with an anti-RGS-His_6 antibody as described in detail previously ***(24)***. Nearly all of the spotted proteins were detectable (~95%) as shown in **Fig. 2** (right).

3.3. Selection of Potential Kinase Targets

For qualitative signal evaluation, the results of two independent experiments with different preparations of the kinase have been used.

The criteria for the selection of the potential kinase targets were:

1. A protein was considered as positive in one experiment if all 4 spots of the corresponding quadruplicate gave a distinct signal on the X-ray film or in the phosphor imager (*see* **Fig. 2**).
2. A protein was regarded as potential target protein if it attained positive results in both experiments.

Thus, for example 21 potential CK2α target proteins were identified out of nearly 800 different barley proteins ***(22)***. The selection of potential targets using a threshold-based quantification system after phosphorylation on microarrays has been described in high throughput studies in Arabidopsis thaliana ***(23)*** as well as in yeast ***(28)***.

3.4. Verification of Potential Phosphorylation Targets

As this microarray-based phosphorylation method is a screening tool to identify potential phosphorylation targets in vitro, we would recommend a verification of the identified targets by other methods. For such verifications various in vitro or in vivo approaches may be applied. A few of them have already been mentioned in the introduction.

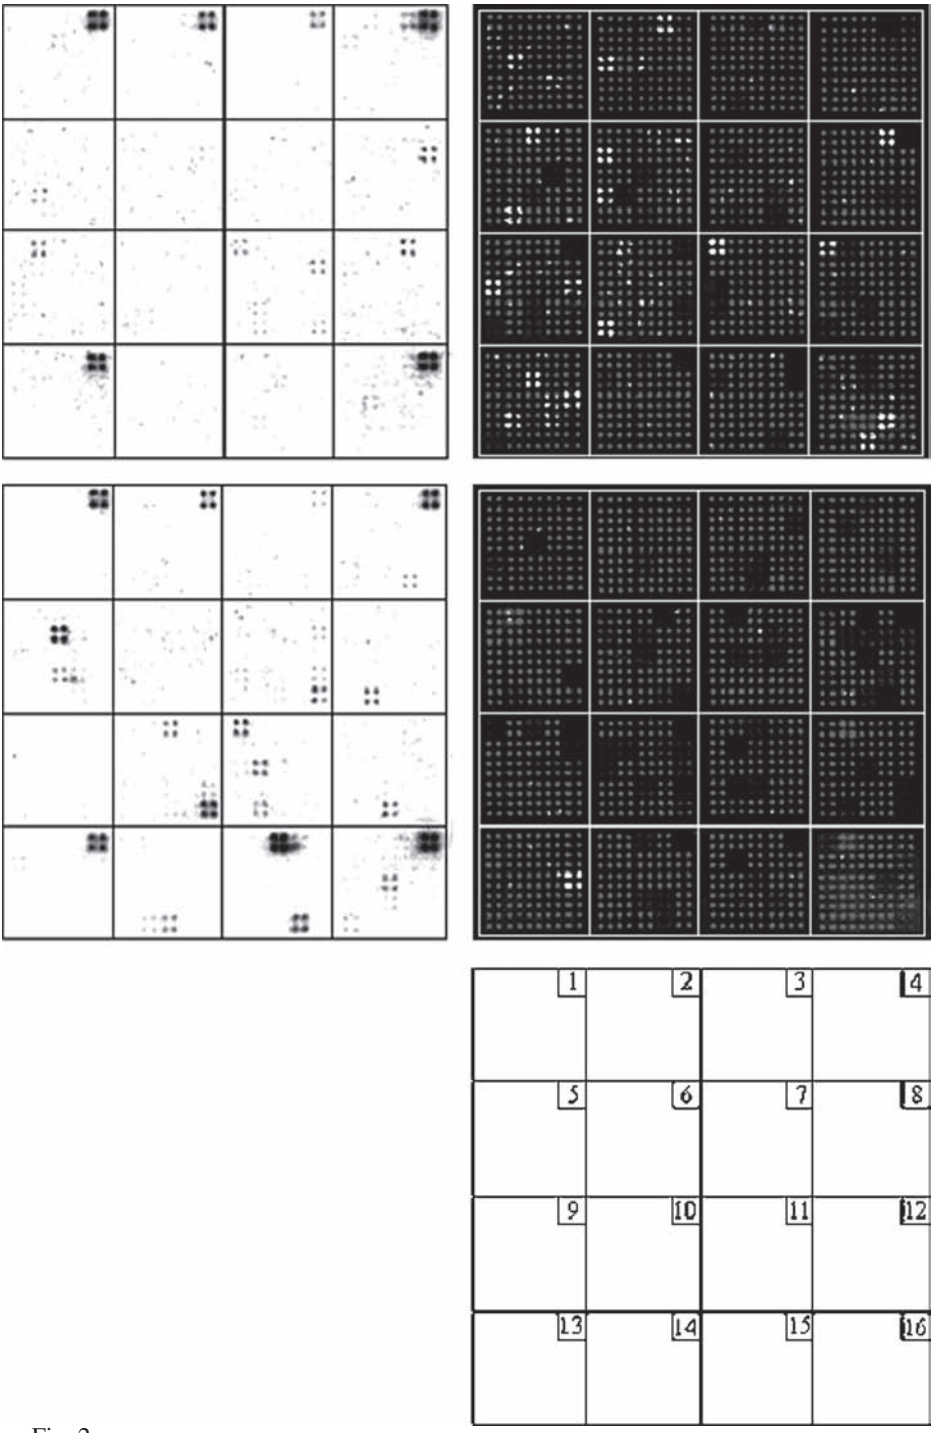

Fig. 2.

We performed an on blot-phosphorylation assay to verify potential substrates:

1. Proteins were separated using an SDS–PAGE, e.g., 15%, followed by blotting the proteins on PVDF membranes. After blotting, gels were Coomassie stained.
2. Phosphorylation reaction was carried out on the blot membrane using reaction conditions as described for the microarray-based assay in an appropriate volume.

Fig. 3 shows a typical example of such an on blot-phosphorylation experiment. Fourty-eight proteins, which were identified in both microarray experiments as potential substrates using a MAP kinase were verified with this method. Nearly all of them were confirmed as shown in **Fig. 3**. We used the same positive controls as in the microarray experiments: different concentrations of myelin basic protein (MBP; artificial substrate of MAP kinases). For negative controls proteins were taken, which were tested in the microarray-based kinase assay and were not identified as potential substrates (*see* **Fig. 3**).

Other *in vitro* verification methods are phosphorylation assays performed in solution with subsequent detection of the phosphorylated proteins by SDS electrophoresis and autoradiography ***(8,23)***. Such assay has been used by Fukunaga and Hunter to verify candidate kinase substrates identified by phosphorylation screening of an expression phage cDNA library ***(8)***.

4. Notes

1. We recommend to store kinases at −80°C by using glycerol (end concentration 20%) or to lyophilise the kinases in their according buffer and to store them afterwards at −80°C. The lyophilised kinases are only being dissolved in ddH_2O shortly before use.
2. Prior to performing micorarray-based kinase experiments we recommend to test the activity of the prepared kinase by in gel assays ***(29)*** or kinase assays in solution ***(8)*** using a known substrate of the respective kinase (*see*

Fig. 2. Kinase- and immunoassay with 768 different barley proteins, immobilized on FAST™-slides (384 proteins in each field). Left: X-ray film image with the results of a representative CK2α-assay. Right: equal microarrays screened with an anti-RGS-His_6 antibody. The map below shows the positions of the 16 controls. The purified proteins and the controls were spotted in quadruplicates. Controls: 1, 4, 13, 16: HMG(1) (GenBank Acc.: CK124404), 0.29 mg/ml; 2: HMG(2) (GenBank Acc.: CK122788), 0.76 mg/ml; 3: HMG(3) (GenBank Acc.: CK124847), 0.28 mg/ml; 5: CK2α (GenBank Acc.: CK123377), 0.22 mg/ml; 6: other library kinase (GenBank Acc.: CK125548), 0.21 mg/ml; 7: human gapdh (His-tagged recombinant human glyceraldehyde-3-phosphate dehydrogenase), 0.36 mg/ml; 8: BSA, 20 pmol/µl in PBS; 9: native elution buffer; 10: denaturing elution buffer; 11: mouse anti-RGS-His_6 antibody, diluted 1:10 in PBS; 12: rabbit-anti-mouse IgG-Cy3 conjugate, diluted 1:25 in PBS; 14: H_2O; 15: PBS. (Reprinted with permission from ***ref. 22***. Copyright 2004 Elsevier Science).

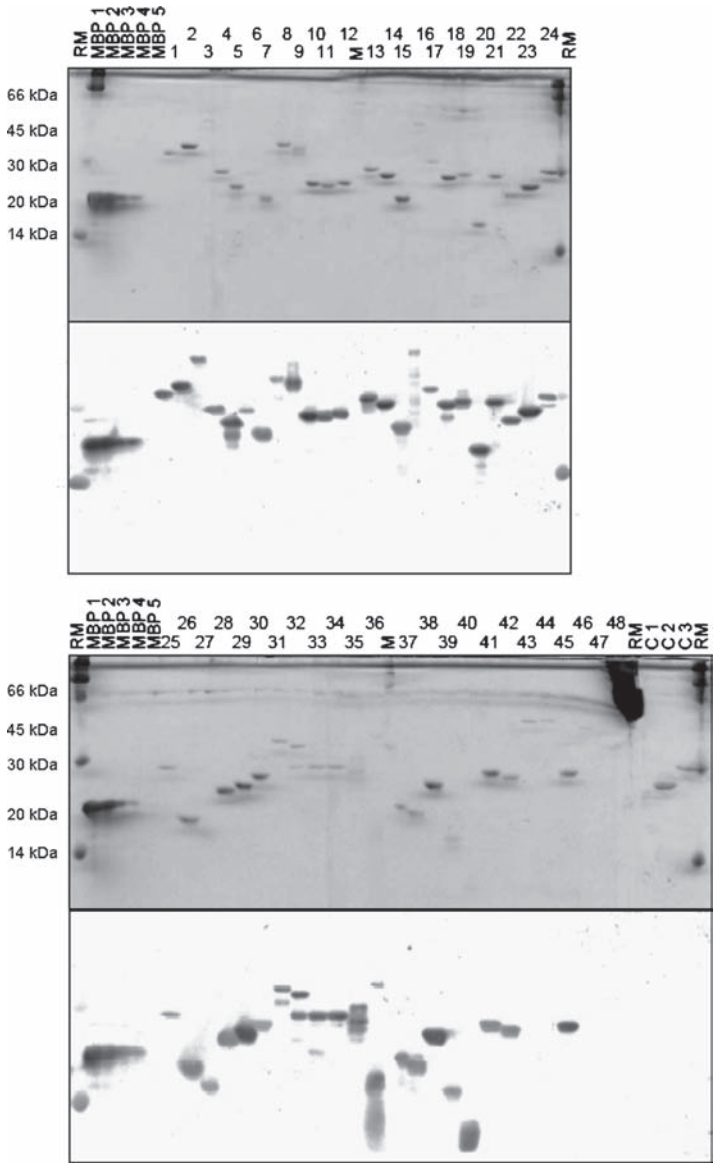

Fig. 3. Verification of kinase substrates. 15% SDS-PAGE gels of potential kinase substrates (upper panel) and autoradiograms of these proteins after blotting and kinase reaction (lower panel). Gels were Coomassie-stained after electrophoresis and blotting. MBP1 – MBP5: positive controls, MBP in various dilution steps (MBP1: 2,000 ng/µl; MBP2: 1,000 ng/µl; MBP3: 500 ng/µl; MBP4: 250 ng/µl; MBP5: 125 ng/µl). 1 – 48: potential kinase substrates identified in the microarray experiments. C1-C3: negative controls; these are proteins, which were not identified as potential substrates using microarrays. RM: rainbow marker; M: molecular weight marker. Approximate size of the protein markers are shown at the left in kDa.

Note 3). The optimal conditions for kinase activation (e.g., optimal buffer conditions, kinase concentration and incubation time of the kinase) must be determined experimentally for each individual kinase, if they are not known from the literature.

3. The use of a positive control is recommendable (e.g., a known substrate of the kinase). In studies with barley CK2α ***(22)*** we used as positive controls different barley proteins, which share a strong homology with different plant HMG (high mobility group) proteins. These proteins are well known targets of the CK2α ***(30,31)***. In another study we analyzed different Arabidopsis MAP kinases ***(23)***. In this case a known artificial substrate, the myelin basic protein (MBP), was used as a positive control.
4. Recombinant proteins often contain 3'- or 5'- tags which are encoded by the cloning vector besides the coding sequence of the respective protein. Phosphorylation of these tags may result in false-positive results and should therefore be excluded prior to microarray experiments. One possibility is to perform test assays in solution with the active kinase using some recombinant proteins which are known to be no substrates of the respective kinase and which were expressed the same manner (same tags) as the recombinant proteins used for the microarray experiments. These selected proteins should yield negative results in the test.
5. With respect to surface coatings we tried to phosphorylate immobilized denatured proteins on FAST™-slides (coated with a nitrocellulose-derived polymer) and epoxy slides. We detected phosphorylation only on FAST™-slides although His-tagged proteins were detectable with anti-RGS-His_6 antibody on both surfaces. In other studies, nanowells ***(19)***, BSA-NHS (BSA-N-hydroxysuccinimide) slides ***(18)***, or SAM2 (streptavidin-coated membrane) slides ***(32)*** have been used as surfaces in microarray-based kinase assays. We reviewed different micorarray surfaces for different microarray applications including phosphorylation studies ***(33)***.
6. The maximum spot density, at these individual spots can still be differentiated in a phosphorylation assay, is highly dependent on the resolution of the phosphor imager, which scanned the imaging plates. For the determination of this density we recommend the use of commercially available protein kinase (e.g., PKA from New England Biolabs GmbH). Our experience is, when using a scanner with a resolution of 10 µm (e.g., BioImager FLA 8,000, Fujifilm, Japan) in combination with spotting patterns up to 11 × 11 (spot distance: 410 µm), that we received sufficient resolution to evaluate the radioactive signals. Applications of higher spotting pattern (14 × 14-pattern with a spot distance of 321 µm; 15 × 15-pattern with a spot distance of 300 µm) were not suitable for radioactive detection, as signals of intense spots were interfering with neighbouring spot signals. This lead

to faulty analysis of the signal intensity of neighbouring proteins as well as faulty background corrections.

7. This washing step in TBST was performed to remove urea from the microarrays, as we recognised that the urea reduces the activity of the kinase in the microarray assay.
8. For the detection of radioactive signals with X-ray film, the film was laid onto the microarrays, which have been covered with cling film. The exposition time is dependent on the signal intensity and can vary between 30 min to a few days. The sensitivity of the X-ray films can cause problems, as the blackening of the films is only in a very limited area linear and proportional to the signal intensity. For the detection with a phosphor imager the imaging plates are laid onto the covered microarrays and are then scanned. Detection by phosphor imager is 10–100 × more sensitive than by X-ray films and therefore it is possible to get faster results and/or detect poor signals respectively. Furthermore, the system has a higher dynamic range compared to the X-ray film. Strong signals as well as poor signals are detected within one exposition and the linear signal-to-intensity range has a dimension over 5 (100,000:1). This shows that the phosphor imager is of better use for quantification of radioactive signals than X-ray films.

Acknowledgments

We grateful thank Armin Kramer for providing **Fig. 1** and Jasmin Bastian for reading the manuscript.

Two-Dimensional Phosphopeptide Mapping

Hikaru Nagahara, Robert R. Latek, Sergei A. Ezhevsky, and Steven F. Dowdy

1. Introduction

A major mechanism that cells use to regulate protein function is by phosphorylation and/or dephosphorylation of serine, theonine and tyrosine residues. Phosphopeptide mapping of these phosphorylated residues allows investigation into the positive and negative regulatory roles these sites may play *in vivo*. In addition, phosphopeptide mapping can uncover the specific phosphorylated residue and hence, kinase recognition site, thus helping in the identification of the relevant kinase(s) and/or phosphatase(s).

Two-Dimensional (2D) Phosphopeptide mapping can utilize in vivo and in vitro ^{32}P labeled proteins ***(1–6)***. Briefly, ^{32}P labeled proteins are purified by SDS-PAGE, transferred to a nitrocellulose filter and digested by proteases or chemicals. The phosphopeptides are then separated by electrophoresis on thin layer cellulose (TLC) plate in the first dimension followed by thin layer chomatography in an organic buffer in the sond dimension. The TLC plate is then exposed to autoradiographic (ARG) film or phosphor-imager screen and the position of the ^{32}P containing peptides are thus identified. Specific phosphopeptides can then be excised from the TLC plate and analyzed further by amino acid hydrolysis to identify the specific phosphorylated residue(s) and/or by manual amino-terminal sequencing to obtain the position of the phosphorylated residue(s) relative to the protease cleavage site ***(3)***. In addition, mixing *in vivo* with *in vitro* ^{32}P-labeled proteins can yield confirmation of the specific phosphorylated residue and the relevant kinase.

2. Materials

2.1. Equipment

1. Multiphor II horizontal electrophoresis apparatus (Pharmacia).
2. Power pack capable of 1000 V constant.
3. Refrigerated circulating water bath.
4. Thin layer chomatography (TLC) chamber, ~30 L × 10 W × 28H cm, and internal stand.
5. Speedy-vac or lyophilizier.
6. Shaking water bath.
7. SDS-PAGE apparatus.
8. Semi-Dry blotting apparatus (Owl).
9. Small fan.
10. Rotating wheel or apparatus.

2.2. Reagents

1. Phosphate-free tissue culture medium.
2. Phosphate-free dialyzed fetal bovine serum (FBS). Alternatively, dialyze 100 ml FBS against 4 L dialysis buffer for 12 h and repeat two more times using 10,000 MWCO dialysis tubing. Dialysis buffer: 32 g NaCl, 0.8 g KCl, 12 g Tris in 4 L, pH to 7.4 with HCl.
3. $^{32}PO_4^{2-}$ orthophosphate, 3–5 mCi per tissue culture dish.
4. Protein extraction buffer (ELB): 20 m*M* HEPES (pH 7.2), 250 m*M* NaCl, 1 m*M* EDTA, 1 m*M* DTT, 0.1–0.5% NP-40 or Triton X-100, 1 µg/ml Leupeptin, 50 µg/ml PMSF, 1 µg/ml Aprotitin, and containing the following phosphatase inhibitors: 0.5 m*M* NaP_2O_7, 0.1 m*M* $NaVO_4$, 5.0 m*M* NaF.
5. Rabbit anti-Mouse IgG.
6. Killed *S. aureus* cells (Zyzorbin).
7. Protein A agarose.
8. 2× Sample Buffer: 100 m*M* Tris-HCl (6.8), 200 m*M* DTT, 4% SDS, 0.2% bromophenol blue, 20% glycerol.
9. Protein Transfer buffer: 20% methanol, 0.037% SDS, 50 m*M* Tris, 40 m*M* glycine.
10. 50 mM N H_4HCO_3, made fresh each usage from powder.
11. 0.5% (w/v) Polyvinyl pyrolidone-360 in 100 m*M* acetic acid.
12. Sequencing grade trypsin (Boehinger Mannheim), resuspend 100 µg in 1.5 ml fresh 50 m*M* NH_4HCO_3, store 10 µg/150 µl aliquots at −20°C.
13. Performic acid: Mix 1 vol hydrogen peroxide with 9 vol formic acid. Incubate for 1.5 h on ice.
14. Scintillation fluid.
15. Thin-layer chomatography cellulose plastic-backed plates, 20 × 20 cm (Baker-flex/VWR).
16. pH 1.9 Electrophorese Running Buffer: 50 ml 88% formic acid, 56 ml acetic acid and 1894 ml H_2O. Do not adjust pH.

17. Electrophoresis color marker: 5 mg/ml DNP-lysine, 1 mg/ml xylene cyanol FF in 50 µl n-butanol, 25 µl pyridine, 25 µl acetic acid, 1.9 ml H_2O.
18. TLC chamber buffer: 75 ml n-butanol, 50 ml pyridine, 15 ml glacial acetic acid, 60 ml H_2O.

3. Methods

3.1. ^{32}P Orthophosphate Labeling

1. For in vivo ^{32}P orthophosphate labeling of cellular proteins, preplate approximately 1×10^6 cells in a 10 cm dish. Rinse adherent cells thee times with 5 ml phosphate-free media. Suspension cells can be rinsed and collected by centrifugation at ~1800 rpm for 5 at RT or 30°C, aspirate the media and repeat as above. Add 3–5 mCi of ^{32}P ortho phosphate in 3.5 ml of phosphate-free media containing 10% dialyzed serum to the 10 cm dish and incubate cells at 37°C for 4–6 h (*see* **Note 1**).
2. Aspirate the ^{32}P containing media with a plastic pipette, transfer supernatant waste into a 50 ml conical disposable tube. Rinse the cells twice with 10 ml PBS(-) and combine with ^{32}P media waste in 50 ml tube and dispose of properly.
3. Add 1 ml ice cold extraction buffer (ELB; 7) and place dish on a flat bed of ice, behind a shield. Tilt dish slightly every 30 s for 3'–5' to continually cover the cells. Collect cellular lysate and debris by tilting dish approximately 30° using a P-1000 pipetman tip and transfer to 1.5 ml eppendorf tube and mix. Alternatively, adherent cells can be released by trypsin/EDTA addition, collected and washed twice in media containing serum to inactivate the trypsin. After the final centrifugation, add 1 ml ELB, mix by using a P-1000 tip and transfer to an eppendorf tube. Place tube on ice for 20'–25' with occasional mild inverting (*see* **Note 2**).
5. Spin out insoluble particular matter from the cellular lysate in microfuge at 12 K, 4°C, for 10'. Transfer supernatant to new eppendorf tube and preclear lysate by the addition of 50 µl killed *S. aureus* cells, cap tube and place on rotating wheel at 4°C for 30'–60'.
6. To remove *S. aureus* cells, centrifuge lysate at 12 K, 4°C for 10 . Transfer lysate to fresh eppendorf tube, making sure to leave the last 50 µl or so of lysate behind with the pellet. The presence of contaminating *S. aureus* cells in this portion of the sample will reduce the amount of immunocomplexes recovered if included.

3.2. Immunoprecipitation and Transfer of ^{32}P-Labeled Protein

1. Add primary antibody to the precleared lysate supernatant, usually 100–200 µl in the case of hybridoma supernatants and 3–5 µl of commercially purified antibodies. Add 30 µl protein A agarose beads, cap the tube, and place on a wheel at 4°C for 2–4 h to overnight. If primary mouse antibody isotype is IgG1 or unknown, add 1 µl Rabbit anti-Mouse IgG to allow indirect binding of the primary antibodies to the protein A agarose *(7)*.
2. After incubation with primary antibody, perform a "1 g spin" by placing the tube on ice for 15', aspirate the supernatant to just above the protein A agarose bed level.

Stop aspirating at the top of the agarose beads, avoiding drying the beads. This supernatant waste is still highly radioactive. Wash the agarose beads by addition of 1 ml ice cold ELB, cap and invert tube several times and centrifuge at 12 K, 4°, 30 s. Aspirate supernatant and repeat two to thee more times. Again, avoid drying the beads.

3. After the final 30 s spin, aspirate supernatant off of the protein A beads until just dry, add 30 µl of 2× Sample buffer. Boil sample for 5 min, centrifuge 12 K for 10 s, cool tube on ice and load immunocomplexes onto a SDS-PAGE *(8)*.
4. After running the SDS-PAGE, separate the glass plates and trim down the gel with a razor blade by removing the stacking gel and any excess on the sides or bottom. Measure the trimmed gel size and cut six sheets of 3 MM Whatman filter paper and one sheet of nitrocellulose (NC) filter to the same size.
5. Soak two sheets of cut 3 MM filter paper in transfer buffer and place on semi-dry transfer unit. This can be done by filling a tupperware-like container with transfer buffer and dipping the 3 MM paper into it. Place one soaked 3 MM sheet on the back of gel and rub slightly to adhere to gel. Then invert the glass plate with the gel-3 MM still stuck to it and peel gel-3 MM away from the glass with the use of a razor blade. Place it 3 MM side down onto the soaked 3 MM sheets on the semi-dry unit. Soak the cut NC filter with transfer buffer and place it on top of gel followed by thee presoaked 3 MM sheets on top of filter. Gently squeegee out bubbles and excess buffer with the back of your little finger or by rolling a small pipette over the stack. It is important to squeegee out the bubbles, but avoid excess squeegeeing that would result in drying the stack. Mop up the excess buffer on the sides of the stack present on the transfer unit. Place the top on the transfer unit. In this configuration, the bottom plate is the cathode (negative) and the top the anode (positive).
6. Transfer the ^{32}P-labeled proteins to the NC filter at 10 Volts constant for 1.5 to 2 h. The starting current will vary from ~180 to 300 mAmp depending on the surface area of the gel and will drop to around 80 to 140 mAmp by the end of the transfer.

3.3. Trypsinization of Protein on Nitrocellulose Filter

1. Following transfer of ^{32}P-labeled proteins to NC filter, open the transfer unit and using a pair of filter forceps place the NC filter, protein side down onto saran-wrap and cover. Expose the saran-wrap covered NC filter to ARG-film for approximately 1 h to 2 h with protein side towards the film. The length of the exposure will vary with the abundance of ^{32}P content and protein, and with the efficiencies of recovery from immunoprecipitation and transfer. Radioactive or luminescent markers are needed on the filter to determine the orientation, position and alignment of the NC filter with respect to the ARG film. Using the markers, line up your filter on top of its ARG. This is best done on a light box. Use a razor blade to excise the slice of NC filter that corresponds to the ^{32}P-labeled protein band.
2. Place the NC filter slice into an eppendorf tube, add ~200 µl of 0.5% PVP-360 in 100 mM acetic acid, cap tube and incubate in a shaking water bath at 37°C for 30 min (*see* **Note 3**).

3. Wash the filter slice five times with 1 ml H_2O and then twice with 1 ml fresh 50 m*M* NH_4HCO_3.
4. Add 10 µg of trypsin in 150 µl of 50 mM NH_4HCO_3 to the NC filter slice. Incubate in a 37°C shaking water bath over-night. Following this incubation, spike the digestion of the NC filter with another 10 µg of trypsin in 150 µl of 50 m*M* NH_4HCO_3 and incubate at 37°C for an additional 4 h.
5. Vortex the tube containing the NC filter/trypsin sample for 1 min, centrifuge at 12 K for 30 s. Transfer the supernatant to a new eppendorf tube. Wash the NC filter slice by addition of 300 µl H_2O, vortex 1 min, centrifuge at 12 K for 30 s, and combine the supernatants.
6. Freeze the trypsinized ^{32}P-labeled peptide sample on dry ice and then completely dry in a speedy-vac (without heat). This generally takes about 4 h to complete. Prepare the performic acid for the oxidation step **(step 8)**.
7. After the sample has been completely dried, add 50 µl of ice cold performic acid and place on ice for 1 h. Stop the reaction by addition of 400 µl H_2O to the sample, followed by freezing on dry ice and then drying in a speedy-vac.
8. Resuspend the sample in 8–10 µl of H_2O. Determine the level of radioactivity by counting 0.5 µl of the sample on a scintillation counter. Usually a total of ≥2000 cpm is sufficient for 2D phosphopeptide mapping.

3.4. Phosphopeptide Separation: First and Second Dimensions

1. Mark the origin on the thin-layer cellulose (TLC) plate by lightly touching a pencil to the TLC plate at the position indicated in **Fig. 1**. Apply multiple 0.5 µl aliquots of the trypsinized ^{32}P-labeled peptides to the origin to achieve ≥2000 cpm. Dry the TLC plate thoroughly between each aliquot application by use of a gentle fan. Pay particular attention to adding each subsequent aliquot to the same small area at the origin. Add 0.5 µl of the color marker 3 cm from the top edge of the TLC plate (**Fig. 1**) and then dry the TLC plate under a fan for an additional 30–60 min.
2. Prepare the Multiphor II apparatus for electrophoresis. Place the Multiphor II in a cold room, connect the cooling plate to the cooling circulator bath hoses and precool to 5°C. Prepare and chill the pH 1.9 running buffer and add to Multiphor II buffer tanks. Insert the electrode paddles into innermost chambers, and attach the wire connections. We have used the IEF electrodes in direct contact with the cellulose plate; however, using the paddles provided and wicking buffer onto the plate yields the best results (*see* **Figs. 1** and **2**). Place the cooling plate into the Multiphor apparatus. Add 1 L of prechilled pH 1.9 running buffer to each chamber of the Multiphor II. (These instructions are provided with the Multiphor II unit.)
3. Place the loaded TLC plate on top of the cooling plate. To dampen the TLC plate with buffer, first cut a 21 × 21 cm piece of 3 MM Whattman paper and make an approximately 1 cm hole at the origin by puncturing the 3 MM paper with a pencil. Soak the cut 3 MM paper in pH 1.9 running buffer, blotting it between two sheets of dry 3 MM paper, and then placing it over the loaded TLC plate sitting on top of the cooling plate. Slowly pipette running buffer onto the 3 MM paper until the entire cellulose plate is damp beneath, avoid excessive puddling. Remove the paper

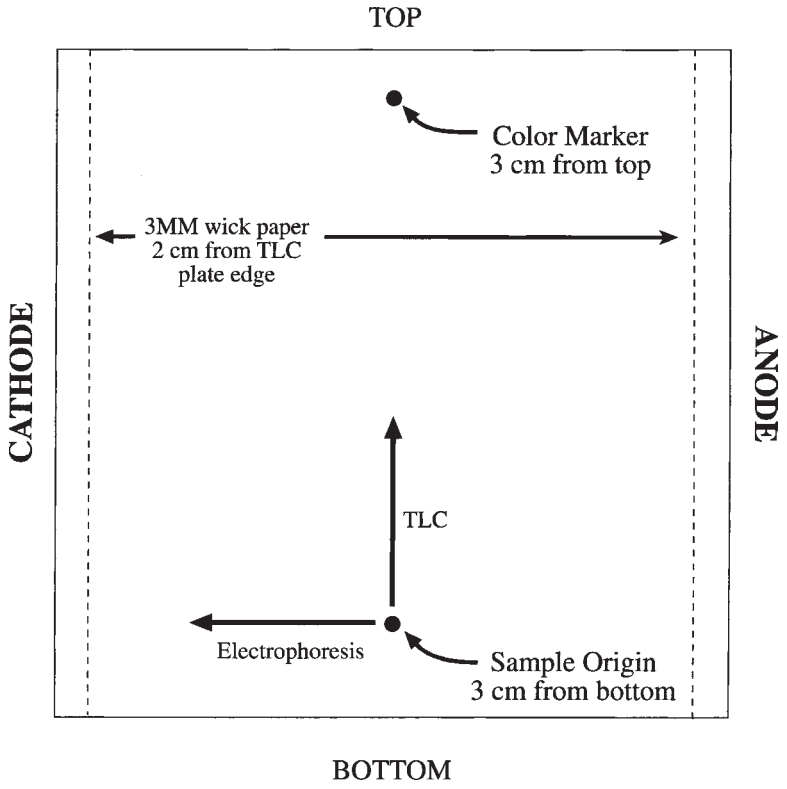

Fig. 1. The location of the origin, anode, cathode and color dye marker dye relative to each other on the 20 × 20 cm TLC plate are depicted (*see* **Subheading 3.4, steps 1** and **2**.

and wick a single piece of 13 × 21 cm buffer-soaked 3 MM filter paper from the buffer chamber onto the 2 cm outer edge on both sides of the plate (*see* **Fig. 2**). Be sure to fold the paper neatly over the edge of the cooling plate and to make sure that it is evenly contacting the TLC plate. Place the glass cover over the TLC plate touching/resting on the 2 cm overhang of the 3 MM paper wicks. Attach the Multiphor II cover.

4. Electrophorese the peptides on the loaded TLC plate at 1000 V constant for 28–30 min. The run time may be increased up to 38 min. If further separation of ^{32}P-labeled peptides in this dimension is required, the run time may be increased up to 38 min.
5. Following the first dimension separation by electrophoresis, remove the TLC plate from the Multiphor II apparatus and dry for 1 h with a fan.
6. Place the TLC plate on a stand in a thin-layer chomatography chamber pre-equilibrated for 48 h in chomatography buffer. The TLC buffer should cover approximately 1 cm of the bottom of the TLC plate when placed on the stand.

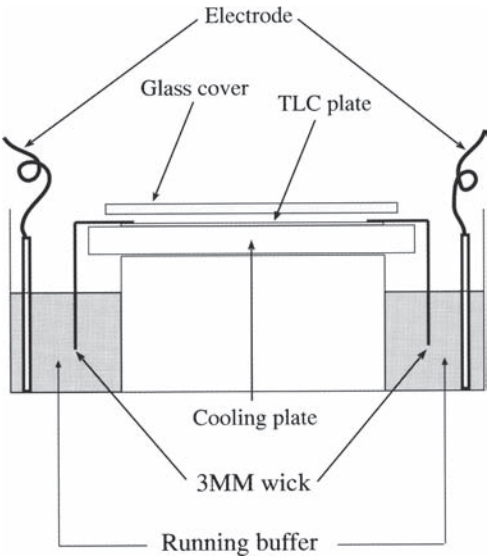

Fig. 2. A cross stional view of the Multiphor II apparatus. Loaded TLC plate, 3 MM Whatman filter paper wicks, and glass cover plate are depicted in the running position (*see* **Subheading 3.4, steps 2** and **3**).

Leave the TLC plate in the chamber until the solvent line diffuses to the dye position at the top of the TLC plate, 3 cm below the top of the plate. This usually takes 7–8 h (*see* **Note 4**).

7. Remove the TLC plate from the chamber and dry for >1 h. Expose the TLC plate to ARG-film or a phosphor-imager screen overnight and develop. If the signal is too weak, expose for 5 to 7 days. The use of a phosphor-imager greatly diminishes the length of time required to obtain a 2D phosphopeptide map (*see* **Fig. 3**).

4. Notes

1. We routinely label 1×10^6; however, depending on the abundance of the specific protein of interest and on the number of phosphorylation sites this number may vary from 1×10^5 to 1×10^7 cells. In addition, adherent and non adherent cells may both be labeled in suspension. The cells can be labeled with ^{32}P orthophosphate in a 15 or 50 ml disposable conical tube or T-flask. Please note that the activity of kinase(s)/phosphatase(s) present in adherent cells may be altered when labeling in suspension. Dish size is not important as long as enough media is added to cover the bottom of the dish/flask. Attempt to achieve a final ^{32}P orthophosphate concentration of 1.0 to 1.3 mCi/ml of media.
2. We use ELB to lyse cells and generate cellular extracts; however, any extraction buffer containing Triton X-100, SDS, DOC, NP-40 or similar detergent that will lyse cells will suffice. If a strong background is observed following the SDS-PAGE, transferring the immobilized protein A agarose

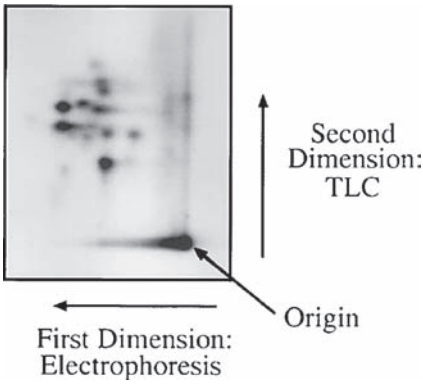

Fig. 3. 2-D phosphopeptide map of the retinoblastoma tumor suppressor gene product (pRb) labeled with ^{32}P phosphate *in vivo*. pRb contains thirteen cyclin-dependent kinase (cdk) phosphorylation sites, hence the complexity of the phosphopeptide map. Note the presence of several levels of ^{32}P intensity associated with specific peptides. This can arise by a number of mechanisms, including *in vivo* site preferences and/or accessibility of the nitrocellulose immobilized ^{32}P-labeled protein to trypsin. The origin, first and sond dimension runs are as indicated (*see* **Subheading 3.4, step 7**).

immunocomplexes to a new eppendorf tube prior to the final wash and centrifugation step can result in a reduced background with minimal loss of specific signal.

3. When running multiple lanes of the same ^{32}P-labeled protein immunocomplexes on SDS-PAGE treat each lane/NC filter slice separately. The trypsinized peptides from as many as five NC filter slices can be combined together, then frozen on dry ice and dried.
4. Seal the top of the TLC chamber with vacuum grease and minimize the amount of time the lid is off of the chamber. Pre-equilibrate chamber for >48 h prior to use. We routinely change the TLC chamber buffer every 8 weeks. Poor separation in the sond dimension is usually indicative of buffer alterations due to evaporation and/or hydration.
5. The procedures described in this chapter can be stopped at the following steps: (1) when the immunocomplexes are in 2× sample buffer following the immunoprecipitation; (2) after lyophilization following trypsinization of the NC filter slices; and (3) after drying the TLC plate following the first dimension eletrophoresis.

Acknowledgments

We thank Fung Chen for protocols and Jeff Settleman for the “1 g spin.” S.F.D. is an Investigator of the Howard Hughes Medical Institute.

Identification of Proteins Modified by Protein (D-Aspartyl/L-Isoaspartyl) Carboxyl Methyltransferase

Darin J. Weber and Philip N. McFadden

1. Introduction

The several classes of *S*-adenosylmethionine-dependent protein methyltransferases are distinguishable by the type of amino acid they modify in a substrate protein. The protein carboxyl methyltransferases constitute the subclass of enzymes that incorporate a methyl group into a methyl ester linkage with the carboxyl groups of proteins. Of these, protein (D-aspartyl/L-isoaspartyl) carboxyl methyltransferase, EC 2.1.1.77 (PCM) specifically methyl esterifies aspartyl residues that through age-dependent alterations are in either the D-aspartyl or the L-isoaspartyl configuration ***(1,2)***. There are two major reasons for wishing to know the identity of protein substrates for PCM. First, the proteins that are methylated by PCM in the living cell, most of which have not yet been identified, are facets in the age-dependent metabolism of cells. Second, the fact that PCM can methylate many proteins in vitro, including products of overexpression systems, can be taken as evidence of spontaneous damage that has occurred in these proteins since the time of their translation.

The biggest hurdle in identification of substrates for PCM arises from the extreme base-lability of the incorporated methyl esters, which typically hydrolyze in a few hours or less at neutral pH. Thus, many standard biochemical techniques for separating and characterizing proteins are not usefully applied to the identification of these methylated proteins. In particular, the electrophoresis of proteins by the most commonly employed techniques of sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) results in a complete loss of methyl esters incorporated by PCM, owing to the alkaline pH of the buffers employed. Consequently, a series of systems employing polyacrylamide gel

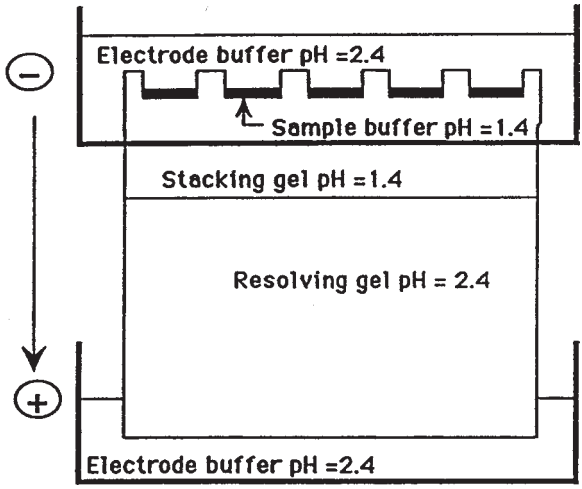

Fig. 1. Schematic of acidic discontinuous gel system. The system employs a pH 1.4 stacking gel on top of a pH 2.4 resolving gel with chloride as the leading ion and acetate as the trailing ion to stack the proteins tightly. The presence of the anionic detergent SDS allows the separation of proteins on the basis of molecular weight. The low pH preserves labile protein methyl esters, and so allows the identification of age-altered substrates of PCM.

electrophoresis at acidic pH have been utilized in efforts to identify the substrates of PCM. A pH 2.4 SDS system ***(3)*** using a continuous sodium phosphate buffering system has received the most attention ***(1,3–14)***. The main drawback of this system is that it produces broad electrophoretic bands. Acidic discontinuous gel systems using cationic detergents, ***(15)***, have proven useful in certain situations ***(16–21)*** and can be recommended if the cationic detergent is compatible with other procedures that might be utilized by the investigator (e.g., immunoblotting, protein sequencing). Recently, we have developed an electrophoresis system that employs SDS and an acidic discontinuous buffering system (**Fig. 1**). This procedure results in sharp electrophoretic bands and would be a good choice for investigators wishing to adhere to SDS as the anionic detergent. This system is described below, and examples of its ability to resolve proteins are provided.

2. Materials

2.1. Equipment

1. Slab gel electrophoresis unit: We have used the mini-gel electrophoresis units from Idea Scientific (Minneapolis, MN) (10 × 10 × 0.1 cm) with great success, as well as the Sturdier large-format gel system from Hoeffer Scientific Instruments (San Francisco, CA) (16 × 18 × 0.15 cm).
2. Electrophoresis power supply, constant current.

3. X-ray film and photo darkroom.
4. Scintillation counter.

2.2. Reagents

1. 40% (w/v) Acrylamide stock solution containing 37:1 ratio of acrylamide to *N,N′* -methylene-bis-acrylamide (Bio-Rad, Richmond, CA).
2. Resolving gel buffer: 0.1 *M* NaH_2PO_4 (Sigma, St. Louis, MO), 2.0 % SDS (United States Biochemical, Cleveland, OH [USB], ultrapure), 6 *M* urea (ultrapure) pH 2.4, with HCl.
3. Modified Clark and Lubs buffer (C & L buffer): Add 25.0 mL of 0.2 *M* NaCl to 26 mL of 0.2 *M* HCl, and bring to a final volume of 0.1 L. The buffer pH should be ~1.4 ***(22)*** (*see* **Note 1**).
4. Stacking gel buffer (2X): 2.0% (w/v) SDS, 6.0 *M* urea and C & L buffer such that the C & L buffer makes up 66% (v/v) of the total volume with the remaining 34% consisting of water and other buffer components. Buffer will be 0.033 *M* in NaCl. Readjust pH to 1.4 with HCl.
5. Sample solubilization buffer (2X): 2.0% (w/v) SDS, 6.0 *M* urea, 10% glycerol ([USB], ultrapure), 0.01% pyronin Y dye (Sigma), and C & L 33% (v/v) of the total volume, with the remaining 67% consisting of water and other buffer components. Buffer will be 0.0165 *M* in NaCl. Readjust pH to 1.4 with HCl.
6. Electrode buffer (1X): 0.03 *M* NaH_2PO_4, 0.1% SDS, 0.2 *M* acetate, pH 2.4 with HCl.
7. Gel polymerization catalysts: 0.06% $FeSO_4$, 1.0% H_2O_2, 1.0% ascorbic acid, prepared fresh in separate containers.
8. Colloidal Coomassie G-250 protein stain stock solution: 125 g ammonium sulfate, 25 mL 86% phosphoric acid, 1.25 g Coomassie brilliant blue G-250 (Sigma), deionized water to 1.0 L. The dye will precipitate, so shake well immediately before use. Stable indefinitely at room temperature ***(11)***.
9. Destain solution: 10% (v/v) acetic acid.
10. Fluorography solution: 1.0 *M* sodium salicylate brought to pH 6.0 with acetic acid ***(23)***.
11. X-ray film: Kodak X-Omat AR or equivalent.

2.3. Gel Recipes

2.3.1. 12% Acrylamide Resolving Gel, pH 2.4

The following volumes are sufficient to prepare one 7.5 × 10.5 × 0.15 cm slab gel:

2X Resolving gel buffer	3.75 mL
40% Acrylamide (37:1)	2.25 mL
0.06% $FeSO_4$	0.06 mL
1.0% Ascorbic acid	0.06 mL
0.3% H_2O_2	0.06 mL

2.3.2. 4.0% Stacking Gel, pH 1.4

The following volumes are sufficient to prepare one 3.0 × 10.5 × 0.15 cm stacking gel:

2X Stacking gel buffer	3.75 mL
40% Acrylamide (37:1)	0.75 mL
0.06% $FeSO_4$	0.06 mL
1.0% Ascorbic acid	0.06 mL
0.3% H_2O_2	0.06 mL

3. Methods

3.1. Sample Solubilization

1. An equal volume of 2X solubilization buffer is added and the samples are heated in a 95°C heating block for no more than 30 s (*see* **Note 2**).
2. To separate samples under reducing conditions, it is critical to add any reducing agent before addition of the solubilization buffer. Up to 10 µg/gel protein band can be resolved with this system; total sample loaded in a single well should not exceed about 100 µg.

3.2. Gel Preparation

3.2.1. Resolving Gel

1. Add all the components listed under **Subheading 2.3.1**, except the 0.3% H_2O_2, together in a small Erlenmeyer side-arm flask.
2. Degas the solution for at least 5.0 min using an in-house vacuum.
3. Assemble together gel plates and spacers that have been scrupulously cleaned and dried.
4. Using a pen, make a mark 3.0 cm from the top of the gel plates to denote the space left for the stacking gel.
5. To the degassed gel solution, add the H_2O_2 catalyst. Gently mix solution by pipeting the solution in and out several times. Avoid introducing air bubbles into the solution.
6. Quickly pipet the acrylamide solution between the glass gel plates to the mark denoting 3.0 cm from the top of the gel plates.
7. Carefully overlay the acrylamide solution with about a 2.0-mm layer of water-saturated butanol using a Pasteur pipet, so that the interface will be flat on polymerization.
8. Allow the gel to polymerize at room temperature until a distinct gel–butanol interface is visible.
9. After polymerization is complete, pour off the overlay, and gently rinse the top of the gel with deionized water. Invert the gel on paper towels to blot away any remaining water between the gel plates.

3.2.2. Stacking Gel

1. Add all the components listed under **Subheading 2.3.2**, except the 0.3% H_2O_2, together in a small Erlenmeyer sidearm flask.

2. Degas the solution for at least 5.0 min using in-house vacuum.
3. Soak the well-forming combs in the H_2O_2 catalyst solution while preparing the stacking gel.
4. To the degassed gel solution, add the H_2O_2 catalyst. Gently mix solution by pipeting the solution in and out several times. Avoid introducing air bubbles into the solution.
5. Quickly pipet the acrylamide solution between the glass gel plates to the very top of the gel plates.
6. Remove the combs from the H_2O_2 catalyst solution, shake off some of the excess solution, and insert the comb in between the gel plates by angling the comb with one hand and guiding the comb between the plates with the other hand.
7. Ensure the comb is level relative to the top of the resolving gel and that no bubbles are trapped under the comb.
8. After the stacking gel has completely polymerized, carefully remove the comb. Remove any unpolymerized acrylamide from each well by rinsing with deionized water (*see* **Note 3**).

3.3. Electrophoresis

1. Assemble the gel in the electrophoresis unit.
2. Add sufficient electrode buffer to cover the electrodes in both the upper and lower reservoirs.
3. Remove any air bubbles trapped under the bottom edge of the plates with a bent 25-gage needle and syringe containing electrode buffer.
4. Rinse each well with electrode buffer immediately before adding samples.
5. Load all wells with 40–60 µL of protein samples; load 1X solubilization buffer into any empty wells.
6. Run the gels at 15 mA, constant current, at room temperature for 4–6 h, or until proteins of interest have been adequately resolved (*see* **Note 4**).
7. Fix the gel in 12% (v/v) TCA with gentle shaking for 30 min.
8. Pour off fixative, and mix 1 part methanol with 4 parts of colloidal Coomassie G-250 stock solution. Slowly shake gel with staining solution for ~12 h (*see* **Note 5**).
9. Pour off staining solution. Any nonspecific background staining of the gel can be removed by soaking the gel in 10% (v/v) acetic acid. Little destaining of protein bands occurs even after prolonged times in 10% acetic acid.

3.4. Detection of Radioactively Methylated Proteins

Several protocols exist for radioactively methylating proteins with PCM ***(2,16)***. Following electrophoresis, gel bands containing radioactively labeled proteins can be detected by fluorography or scintillation counting of gel slices.

3.4.1. Fluorography of Gels

1. If gels have been stained, they are destained using 10% methanol/7% acetic acid to decolorize the gel bands.
2. Expose the gel to fluorography solution for 30 min at room temperature with gentle shaking.

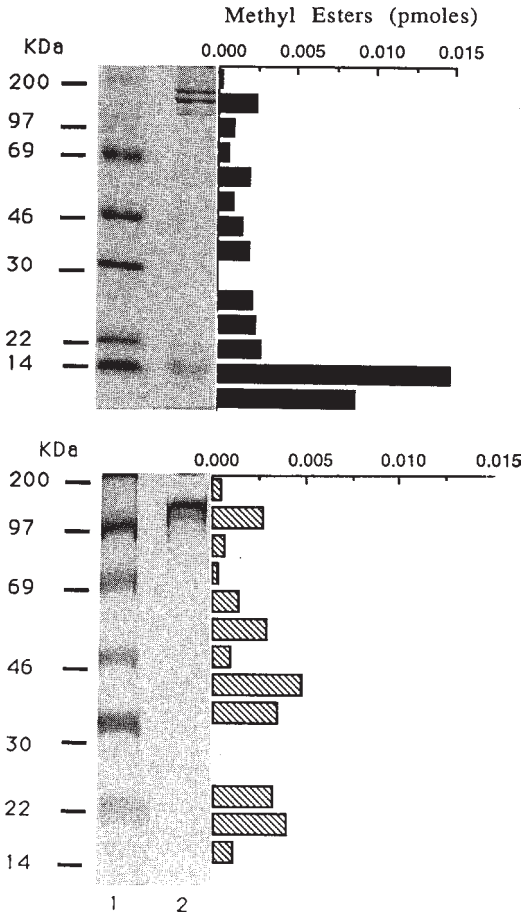

Fig. 2. Comparison of discontinuous acid gel with continuous acid gel. The following experiment tested for the presence of age-altered proteins in a commercial preparation of collagenase. The collagenase preparation (Sigma, type IV) was methylated with purified rabbit erythrocyte PCM and ^{3}H-AdoMet. Aliquots from the same methylation reaction were then resolved on (top) 12% discontinuous acid gel, described in text, or (bottom) 12% continuous acid gel system prepared according to the method of Fairbanks and Auruch ***(3)***. *Lane 1*: Rainbow molwt markers (Amersham); *Lane 2*: 18 µg of methylated collagenase were loaded on each gel. Following electrophoresis and staining, 0.5-cm gel slices were treated with base to detect radioactivity as described under **Subheading 3**. Both gel systems are capable of preventing the loss of methyl esters from protein samples, but the discontinuous system provides much higher resolution of individual polypeptide bands.

3. The gels are then placed on a piece of filter paper and dried under vacuum without heat for 3 h.
4. In a dark room, X-ray film (Kodak X-Omat AR) is preflashed twice at a distance of 15 cm with a camera flash unit fitted with white filter paper (3M) to act as a diffuser.
5. The gel is placed in direct contact with the film and taped in place. For future alignment, puncture holes in an asymmetric pattern in a noncrucial area of the gel-film sandwich. A 25-gage needle is useful for this purpose.
6. After sealing in a film cassette, the cassette is wrapped with aluminum foil, and exposure takes place at −70°C for several weeks.
7. After exposure, remove the cassette from −70°C, and allow to warm to room temperature. Develop film in darkroom.
8. An example of this technique is shown in **Fig. 2**.

3.4.2. Scintillation Counting Radioactive Methanol Evolved by Base Hydrolysis of Protein Methyl Esters in Gel Slices

1. Stained gels are soaked in 10% acetic acid containing 3% (v/v) glycerol for 1.0 h, placed on a piece of filter paper, and dried under vacuum without heat for 3.0 h. The glycerol keeps the gel from cracking and keeps it pliable for the steps described below.
2. Using a ruler and fine-tip marking pen, a grid is drawn directly on the surface of the dried gel.
3. A sharp scalpel is then used to cut out uniform slices precisely from each gel lane. Alternatively, selected bands can be individually excised from the gel.
4. 4.0 mL of scintillation fluid are added to each 20-mL scintillation vial. A glass 1-dram vial is then placed inside the scintillation vial, carefully avoiding spilling scintillation fluid into the 1-dram vial.
5. Each dried gel slice is then placed in the inner dram vial of a scintillation vial.
6. After all the gel slices have been placed in a separate inner 1-dram vial, 0.3 mL of 0.2 *M* sodium hydroxide is added to each inner vial. The scintillation vial is then immediately tightly capped and allowed to sit undisturbed for at least 3 h. Several hours are required for any volatile methanol that has formed by methyl ester hydrolysis to equilibrate and partition into the organic scintillation fluid, where it can then be detected by the scintillation counter.
7. Controls for measuring the efficiency of equilibration are performed by using a ^{14}C methanol standard, which is added to an inner 1-dram vial containing a nonradioactive gel slice and base hydrolysis solution. This is then placed inside a scintillation vial and allowed to equilibrate along with the other samples. An equal aliquot of the ^{14}C methanol standard is mixed directly with the scintillation fluid.
8. **Figures 3** and **4** show examples of gels that have been sliced and counted in a scintillation counter under the conditions just described.

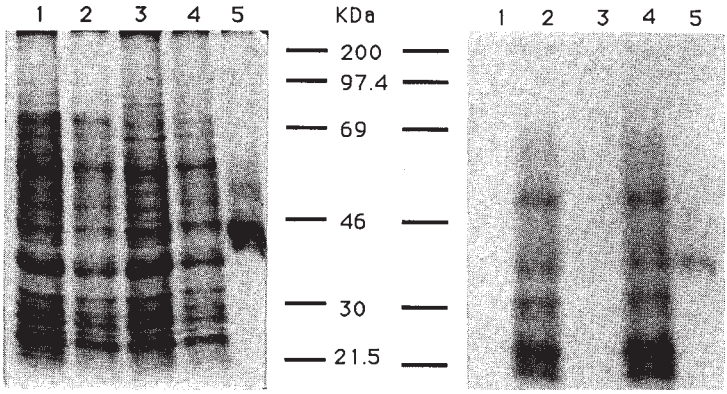

Fig. 3. Coomassie staining and autoradiography of complex protein mixtures by acidic discontinuous SDS gel electrophoresis. The following experiment was performed to measure the varieties of age-altered proteins in a cell cytoplasm. (**Left Panel**) Coomasie G-250 stained acidic discontinuous gel. (**Right Panel**) Autoradiogram of same gel. *Lane 1*: Cytoplasmic proteins, following incubation cells with ^{3}H-*S*-adenosyl-methione (AdoMet). *Lane 2*: Cytoplasmic proteins, following incubation of PC12 cytoplasm with ^{3}H-AdoMet. *Lane 3*: Cytoplasmic proteins, following incubation of intact PC12 cells with ^{3}H-AdoMet and purified rabbit PCM. *Lane 4*: Cytoplasmic proteins, following incubation of lysed PC12 cells with ^{3}H-AdoMet and purified rabbit PCM. *Lane 5*: Positive control; 20 µg of ovalbumin methylated with ^{3}H-AdoMet and purified rabbit PCM. Cells, lysates, and subfraction incubated with IU PCM, 300 pmol Adomet in final volume of 50 µL 0.2 *M* citrate, pH 6.0, 20 min at 37°C.

4. Notes

1. The buffering system employed in the stacking gel and sample solubilization buffer is based on a modification of the C & L buffering system. NaCl is employed rather than KC1 of the original system, because K^+ ions cause SDS to precipitate out of solution.
2. On occasion, the solubilization buffer will contain precipitates. These can be brought back into solution by briefly heating the buffer at 37°C. The solubilization buffer is stable for at least 2 wk at room temperature; by storing the buffer in small aliqouts at –20°C, it is stable indefinitely.
3. Gels can be stored for up to two weeks at 4°C by wrapping them in damp paper towels and sealing tightly with plastic wrap.
4. Since the dye front is a poor indicator of protein migration, use of prestained mol-wt markers, such as the colored Rainbow markers from Amersham, allows the progress of protein separation to be monitored by simply identifying the colored bands, which are coded according to molecular weight.
5. It is essential that all fixing and staining steps occur at acidic pH. The colloidal Coomassie G-250 procedure described under **Subheading 3**. has

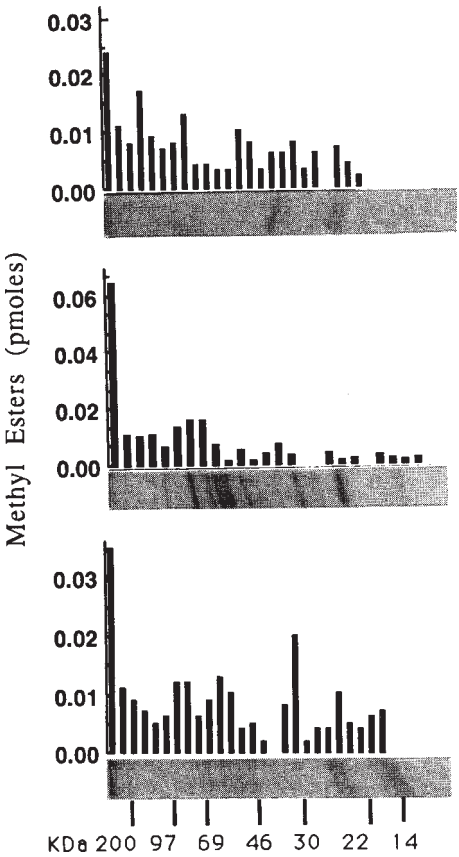

Fig. 4. Coomassie staining and radioactive methyl ester determination in gel slices of electrophoresed proteins from diseased human brain tissue. Extracts prepared from homogenates of Alzheimer's diseased brain (obtained from the Department of Pathology, Oregon Health Sciences University) were methylated in vitro with purified rabbit erythrocyte PCM and ^{3}H-AdoMet. Methylated proteins were then separated on 12% discontinuous, acidic gels, and radioactivity in each gel slice was quantified with scintillation counting as described under **Subheading 3**. *Top*: Distribution of methyl acceptor proteins in tissue protein that was insoluble in the nonionic detergent Triton X-100. *Middle*: Distribution of methyl acceptor proteins in tissue proteins that was soluble in an aqueous homogenization buffer. *Bottom*: Distribution of methyl acceptor proteins in crude homogenates of Alzheimer's diseased brains. Incubation conditions are similar to those described in **Fig. 3.**

several advantages: it is acidic, simple to perform, and has higher sensitivity than other dye-based staining methods, including those using Coomassie R-250. Additionally, nonspecific background staining is very low, so only minimal destaining is necessary to visualize protein bands.

6. Avoid using higher glycerol concentrations or prolonged incubation of the gel in this solution. Otherwise, the gel will be sticky after drying and contract sharply away from the paper backing on cutting.

Analysis of Tyrosine-*O*-Sulfation

Jens R. Bundgaard, Jette W. Sen, Anders H. Johnsen, and Jens F. Rehfeld

1. Introduction

Tyrosine *O*-sulfation was first described about 50 years ago as a post-translational modification of fibrinogen ***(1)***. In the following thirty years it was considered to be a rare modification affecting only a few proteins and peptides. However, in the beginning of the 1980s tyrosine (Tyr) sulfation was shown to be a common modification and since then an increasing number of proteins have been identified as sulfated. The target proteins belong to the classes of secretory, plasma membrane, and lysosomal proteins, which reflects the intracellular localization of the enzymes catalyzing Tyr sulfation, the tyrosylprotein sulfotransferases (TPSTs). TPSTs are type II integral membrane glycoproteins that reside in the *trans* Golgi network and use adenosine 3′-phosphate 5′-phosphosulfate (PAPS) as a co-substrate and sulfate donor. In higher organisms, 2 enzymes have been identified and cloned and they appear to be ubiquitously expressed in tissues ***(2–4)***. Moreover, homologous genes are present in lower eukaryotes as well as in the nematode *Caenorhabditis elegans*, fruit fly, and zebrafish. Both TPST-1 and TPST-2 knock-out mice models have been established and both display distinct phenotypes. The TPST-1 knock out mice are slightly smaller than wild-type mice and the female produces smaller litters ***(5)***. The TPST-2 knock-out mouse has delayed growth but reaches normal weight at 10 wk. Strikingly, the TPST-2 knock-out male is infertile ***(6)***. The biological function of Tyr sulfation is modulation of protein-protein interactions. For instance, Tyr sulfation is necessary for binding of the peptide hormone cholecystokinin (CCK) to the CCK-1 receptor ***(7)***; it is critical for interactions between p-selectin and PSGL-1 (P-Selectin Glycoprotein Ligand-l) ***(8)***; between hirudin and thrombin ***(9)***; and it modulates the ability of HIV −1 virus to enter cells via the chemokin receptor CCR5 and CD4 ***(10)***. In addition, sulfation has been reported to modulate

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

proteolytic processing ***(11)*** and secretion rates of secretory proteins ***(12)***. From these functions, it follows that it is not only important to detect Tyr sulfation, but also to identify the sulfation site to establish effects on the activity on the protein. Attempts have been made to determine a consensus site for tyrosine sulfation and generate algorithms that predict sulfation sites ***(13–15)***, one of these is the "sulfinator," which is available at www.expasy.org. However, it is known that the sulfinator at best gives an indication of possible sulfation sites, and it has been shown that nontypical structures, which are not identified by the sulfinator, can be sulfated ***(16,17)***.

Traditionally, Tyr sulfation has been analyzed by incorporation of radio labelled sulfate into target cells followed by purification of the target protein. Subsequently, the protein is degraded enzymatically or by alkaline hydrolysis followed by thinlayer electrophoresis to demonstrate the presence of radioactively labeled tyrosine. These techniques have been described in detail previously ***(18)***. The aim of this chapter is to present alternative analytical methods of Tyr sulfation other than radioisotope incorporation before analysis. Thus, sulfation of protein or peptide fragments can be demonstrated by a combination of chromatography and specific assays. This has several advantages. First, depending on the assay used, the analysis can be quantitative. Second, problems with incorporation of isotope and the high degree of incorporation of radiolabeled sulfate into carbohydrate moieties that might interfere with detection can be avoided. In addition, it allows two ways of identification of sulfated tyrosines depending on purity of the protein. One strategy demands purified protein using mass spectrometry or chromatography, whereas another uses Tyr sulfate sensitive antisera to distinguish between sulfated and nonsulfated forms in a crude extract. We provide protocols for establishment of sulfation specific antisera and give examples of chromatographic systems that are useful for analysis of Tyr sulfation.

Establishment of a specific immunoassay is costly and time-consuming, and initiation of such a process demands an interest exceeding the mere confirmation of the modification. If such an assay is desirable, a number of considerations have to be taken into account. The size of an antibody binding site is complementary to that of a peptide ligand (or epitope) of 4–6 amino acid residues ***(19)***. Within such an epitope the exact structure of each residue profoundly influences the binding of the antibody ***(20)***. Moreover, the protein or peptide structures surrounding the particular epitope also modulate binding affinity considerably ***(21)***. Accordingly, it is not surprising that attempts to raise antibodies that specifically bind a single *O*-sulfated Tyr residue as such—irrespective of neighboring structures—have failed (Hakanson, R. and Huttner, W. B. personal communications, and our own results). However, recently a promising monoclonal antibody was reported, which was raised against tyrosine sulfated P-selectin glycoprotein ligand-1. It has tyrosine sulfate specificity and show a wide tolerance to sequence variance around the sulfated tyrosine.

Nevertheless, it does not bind sulfotyrosine alone and is thus not entirely sequence independent ***(22)***.

The discrepancy with the success to raise antibodies against the structurally similar phosphorylated Tyr residues ***(23)*** is at present unexplained. In accordance with the aforementioned consideration and with prevailing immunochemical theories, antibodies that recognize sulfation of a given Tyr residue consequently have to be raised against the entire epitope containing the sulfated tyrosine, i.e., a peptide sequence of approx 5 or 6 amino acid residues. It has, however, proven difficult to raise high-titer and high-affinity antibodies or antisera against peptides of less than 10 residues ***(24)***. Therefore, a peptide of approx 10 residues containing the desired epitope in an otherwise expedient sequence should be designed, synthesized, and used for immunization. Hence, measurement of Tyr sulfation by immunochemical methods requires precise knowledge of the sequence and structure surrounding the *O*-sulfated residue in a peptide or protein. It is necessary to consider different strategies in the design of appropriate radioimmunoassays (RIA) (*see* **Note 1**).

Sulfation of a protein or peptide introduces a highly acidic group that alters its local physical and chemical properties such as conformation, hydrophilicity, and pK-value. This can be used to separate sulfated and nonsulfated forms, by various chromatographic techniques, e.g., ion-exchange chromatography and reverse phase high-performance liquid chromatography (RP-HPLC) at near neutral pH under which the conditions for ionization of the sulfate group induces the maximum difference between the two forms (*see* **Note 2**). Also, removal of the sulfate group by digestion with arylsulfatase combined with chromatographic analysis of the peptide before and after the digestion can reveal the presence of Tyr sulfate. Often, identification of sulfated Tyr within a protein requires digestion of the protein into smaller peptides followed by separation of the fragments and isolation of relevant peptide. A number of proteinases may be used, for example trypsin or the endoproteinases Lys-C, Glu-C, and Asp- N, the choice being partly dependent on the individual protein. The details for these techniques are beyond the scope of the present chapter, but may be found in other volumes of this series. These analytical methods can profit from the availability of specific antisera or be carried out using pure proteins.

Having a purified protein offers alternative ways of analysis of Tyr sulfation. The sulfate ester bond is generally considered as labile and particularly susceptible to acidic hydrolysis. Despite of this, the tyrosine sulfate can generally withstand pH in the range of 1–3, often used during many standard analyses such as reversed phase chromatography and mass spectrometry, as long as the temperature is kept at room temperature or below and the exposure time is limited ***(25)***. However, sulfated Tyr can not be identified by protein sequence analysis because of the highly acidic environment and elevated temperatures during the analysis. Instead, nonderivatized Tyr will result. Likewise, the standard acidic

hydrolysis used for amino acid analysis is not feasible; instead, demonstration of the presence of intact tyrosin sulfate in a peptide was originally obtained by basic hydrolysis before amino acid analysis ***(26)***. This technique has a limited sensitivity because of an inevitable background. Alternatively, nondestructive digestion can be obtained by aminopeptidase M or a combination of aminopeptidase M and prolidase followed by amino acid analysis ***(27)***. However, these techniques are not used much anymore. Mass spectrometry (MS) is now the preferred tool of analysis of many post-translational modifications. MS in combination with protein sequence analysis can disclose the presence of a sulfated Tyr. Thus, if the identified sequence contains Tyr and the measured mass is 80 Da higher than the calculated value, it is a good indication that the Tyr is sulfated. However, phosphorylation also results in an 80 Da increase of the molecular mass (*see* **Note 3**; **Fig. 1**). It should also be noted that the sulfate group is lost during ionization in both matrix assisted laser desorption/ionisation (MALDI) and to some degree in electrospray ionization (ESI), resulting in a false negative result. Using MALDI time-of-flight (TOF) MS, the loss of sulfate can be turned into a diagnostic advantage because the loss is often complete in the positive mode ***(31)*** and limited in negative mode. Hence, comparison of spectra obtained in positive and negative linear mode of the same sample will show a vast difference in the yield of the sulfated and nonsulfated species (*see* **Note 4**), whereas the picture will be more complex in the reflector mode (*see* **Note 5**; **Fig. 2**). In experiments using hybrid instruments of the quadrupole-TOF type it is possible to see fractions of the sulfated species in positive mode even though the desulfated species is generally dominating. The fact that tyrosine sulfate is unstable even at standard collision energy in a quadrupole-TOF instrument, can be used in identifying new sulfated targets by using neutral loss scan experiment detecting the loss of 79.957 ***(32)***. Though tyrosine sulfate and tyrosine phosphate has almost identical mass, it is possible to distinguish between the two as the tyrosine sulfate is generally much more unstable than the tyrosine phosphate, which is not nearly as prone to neutral loss as the tyrosine sulfate. Furthermore when performing MS/MS experiments the tyrosine phosphate gives rise to a stable immonium ion of 216.043 whereas the immonium ion of tyrosine sulfate is not detected. This can be used to further confirm the identification of a phosphate or sulfate. Another option is to investigate tyrosine sulfation by a mass spectrometer capable of electron capture dissociation (ECD). This is a fragmentation method that, to a higher degree, maintains the sulfate during peptide backbone fragmentation but requires specialized and expensive instrumentation ***(33,34)***. Recently, a new method for stoichiometric identification of tyrosine sulfate in proteins using tandem mass spectrometry was described (***35***). The method utilize sulfosuccinimidyl acetate to block unsulfated tyrosines, followed by analysis under conditions that hyrolyze tyrosine sulfate, leaving unmodified

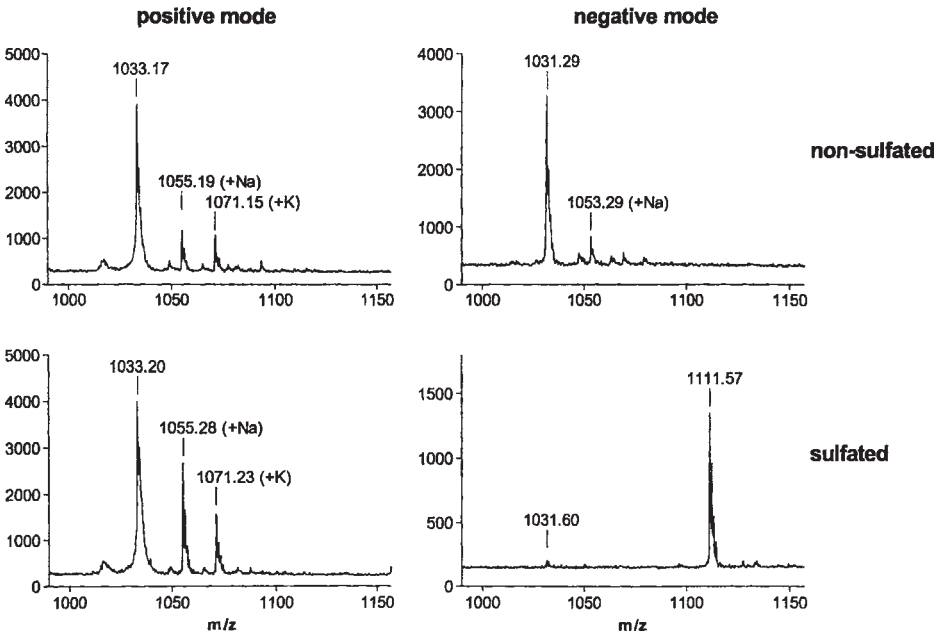

Fig. 1. Mass spectra obtained in the positive and negative mode in a mass spectrometer equipped with delayed extraction (Bruker Daltonik Biflex). As model peptides were used nonsulfated and sulfated shark gastrin-8 (Asp-Tyr(SO_3)-Thr-Gly-Trp-Met-Asp-Phe-NH_2) with the theoretical monoisotopic molecular masses 1032.40 and 1112.36 Da, respectively. In the positive mode the measured *m/z* values represent the protonated molecular ion (+1.01) and to a certain degree the Na^+ and K^+ adducts, whereas the deprotonated form (−1.01) is recorded in the negative mode. In this example the intact sulfated peptide is only observed in the negative mode together with a small fraction of the desulfated form. *See also*, however, **Note 3**. *y*-axis: number of collected ions.

tyrosines as indicators of a previously sulfated site. This method is generally applicable and sensitive, but like other present methods it is not well suited for general screening of sulfated proteins.

2. Materials

2.1. Generation of Tyr Sulfation Sensitive Radioimmunoassays

2.1.1. Preparation of immunogen (common for all Three Coupling Methods) (see **Note 6***)*

1. 5 mg sulfated peptide.
2. *N, N*-dimethylformamide.
3. 25 mg bovine serum albumin.

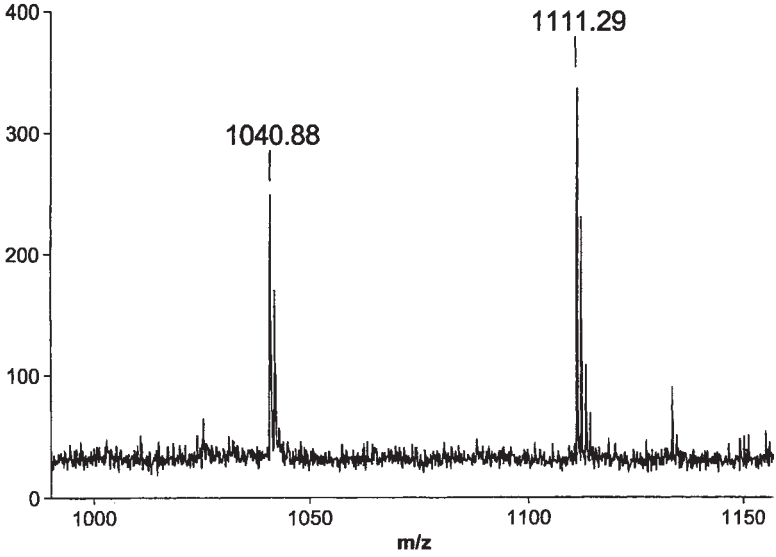

Fig. 2. Mass spectrum of sulfated shark gastrin-8 (*see* **Fig. 1**) obtained in the negative reflected mode using α-cyano-4-hydroxycinnamic acid as matrix. The peak at *m/z* 1111.29 represents the intact peptide (theoretical value 1112.36 −1.01) whereas the peak at 1040.88 represents the in-flight desulfated peptide. The difference between the two is considerably less than the expected 80 (*see* **Note 5**). Note that the resolution is higher in the reflected mode than in the linear mode (**Fig. 1**).

4. 0.05 *M* sodium phosphate buffer, pH 7.5.

For carbodiimide-coupling:

5. 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide HCl.

For glutaraldehyde-coupling:

6. 500 g/L g lutaraldehyde.
7. One Sephadex G-10 column with a fraction collector.

For maleimidobenzoyl-succinimede ester-coupling:

8. 25 mg *m*-maleimidobenzoyl-N-hydroxysuccinimide ester (MBS).
9. One Sephadex G-25 column with a fraction collector.

2.1.2. Immunization

1. 6–8 rabbits.
2. 8.5 g/L saline buffer.
3. Freund's complete adjuvant.
4. Freund's incomplete adjuvant.

2.1.3. Preparation of Tracer (*see* **Note 7**; **Fig. 3**)

1. Synthetic peptide
2. HPLC apparatus with reverse-phase column (Aquapore C-8 column, RP-300, 220 × 4.6 mm, 7- µm bead size) and fraction collector.

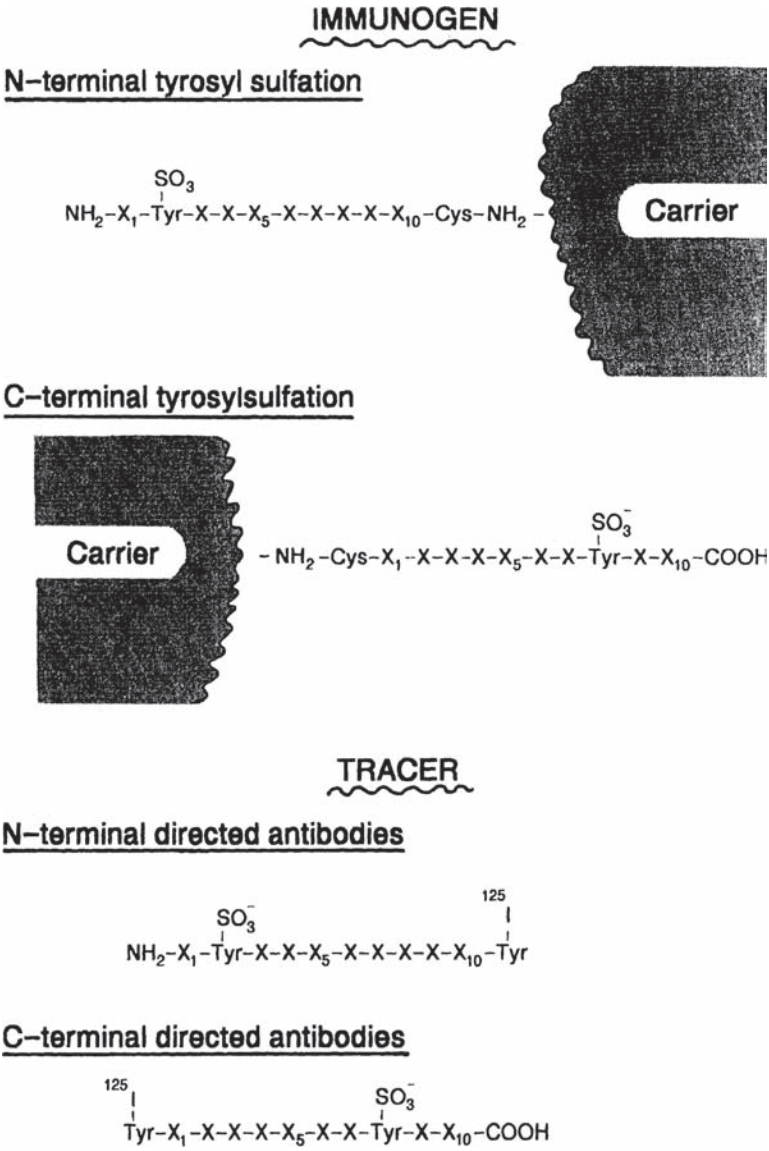

Fig. 3. The structure of immunogens used for production of antibodies directed against tyrosyl *O*-sulfated peptides (upper part of the figure), and the structure of corresponding radioactive tracers (lower part of the figure).

3. Ethanol or acetonitrile (HPLC grade).
4. 1.0 mL/L trifluoroacetic acid (TFA; HPLC grade in water).
5. 0.02 *M* Barbital buffer, pH 8.4.

Iodination using chloramin T:

6. I^{125} (Amersham IMS 30, specific activity 16.85 mCi/μg of iodine).
7. 0.05*M* phosphate buffer, pH 7.5.
8. Disodium sulfite (Na_2SO_3).
9. Chloramine T.
   Iodination using Bolton Hunter reagent:
10. Bolton and Hunter reagent for protein iodination (Amersham).
11. 0.2*M* sodium borate buffer, pH 8.5: mixture of 0.2*M* $Na_2B_4O_7$ and 0.2*M* H_3BO_3 with pH adjusted.
12. 0.1*M* sodium borate buffer with 0.2*M* glycine, pH 8.5 (prepared from the buffer above).

2.1.4. RIA Procedure

1. Synthetic peptide for standard (*see* **Note 8**).
2. Disposable plastic tubes.
3. 0.02*M* barbital buffer, pH 8.4, containing 1 g/L bovine serum albumin.
4. Activated charcoal.
5. Blood plasma: this is a mixture of buffer and outdated human plasma from Blood Banks in 0.02*M* sodium phosphate, pH 7.4. The optimal concentration normally varies between 10–50% plasma.
6. γ-scintillation counter.

2.2. Analysis of Tyr Sulfation Using FPLC Based Ion-Exchange Chromatography (*see* **Note 9**)

1. An FPLC system equipped with an ion-exchange column, e.g., an 5/5HR MonoQ anion-exchange column (Pharmacia) and a fraction collector.
2. Buffer A: 50 m*M* Tris-HCl, pH 8.2 added 10% (v/v) acetonitrile.
3. Buffer B: 50 m*M* Tris-HCl, pH 8.2 added 10% (v/v) acetonitrile and 1*M* NaCl.

Both buffers are filtered through a 0.45 μm filter, degassed and stored at 4°C where it is stable for months.

2.3. Analysis of Tyr Sulfation Using Reverse Phase HPLC

1. An HPLC instrument with gradient formation capability and equipped with a suitable RP (reversed phase) column (C8 or C18).
2. Solvents: Stock solution of 0.5*M* ammonium acetate in water, filtered through 0.45 μm filter (can be kept for several months at 4°C). Solvents A and B are prepared by addition of 20 mL/L of H_2O and acetonitrile, respectively (both HPLC grade), to form 10*M* ammonium acetate.

2.4. Analysis of Tyr Sulfation Using Mass Spectrometry

1. Instrument: A mass spectrometer for MALDI-TOF MS.
2. Matrix solution: Prepare a 20 mg/mL solution of α-cyano-4-hydroxycinnamic acid in 30% (v/v) acetonitrile/0.1% (v/v) TFA in an Eppendorf tube and centrifuge; use the supernatant as matrix solution. Alternatively 2,5-dihydroxybenzoic acid (DHB)

20 mg/mL in 50% Acetonitrile/1% phosphoric acid can be used (*see* **Note 10**). For larger peptides 3,5-dimethoxy-4-hydroxy-*trans*-cinnamic acid (sinapinic acid) can be used. Premade matrix solutions ("MALDI-grade") are also commercially available (Hewlett-Packard).

3. For neutral loss scanning on quadrupole-TOF instrument Instrument: A hybrid instrument of quadrupole time-TOF type. For complex samples connected to a HPLC instrument equipped with a reversed phased column for separation of peptides. Desalted sample dissolved in 30–50% Acetonitrile 0.2% formic acid for direct infusion, or sample dissolved in aqueous solution for injection on reversed phase column.
4. Solution A: 95% Acetonitrile/0.2% formic acid, solution B: 5% Acetonitrile/0.2% formic acid.

2.5. Arylsulfatase Treatment

1. Arylsulfatase type VIII (Sigma, 20–40 U/mg).
2. Acetate buffer: 0.2 *M* sodium acetate, pH 5.0.
3. 0.2% Sodium chloride.

3. Methods

3.1. Generation of Tyr Sulfation Sensitive Radioimmunoassays

3.1.1. Preparation of the Immunogen

3.1.1.1. Carbodiimide Coupling

1. Dissolve 5 mg peptide hapten in 1 mL of *N,N*-dimethylformamide.
2. Dissolve 25 mg bovine serum albumin in 2.5 mL of 0.05 *M* sodium phosphate, pH 7.5.
3. Conjugate by the addition of 125 mg of 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide HCl to give molar ratios between the peptide, albumin and ethylcarbodiimide of 1:0.1:40. Mix the reagents and incubate for 20 hours at 20°C.
4. Divide the mixture into six portions and store at −20°C until immunization (stable up to one year).

3.1.1.2. Glutaraldehyde Coupling

1. Dissolve 2.5 mg of sulfated peptide hapten together with 7.5 mg bovine serum albumin in 5 mL of 0.05 *M* sodium phosphate, pH 7.5.
2. Conjugate by dropwise addition of 100 µL of 500 g/L glutaraldehyde.
3. Mix the solution and incubate for 4 h at 20°C.
4. Apply the mixture to a calibrated Sephadex G-10 column and elute at 20°C with 0.05 *M* sodium phosphate, pH 7.5, in fractions of 1 mL.
5. The void volume fractions containing the conjugate are then pooled, divided into 6 portions, and stored at −20°C until immunization (stable for months).

3.1.1.3. Maleimidobenzoyl-Succinimide Ester Coupling

1. Dissolve 5 mg sulfated peptide hapten together with 25 mg of bovine serum albumin (BSA) in 10 mL 0.05 *M* sodium phosphate buffer (pH 7.5).

2. Dissolve 25 mg of *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS) in 1 mL *N, N*-dimethylformamide.
3. Conjugate by dropwise addition of the MBS-solution to the sulfated peptide/BSA solution.
4. Stir at room temperature for 30 min.
5. Free MBS is separated from the activated albumin by Sephadex G-25 gel filtration (eluted at 20°C with 0.05 *M* sodium phosphate, pH 7.5, in fractions of 1 mL).
6. Add the sulfated and cysteinylated peptide to the MBS-activated bovine serum albumin and stir the mixture stirred for 3 h at room temperature and a pH of 7.5.

3.1.2. Immunizations

1. The first portion of the antigen is suspended in 8.5 g/L saline to a volume of 5 mL and carefully emulsified with an equal volume of Freund's complete adjuvant. We recommend emulsification by pushing the saline-adjuvant forwards and backwards between two connected 10-mL syringes until a drop of the emulsion remains coherent and condensed on a larger water surface. Randomly bred rabbits are used for immunizations in series of 6–8 rabbits each.
2. Two subcutaneous injections of the mixture are given over the hips in amounts corresponding to 40 µg hapten per animal.
3. Five or more booster injections using Freund's incomplete adjuvant (prepared as described in 1) are then administered simultaneously in all rabbits at 8-wk intervals, using one-half of the initial dose of antigen per immunization.
4. The rabbits are bled from an ear vein 10 d after immunization. Sera from the bleedings are separated and stored at −20°C.
5. The antiserum obtained is evaluated (*see* **Note 11**).

3.1.3. Preparation of Tracer for Radioimmunoassay (*see* **Note 7**)

3.1.3.1. Iodination using chloramine T

1. Dissolve 500 µg peptide in 1 mL 0.05 *M* phosphate buffer, pH 7.5. Aliquot in 10 µL portions and store at −20°C.
2. Dilute 2 mCi I^{125} (~20 µL) with 85 µL 0.05 *M* phosphate buffer, pH 7.5 (final activity about 200 µCi/10 µL).
3. Dissolve 5 mg chloramin T in 10 mL 0.05 *M* phosphate buffer pH 7.5.
4. Dissolve 2 mg disodium sulfite in 10 mL 0.05 *M* phosphate buffer pH 7.5.
5. Mix 10 µL peptide, 10 µL I^{125} and 10 µL chloramin T gently. After 30 s the reaction is arrested with 25 µL disodium sulfite. Shake gently. If more tracer is prepared, do iodination in batches and pool the preparations.
6. Purify the tracer by HPLC. Fractions with maximal counts of reactivity is diluted with 0.02 *M* barbital buffer, pH 8.4 to a final activity of 106 cpm/mL. Store the tracer in 500 µL aliquots at −20°C.

3.1.3.2. Iodination Using the Bolton Hunter Reagent

1. Evaporate the water from the I^{125} Bolton Hunter reagent under a slow flow of nitrogen.
2. Dissolve 5 µg of peptide in 10 µL water and add 10 µL 0.2 *M* sodium borate buffer.

3. Add the peptide solution to the Bolton Hunter reagent and incubate the mixture at 4°C for about 20 h.
4. Add 500 µL 0.1 *M* borate buffer with 0.2 M glycine. Continue directly with HPLC purification of the tracer as described above, or store at 4°C.

3.1.4. RIA Procedure

1. At room temperature, prepare the following mixtures of total volumes of 2.4 mL (RIA is carried out as an equilibrium system at pH 8.4, using 0.02 *M* barbital buffer, pH 8.4, containing 1 g/L bovine serum albumin) in disposable plastic tubes: 2.0 mL of antiserum dilution, 250 µL of tracer solution (giving 1000 cpm, corresponding to 0.5 fmol of freshly prepared ^{125}I-labeled tracer-peptide), and 150 µL of standard solution or sample. All samples should be assayed in duplicate.
2. Incubate at 4°C for 2–5 days to reach equilibrium.
3. Antibody-bound (B) and free (F) tracers are separated by the addition of 0.5 mL of a suspension of 20 mg of activated charcoal and diluted blood plasma to each tube. The tubes are centrifuged for 10 min at 2000 *g*.
4. Count the activities of the supernatant (B) and sedimented charcoal (F) in automatic γ-scintillation counters for 5 min.
5. Calculate the binding percentage as $B - [(B + F) \times D] / (B + F) - [(B + F) \times D] \times 100$, where the "damage" ($D$) is defined as $B \times 100 / (B + F)$ in the absence of antiserum. The damage is usually 2–3%. The peptide concentration is determined from a standard curve based on known standards.

3.2. Analysis of Tyr Sulfation Using FPLC Based Ion-Exchange Chromatography

1. Equilibrate the column to start conditions and inject sample.
2. Elute with an appropriate gradient at the flow of 1 mL/min and collect fractions if necessary.
3. The eluting peptide is monitored by the UV signal recording or any appropriate specific assay. An example of an elution profile examined by radioimmunoassay is given in **Fig. 4**.

3.3. Analysis of Tyr Sulfation Using Reverse Phase HPLC

1. Equilibrate column to start conditions and inject sample.
2. Elute with an appropriate gradient.
3. Record UV signal at 214 nm and—if further analyses are wanted—collect fractions automatically at regular intervals or collect peak manually. An example of an elution profile is given in **Fig. 5**.

3.4. Analysis of Tyr Sulfation Using Mass Spectrometry

3.4.1. MALDI-TOF

1. Samples should be in a final concentration of 0.05–5 pmol/µL, sensitivity depends highly on the nature of the peptide (*see* **Note 12**).

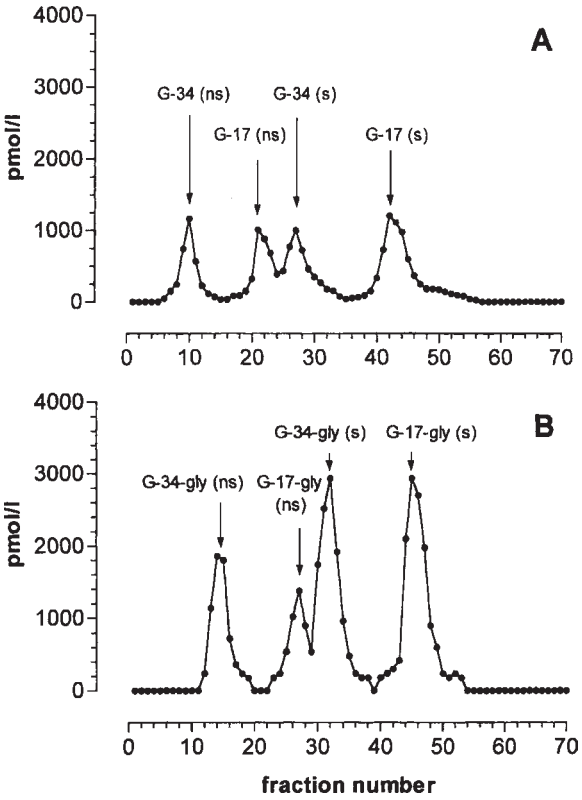

Fig. 4. Anion exchange chromatography using a FPLC system of the main processing forms of human gastrin heterologously expressed in a hamster β-cell line, HIT. **Panel A** shows carboxyamidated gastrin forms of 17 and 34 residues and demonstrates the separation of sulfated and nonsulfated forms. **Panel B** shows the immediate precursor of carboxyamidated gastrin, with the free C-terminus extended with a Gly. Fractions were eluted using a linear gradient of 20–55% buffer B over 60 min at a flow of 1 ml/min. Fractions were analyzed using specific radioimmunoassays. (Elution positions can be verified using synthetic peptides or by analysis of elution positions following arylsulfatase treatment.)

2. Mix 0.5 µL of sample with 0.5 µL MALDI matrix solution. For manual preparation, this can be done in a microcentrifuge tube, or many samples can be prepared consecutively at different positions in a trough made from a cutthrough polypropylene tube.
3. Apply immediately 0.5 µL of the mixture to the sample target (volume may depend on the target size) and let sample dry.
4. Insert sample(s) into the mass spectrometer and record the mass spectrum according to the instrument manual.

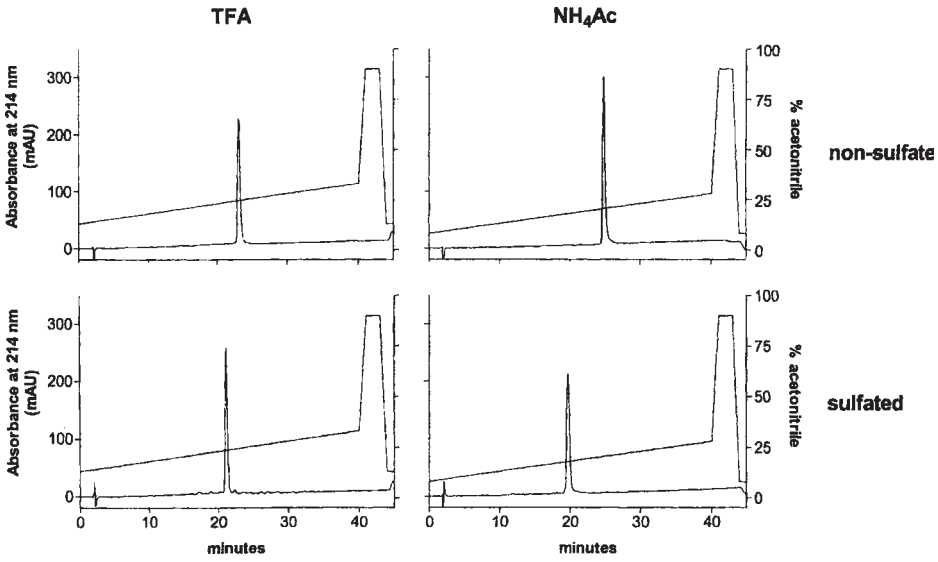

Fig. 5. HPLC separation of the model peptides, non-sulfated and sulfated shark gastrin-8 (*see* **Fig. 1**). The use of 0.1% trifluoroacetic acid (TFA) and 10 m*M* ammonium acetate (NH_4Ac) as buffering component are compared. In both cases 0.5%/min. gradients from H_2O to acetonitrile were employed, starting from 13% acetonitrile in the TFA system and from 8% in the NH_4Ac system (indicated by the straight lines). Although the two forms are indeed separated in the TFA system (by 1% acetonitrile) the separation is much more pronounced in the NH_4Ac system (by 2.5% acetonitrile). For bigger peptides, where sulfation influences the chromatographic behavior relatively less, use of the NH_4Ac system may be crucial for the separation of the non-sulfated and sulfated form.

3.4.2. Neutral Loss Experiment on Quadrupole-TOF: Analyses of complex samples:

1. The LC part of the system is programmed to run a gradient appropriate to the sample, e.g., 5–40% B over 120 min. (*see* **Note 13**).
2. The instrument is programmed to do neutral loss scanning for loss of 79.9568 Da and with alternating slightly higher and slightly lower collision energy than standard settings during the run of the gradient (e.g., on a Q-TOF2 instrument (Waters) collision energies 13 and 8 as opposed to a standard setting of 10), *see* **Fig. 6**.
3. Peptides detected by neutral loss scanning are sequenced by MS/MS (*see* **Note 14**).
4. Tyrosine sulfated peptides are confirmed by the MS/MS data that should not contain the tyrosine phosphate immonium ion of 216.043 Da.

3.4.3. Direct Infusion of Simple Samples

1. For direct infusion, e.g., by nanospray without reversed phase separation the sample has to be clean from salts and only contain a limited number of peptides.

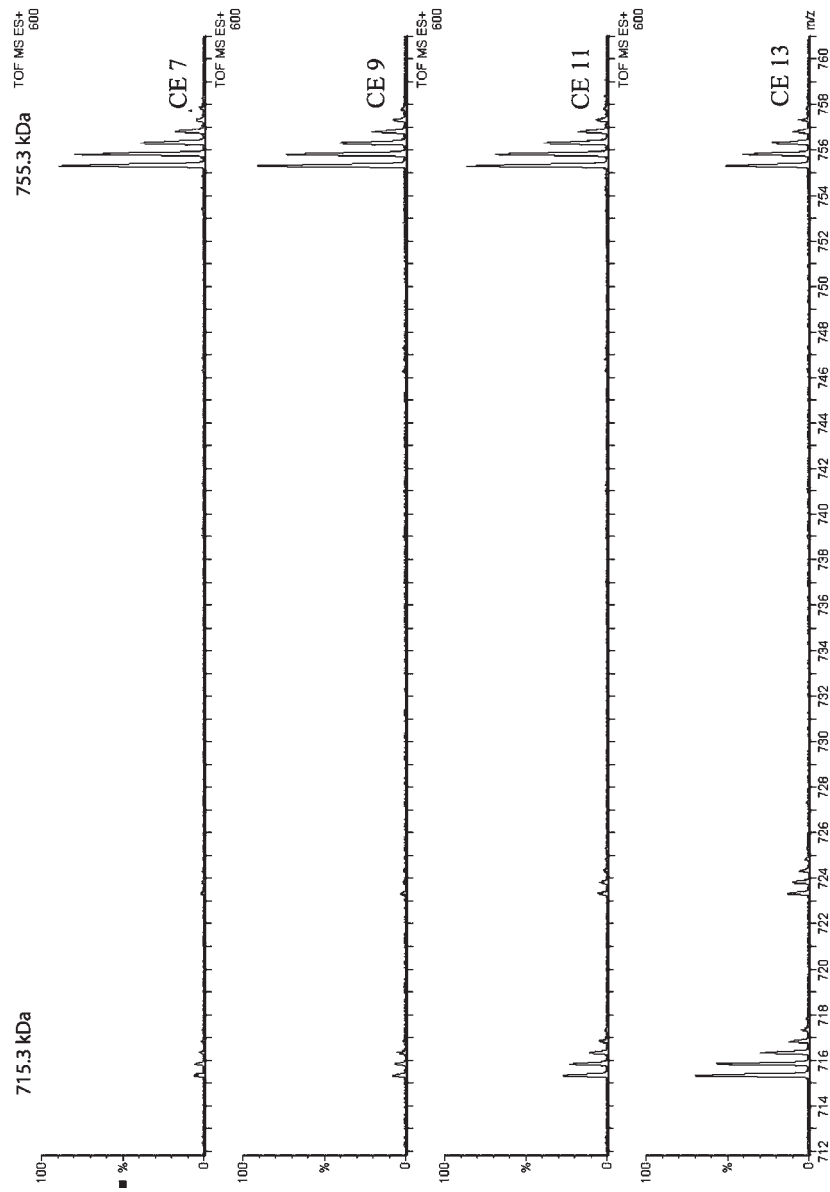

Fig. 6. Mass spectra of tyrosine sulfated drosulfokinin showing the increased neutral loss as the collision energy (CE) is increased in intervals of 2 from 7 to 13. The spectra were obtained on a Q-TOF2 using nanospray ionization. Sulfated drosulfokinin is seen at 755.3 Da and desulfated drosulfokinin at 715.3 Da. Both ions are doubly charged and the neutral loss is therefore observed as 40 Da.

2. The experiment is run as described above but without the LC part. Alternatively collision energy can be changed manually and mass shift for the peptide suspected of being tyrosine sulfated monitored.

3.5. Arylsulfatase Treatment (*see* Note 15)

1. Prepare an enzyme solution of arylsulfatase VIII of 2 mg/mL in 0.2% sodium chloride.
2. Prepare the lyophilized sample by resuspension in 400 µL acetate buffer.
3. Add 100 µL enzyme solution to the sample preparation. The final concentration of arylsulfatase is 0.4 mg/mL (equivalent to 0.55 U/mL).
4. Incubate for 3 h at 37°C.
5. Terminate the reaction by boiling for 10 min.

4. Notes

1. The strategy depends on several factors: (1) The size of the protein or peptide; (2) the position of the sulfated Tyr within the protein; (3) the biology of the sulfated protein or peptide (a large membrane protein; a circulating hormone; or a small neurotransmitter peptide, etc.); and (4) the concentration range in which to measure. If the sulfated Tyr is positioned at the N- or the C-terminus, production of antibodies against a synthetic analogue of the terminally sulfated decapeptide is straightforward. If, however, the sulfated Tyr is located in the middle of a protein or a long polypeptide chain, antibodies should be raised against a fragment containing the sulfated tyrosine, preferably a fragment that can be released from the protein by appropriate proteolytic cleavage. Finally, if the sulfated protein is available in substantial quantities for large immunization series, "shotgun" immunization with the entire protein and subsequent identification of epitope specificity can be attempted.
2. The presence of Met in the peptide presents a possible pitfall, because oxidation of Met to the sulfoxide (which may occur spontaneously in the presence of atmospheric oxygen) increases the hydrophilicity considerably, thus causing the peptide to elute significantly earlier than the reduced form in both a RP-HPLC and in an anion exchange chromatography system.
3. Both sulfation and phosphorylation add 80 Da to the molecular mass of the peptide (the exact monoisotopic values being 79.957 and 79.966, respectively). However, it is possible to distinguish the two by several criteria. Thus, under the standard conditions used for Edman sequencing peptides phosphorylated at Ser, Thr or Tyr give no signal (although for different reasons, ***(28,29)***) resulting in a blank cycle, whereas sulfated Tyr is hydrolyzed and seen as Tyr in almost normal yield. Furthermore, in contrast to Tyr-sulfated peptides (**Fig. 1**), phosphorylated peptides are recorded as

the intact species in MALDI-TOF linear mode ***(30)***. In the reflector mode a typical triplet is observed from phosphorylated peptides consisting of the intact molecular ion accompanied by a major and a much less abundant fragment because of the loss of H_3PO_4 (98 Da) and HPO_3 (80 Da), respectively ***(30)***. This is in contrast to the singular loss of 80 Da from a Tyr-sulfated peptide (*see* **Note 5**).

4. The relative yields of the sulfated and nonsulfated form depend on the composition of the peptide. Small acidic peptides like the model peptide give almost clean peaks representing the sulfated and nonsulfated form in the negative and positive (linear) mode, respectively **(Fig. 1)**, whereas larger and more neutral peptides give a more mixed picture.
5. A MALDI-TOF mass spectrum obtained in the negative mode using reflector will show the correct molecular ion and an additional peak at a distance *less* than 80 Da below the value for the molecular ion **(Fig. 2)**. This is caused by rupture of the sulfate ester bond in the linear flight tube after the peptide was accelerated but before the peptide reaches the reflector, and the calibration for the reflector requires ions with full accelerating energy. The decrease in molecular mass caused by sulfate loss observed in the reflected mode is instrument dependent, but once established it can also be used as an indicator of a sulfated peptide.
6. The tyrosine 0-sulfated peptide, synthetic or purified has to be available in mg amounts. After dissolution in an appropriate buffer, the peptide is coupled to a protein carrier in amounts that ensure a coupling ratio of approx 5–10 molecule haptens per carrier molecule. There are several useful carrier candidates. We recommend bovine serum albumin (BSA, approx 5 mg/mg hapten decapeptide). BSA is easily available, inexpensive and in our experience as effective as any other protein carrier. When peptide hapten has to be synthesized, we recommend synthesis of an analogue of the genuine hapten equipped with a N- or C-terminal cysteinyl residue. Which terminus or end depends on the position of the sulfated tyrosyl residue **(Fig. 3)**. The peptide hapten is then coupled to a free amino group in the carrier protein through the terminal cysteine using maleimidobenzoic acid N-hydroxysuccinimide ester as coupling reagent ***(36)***. Again, depending on the position of the sulfated tyrosyl residue, conventional coupling using either ethylcarbodiimide or glutaraldehyde may also be used ***(36)***.
7. With directional N- or C-terminal carrier coupling **(Fig. 3)**, it is important to design a tracer that corroborates and further advances the antibody specificity achieved. Because ^{125}I is the preferred RIA-isotope, and because iodine easiest is coupled to tyrosyl- residues, we recommend synthesis of a tyrosylated hapten decapeptide in which the additional tyrosyl-residue for

iodination is placed in the same position as cysteine in the hapten analogue, i.e. at the terminus opposite to the epitopic part of the hapten containing the 0-sulfated tyrosine (**Fig. 3**). In this way, iodinated tyrosine will not interfere with the antibody binding. There is no risk for iodination of the O-sulfated tyrosine-residue. The sulfonate group blocks incorporation of iodine. Natural occurrence of an additional unsulfated tyrosyl in the short hapten sequence has not been experienced so far; but in such situation a new labeling strategy has to be delineated- based on the exact positions of the additional and the sulfated tyrosyl residue. The tyrosine extended peptide analogue **(Fig. 3)** (4 nmoles) can be monoiodinated using the mild chloramine-T method, previously described ***(37)***. If mild oxidation damages the peptide (containing for instance methionyl residues), it is possible to use the nonoxidative Bolton-Hunter iodination ***(38)***. Subsequent purification on reversed-phase HPLC ensures a high specific radioactivity of the tracer. To evaluate the chromatographic separation of labeled and nonlabeled peptides, 1 ml of the monoiodinated peak fraction is mixed with 10 pmol of the relevant tyrosine-extended peptide and reapplied to the HPLC column as described. Both the radioactivity of the labeled peptides and the immunoreactivity are measured. Using the assumption that iodinated and unlabeled peptides are measured with identical affinity the specific radioactivity of the tracers can be determined by self-displacement ***(39)***. The essence of the described procedure is to ensure monoiodination without oxidative damages to the peptide. High specific radioactivity is then achieved by efficient chromatographic purification.

8. As standard substance for RIA-measurements using antibodies specific for sequence containing a sulfated tyrosyl-residue, it is straightforward to use a peptide corresponding to the hapten decapeptide. If, however, this decapeptide in some way is partly or completely hidden within the structure or conformation of the genuine tyrosyl sulfated protein, or if the antibody requires that epitope has a free N- or C-terminus (**Fig. 3**), it may be necessary to release the hidden epitope by cleavage with proteases that expose the epitope for antibody binding ***(40)***. If the natural occurring tyrosyl sulfated protein or polypeptide is recognized without cleavage, the protein may as well be used as standard- if available in sufficiently pure form.
9. In this example the peptide analyzed are acidic (the sequence of gastrin-17 is: pQGPWLEEEEEAYGWMDF-NH_2) for which reason an anion exchange column is used. Because Tyr sulfation predominantly occurs in acidic regions of proteins and peptides, similar conditions this will often be appropriate. However, it is also possible to use cation exchange chromatography to separate peptide forms or alternatively, if the net charges of the fragments are neutral, the pH of the buffers may be adjusted.

10. α-cyano-4-hydroxycinnamic acid gives a more homogeneous matrix than DHB and generally also a better signal. However, DHB is a cool matrix compared to α-cyano-4-hydroxycinnamic acid, and hence gives a reduced loss of sulfate in general and especially in reflector mode.
11. Four characteristics of sera from the immunized animals have to be examined (1) The *titer* is defined as the antiserum dilution that binds 33% of the 0.5-fmol tracer at equilibrium. (2) *Affinity* is expressed by the "effective" equilibrium constant (K^0eff), determined as the slope of the curve at zero peptide concentration in a Scatchard plot ***(41)***. (3) *Specificity* is determined in percentage as the molar ratio of the concentrations of the sulfated standard peptide, the unsulfated peptide and other related peptides that produce a 50% inhibition of the binding of the tracer. (4) *Homogeneity* of the antibodies with respect to binding kinetics is expressed by the Sips index ***(42)***. An index of 1 indicates homogeneity of both the tracer and the antiserum in the binding, otherwise seen only for monoclonal antibodies ***(21)***. The ability of the peptides to displace tracers from the antisera may be tested in peptide concentrations of 0, 3, 10, 30, 100, 1000, 10 000, and 100 000 pmol/L.
12. Samples in HPLC buffers are preferable (0.1% TFA in 30% acetonitrile is ideal for MALDITOF). Salt and buffer concentrations should be kept as low as possible. Volatile buffers may be removed in a vacuum centrifuge and the dried sample redissolved in 0.1% TFA/30% acetonitrile. Most detergents, especially SDS, will completely abolish the signal.
13. The gradient should be chosen to give a good separation of peptides. The tyrosine sulfate containing peptides are increasingly suppressed as more peptides are eluted simultaneously. This results in higher risk of missing a tyrosine sulfated peptide in the neutral loss scanning procedure.
14. Note that the sulfate group will be completely lost during MS/MS and the spectrum will show the fragmentation pattern of the desulfated peptide, whereas the precursor ion is that of the sulfated peptide. This constitutes a problem to the general search engines, which are dependent on intact fragment ions of modified peptides to do correct annotation. Therefore manually annotation has to be applied or the parent ion mass must be altered before search.
15. It is our experience that the arylsulfatase treatment is tricky and sometimes very inefficient. We therefore recommend that experiments with negative outcome are repeated and, whenever possible, the inclusion of a positive control peptide with the experiments.

Analysis of Protein Palmitoylation by Metabolic Radiolabeling Methods

Katherine H. Pedone, Leah S. Bernstein, Maurine E. Linder, and John R. Hepler

1. Introduction

Many eukaryotic signaling proteins are modified by the covalent attachment of long-chain lipids. These highly hydrophobic molecules bind target proteins and facilitate interaction with cellular membranes, lipid molecules and other proteins. Generally, there are three classes of lipids that modify target proteins: myristate, isoprenoids and palmitate (for reviews, *see* ***refs. 1,2***). Myristate, a 14-carbon saturated fatty acid, binds proteins at N-terminal glycine residues via an amide linkage. This usually occurs cotranslationally after removal of the initiating methionine, although it also can occur after proteolytic cleavage and exposure of an internal glycine. Long-chain isoprenoid lipids, including farnesyl and geranylgeranyl groups, modify proteins posttranslationally and attach via a thioether linkage to C-terminal cysteine residues. Palmitate is a 16-carbon saturated fatty acid that modifies proteins posttranslationally through thioester incorporation at cysteines. Palmitate also can modify proteins at additional sites and by alternative mechanisms, as in proteins palmitoylated at serine and threonine residues via oxyester linkages and by amide-linked N-terminal cysteines and glycines. In addition, other fatty acid species form thioester linkages with proteins. For these reasons, the general term for protein lipid modification by thioester attachment is *thioacylation*, or *S-acylation*, and the term *palmitoylation* refers specifically to protein modification by palmitate. Proteins that undergo palmitoylation by thioester attachment at cysteine residues, or *S-palmitoylation*, represent the majority of protein targets of palmitoylation. This chapter will focus on methods for identifying protein substrates for thioester incorporation of palmitate.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

A wide range of proteins become palmitoylated, including intracellular signaling proteins, transmembrane enzymes, secreted morphogens and cell surface receptors. Although the precise role of palmitoylation has proven difficult to discern, the modification has well-described pleiotropic effects on protein function. The common feature shared by all palmitoylated proteins is the capacity for interaction with cellular membranes. The extended hydrocarbon chain of the palmitate group acts as a stable membrane attachment point. This is particularly important for peripheral membrane proteins that otherwise are inherently soluble. The palmitate groups have high affinity for the membrane microdomain structures called lipid rafts in particular, and modification by palmitate is thought to target proteins to these membrane regions for selective protein interactions and signaling purposes. Preventing protein palmitoylation by point mutation or pharmacologic inhibition can exclude proteins from lipid rafts, impair biological activity and has effects on protein-protein interactions, protein stability and subcellular trafficking. For comprehensive reviews of protein palmitoylation, *see* ***refs. 3–5***.

Protein palmitoylation is an enzyme-regulated process that differs from other types of lipid modifications by its reversible nature. Both myristoylation and prenylation are considered stable modifications for the lifetime of the protein, but some palmitoylated proteins exhibit measurable half-lives for the lipid modification. Some intracellular signaling proteins can undergo multiple cycles of depalmitoylation followed by reloading with fresh palmitate. Guanine nucleotide-regulated proteins like Ras and heterotrimeric Gα protein subunits are examples of palmitoylated proteins that dynamically incorporate palmitate during signaling events. The rate of palmitate turnover on these proteins is enhanced dramatically by pharmacologic stimulation of cell surface receptors or direct protein activation (reviewed in ***ref. 6***). For this reason, reversible attachment of palmitate to signaling proteins is thought to be a regulatory mechanism for controlling biological activity of the targeted proteins. Two classes of enzymes that regulate this process have been identified: protein acyltransferases (PATs) catalyze the transfer of palmitate from an intracellular donor such as palmitoyl-coenzyme A to a protein substrate, and protein thioesterases (PTEs) control removal of the lipid. For detailed information on these enzymes and the molecular mechanisms that underlie protein palmitoylation, *see* ***ref. 7***.

The protocols presented in this chapter outline how to assess if a protein is palmitoylated in living cells. The general approach is to incubate cells expressing the protein of interest with [^{3}H]palmitate, isolate the protein from the cells by immunoprecipitation, and use SDS-PAGE and fluorography to determine whether it incorporated radioactive palmitate. In some cases, palmitate may be incorporated into serine or threonine residues through an oxyester linkage, thus it is necessary to verify that a labeled protein is a result of authentic, thioester-linked lipid. This

is accomplished by treatment of the gel containing the labeled proteins with neutral hydroxylamine, which hydrolyzes only thioester-linked lipids. This method also is useful for analysis of proteins that have an N-terminal glycine to discern [^{3}H]palmitate incorporation from incorporated [^{3}H]myristate, metabolically converted from the [^{3}H]palmitate. Identity of the attached fatty acid is confirmed by cleaving thioester-linked fatty acids with base. The fatty acids are then extracted from the hydrolysate and analyzed by HPLC or TLC.

The methods described here for palmitoylation analysis by metabolic radiolabeling and fluorography have many advantages. The general experimental techniques are basic and commonly employed in labs utilizing cell culture systems. The specific methods are straightforward and require standard laboratory equipment and few reagents. The primary limitation of this approach is that it only provides a qualitative measure of palmitoylation. The stoichiometry of palmitate incorporation in a protein substrate cannot be determined using these methods. Other methods are available for quantitative analysis of protein palmitoylation. A newly developed technique called fatty acyl exchange labeling is a sensitive and quantitative approach to evaluating protein palmitoylation. In this method, palmitate molecules are cleaved from the modified protein by treatment with neutral hydroxylamine, and the resulting free sulfhydryl groups are coordinated with radiolabeled, thiol-specific reagents like [^{3}H]N-ethylmaleimide (NEM) ***(8)***. This approach also can be adapted for use with non-radioactive (e.g. biotin-conjugated) reagents to bind available cysteine residues. Other methods for analyzing protein palmitoylation include mass spectrometry and in vitro palmitoylation assays with purified and partially purified PATs. These methods are described in more detail with good discussion on advantages and limitations of the techniques, particularly for fatty acyl exchange labeling, in reference ***(8)***.

Once it is established that a protein is palmitoylated, the site(s) for palmitate attachment can be determined by mutation of cysteines to alanine or serine and the mutant protein assayed for loss of palmitoylation. There is no known consensus sequence for palmitate incorporation, so every cysteine on the surface of a protein should be considered a candidate site for palmitoylation. For a review of some shared sequence motifs in palmitoylated proteins, see reference ***(6)***. Proteins that incorporate palmitate at more than one site may contain a primary cysteine, where palmitoylation is required prior to incorporation at other sites within the protein. For this reason, it is important to design both individual and multi-site cysteine mutants to properly map the sites and/or sequence requirements for palmitate incorporation. For our studies, we use the PCR-based QuikChange® Site-Directed Mutagenesis Kit from Stratagene for creating individual and combination cysteine-to-serine point mutations in our proteins of interest (*see* **Fig. 1**). It is important to note that site-directed mutagenesis is an effective way to establish the dependence of the modification on a specific amino acid

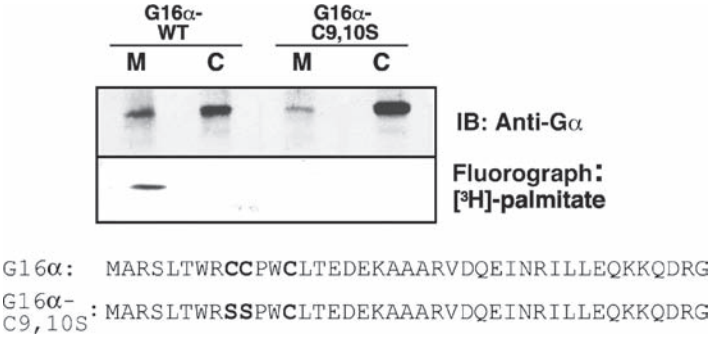

Fig. 1. Palmitoylation of G16α at N-terminal cysteines determined by metabolic radiolabeling analysis combined with site-directed mutagenesis. Top, upper panel: Immunoblot analysis of G16α-EE wild type (WT) and C9,10S protein immunoprecipitated (anti-EE antibody) from membrane (M) and cytosol (C) fractions of transfected HEK293 cells. Immunoblot analysis was performed with a Gq-family-specific antibody (Z811) kindly provided by Dr. Paul Sternweis (UT Southwestern Medical Center, Dallas, TX). Top, lower panel: Fluorography of G16α-EE WT and C9,10S protein immunoprecipitated from fractionated cells as described above. Exposure time was 56 days at −80°C. Bottom: Sequence alignments of the first 41 amino acids of G16α WT and C9,10S. Cysteine residues for putative palmitoylation and selected cysteine-to-serine mutations are indicated in bold type. Cysteine-to-serine mutations were generated using QuikChange® Site-Directed Mutagenesis kit from Stratagene (cat. no. 200518). (Reproduced from ref. 14 with permission of American Society for Biochemistry and Molecular Biology).

residue. However, definitive proof of site-specific modification requires isolation and identification of the acylated peptide by mass spectrometry.

To successfully perform the techniques described in this chapter, several general considerations should be made. First, specific antibodies are required in order to immunoprecipitate the expressed protein. Since it often is difficult to produce antibodies against proteins directly, epitope-tagged versions of proteins can be engineered. In this chapter, we describe palmitoylation analysis of a G protein, G16α, that contains an internal glutamate-glutamate (EE) epitope tag. Other convenient epitopes can be used instead.

Second, sufficient quantities of protein need to be expressed in order to produce a [^{3}H]-labeled signal. Sf9 insect cells have provided an excellent expression system for palmitoylation studies, particularly for heterotrimeric G protein alpha subunits (Gα) ***(9)***. The primary advantage of insect cells is that infection with recombinant baculovirus produces relatively high levels of heterologous protein expression. Because they are eukaryotic cells, Sf9 contain the cellular enzyme machinery to modify expressed proteins. Detailed protocols for radiolabeling of Sf9 cells and for analysis of lipid modifications can be found in ***ref. 10***.

Although Sf9 cells have proven to be a good model system for palmitoylation studies of Gα proteins, some mammalian proteins may be processed or regulated inappropriately in an insect expression system. Subtle processing differences can have significant effects on palmitate incorporation into the protein. While it is desirable to analyze palmitoylation of any protein in a native system, often proteins are difficult to detect in the endogenous cells or tissues. In this chapter, we describe methods for analyzing palmitoylation of recombinant proteins heterologously expressed in a mammalian cell line. These methods have been used regularly by our labs to evaluate palmitoylation of various G protein subunits and protein Regulators of G Protein Signaling (RGS proteins) ***(9,11–14)***. In this chapter, our example protein is G16α, a G protein alpha subunit from the Gq family of heterotrimeric G proteins. We recently showed that G16α is posttranslationally modified by palmitate and that at least two of three cysteine residues in the N-terminus of the protein are essential for palmitoylation (**Fig. 1**) ***(14)***. We used HEK293 cells for our studies, although COS-7, CHO, or other readily transfectable adherent cell line may be substituted (*see* **Note 1**). Most of the methods described here for mammalian cells are the same or similar to those for Sf9 cells ***(10)***. The differences between the two expression systems are the methods for introduction of the construct into the cells and cell lysis. Since many laboratories are equipped for mammalian cell culture, these protocols are likely to be straightforward to adopt.

2. Materials

2.1. Measuring Palmitate Incorporation into Recombinant EE-Tagged G16α Protein in Mammalian Cell Culture Systems

2.1.1. Transfection and Metabolic Labeling of EE-Tagged G16α in Mammalian Cells

1. HEK293 cells (American Type Culture Collection).
2. Transfection-quality G16α-EE plasmid DNA (*see* **Note 2**).
3. Lipofectamine™ 2000 Transfection Reagent (Invitrogen).
4. Opti-MEM® I reduced-serum media (Invitrogen).
5. Complete HEK293 medium: Dulbecco's Modified Eagle's Medium (DMEM; Invitrogen), 10% fetal bovine serum (Atlanta Biologicals), penicillin/streptomycin (CellGro).
6. [^{35}S]methionine wash medium: 95% methionine-free DMEM (Invitrogen, cat. no. 21013-024), 5% DMEM, 2.5% dialyzed fetal bovine serum (Invitrogen).
7. [^{35}S]methionine labeling medium: 95% methionine-free DMEM, 5% DMEM, 2.5% dialyzed fetal bovine serum, 1 m*M* sodium pyruvate (Invitrogen), 100 μCi/mL L-[^{35}S]methionine (>1000Ci/mmol) (Amersham Biosciences). Aliquot the [^{35}S]methionine and store at −80°C. Make media fresh before use.

8. [^{3}H]palmitate labeling medium: 1 mCi/mL [^{3}H]palmitate ([9,10-^{3}H]-Palmitic Acid (31 Ci/mmol), (PerkinElmer Life and Analytical Sciences), 1% DMSO, 2.5% fetal bovine serum, 1 m*M* sodium pyruvate, 1 m*M* non-essential amino acids (Invitrogen). Make fresh before use (see **Note 3**).
9. Nitrogen gas.

2.1.2. Subcellular Fractionation

1. Potter-Elvehjem tissue grinders with polytetrafluoroethylene (PTFE)-coated pestle, 2 mL capacity, 0.1–0.15 mm clearance (Wheaton Potter-Elvehjem Tissue Grinder, Thermo Fisher Scientific).
2. Ice-cold phosphate-buffered saline (PBS).
3. Hypotonic lysis buffer: 50 m*M* HEPES, pH 8.0, 1 m*M* EDTA, 1 m*M* DTT, protease inhibitors (2 µg/mL aprotinin, 1 µg/mL leupeptin, 100 µ*M* phenylmethylsulfonyl fluoride (PMSF)). Add DTT and protease inhibitors just before use.
4. 2X isotonic buffer: 50 m*M* HEPES, pH8.0, 10 m*M* $MgCl_2$, 300 m*M* NaCl, 1 m*M* EDTA, 500 m*M* sucrose, protease inhibitors (4 µg/mL aprotinin, 2 µg/mL leupeptin, 200 µ*M* PMSF). Add protease inhibitors just before use.
5. 1.5 mL capacity microfuge tubes for high-speed centrifugation (Microfuge Tube Polyallomer, Beckman).
6. 2 mL capacity microfuge tubes.
7. 1X Immunoprecipitation (IP) buffer: 50 m*M* HEPES, pH8.0, 5 m*M* $MgCl_2$, 150 m*M* NaCl, 1 m*M* EDTA, 250 m*M* sucrose, protease inhibitors (2 µg/mL aprotinin, 1 µg/mL leupeptin, 100 µ*M* PMSF). Add protease inhibitors just before use.
8. IP buffer with 4% DβM: 4% *n*-dodecyl-β-D-maltoside (DβM; Calbiochem) in 1X IP buffer. DβM is used at a final concentration of 2% for extraction of membrane proteins.

2.1.3. Immunoprecipitation of labeled protein, SDS-PAGE and fluorography

1. Anti-GLU-GLU (EE) monoclonal antibody (Covance).
2. Protein A Sepharose (nProtein A Sepharose® 4 Fast Flow, GE Healthcare).
3. Bovine serum albumin (Sigma).
4. Coomassie blue stain: 30% isopropanol, 10% acetic acid, 0.25% Coomassie brilliant blue R-250.
5. Destain solution: 30% methanol, 10% acetic acid.
6. En^{3}Hance autoradiography enhancer solution (En^{3}Hance™, PerkinElmer Life and Analytical Sciences, cat. no. 6NE9701) (*see* **Note 4**).
7. 2X Laemmli sample buffer: 100 m*M* Tris-HCl pH6.8, 0.5% SDS, 20% glycerol, 0.5% β-mercaptoethanol, 0.004% bromophenol blue. Prepare stocks of 2X Laemmli sample buffer with and without 20 m*M* DTT.

2.2. Hydroxylamine Sensitivity by Thin Layer Chromatography

1. Hydroxylamine solution: 0.5 *M* hydroxylamine hydrochloride (Sigma-Aldrich), pH7.0, in 50% isopropanol. Use concentrated NaOH to pH the solution.
2. 0.5 *M* Tris-HCl, pH7.0, in 50% isopropanol.

2.3. Identification of Fatty Acids on Labeled Protein

1. 13 × 100 mm glass tubes with Teflon-lined caps (Corning, cat. no. 9826-13).
2. HPLC grade methanol, chloroform, acetonitrile, acetic acid.
3. [^{3}H]-fatty acid standards: [^{3}H]palmitate, [^{3}H]myristate, [^{3}H]stearate (Perkin Elmer Life and Analytical Sciences).
4. Nitrogen gas.
5. NaOH.
6. 6N HCl, high grade (Pierce Chemicals).
7. Palmitic acid (Sigma).
8. Trifluoroacetic acid.
9. C:18 reversed-phase thin-layer chromatography plates (Whatman).
10. En^{3}Hance™ Spray Surface Autoradiography Enhancer (Perkin Elmer Life and Analytical Sciences).

3. Methods

3.1. Measuring palmitate incorporation into recombinant G16α-EE protein in mammalian cells

3.1.1. Transfection and metabolic labeling of G16α-EE protein in mammalian cells

This protocol calls for metabolically labeling parallel dishes of transfected cells: one with [^{3}H]palmitate, the counterpart with [^{35}S]methionine. The purpose of labeling cells with [^{35}S]methionine is to control for expression and recovery of the recombinant protein of interest. Alternatively, immunoblot analysis of the protein of interest immunoprecipitated from unlabeled cells may be substituted for radiolabeling with [^{35}S]methionine (**Fig. 1**).

1. Plate 2–10 cm^2 dishes of HEK293 cells so that they will be 85–90% confluent the next day.
2. Transfect HEK293 cells with G16α-EE DNA construct using Lipofectamine™ 2000 Transfection Reagent according to manufacturer's instructions (*see* **Note 5**). Incubate 5 h, 37°C, 5% CO_2/95% air.
3. Replace transfection media with complete media, and allow cells to recover in 37°C incubator overnight (*see* **Note 6**).
4. Approximately 36 h after beginning the transfection, label one plate with [^{35}S] methionine: wash once in [^{35}S]methionine wash media, then add labeling media. Incubate overnight in the 37°C incubator.

5. The following day, label the second plate with [^{3}H]palmitate: wash cells once with pre-warmed DMEM, then incubate for 1–2 h in [^{3}H]palmitate labeling medium (*see* **Note 7**).
6. Harvest each plate 48 h post-transfection: using a clean razor blade or rubber policeman, scrape cells into separate conical tubes on ice.
7. Collect cells by centrifugation at 500 *g*, 4°C for 4 min.
8. Aspirate media into a receptacle for radioactive liquids. Resuspend cells in 5 mL ice-cold PBS to wash away residual media.
9. Collect cells by centrifugation at 500 *g*, 4°C for 4 min.

3.1.2. Subcellular Fractionation (*see* **Note 8**)

1. Aspirate PBS, and resuspend each cell pellet in 0.5 mL hypotonic lysis buffer. Transfer cells to separate Potter-Elvehjem tissue grinders on ice.
2. Homogenize cells with 30–50 strokes, and transfer lysates to separate 1.5 mL microfuge tubes on ice (*see* **Note 9**).
3. Add 0.5 mL 2X isotonic buffer to each tube to restore normal osmotic pressure.
4. Centrifuge lysates at 600 *g*, 4°C for 10 min to collect nuclei, unbroken cells, and plasma membrane sheets.
5. Transfer the supernatants to Beckman polyallomer microfuge tubes. Spin in TLA100.3 rotor with adaptors, 100,000 *g*, 4°C for 30 min.
6. Remove supernatants from the high-speed spin (cytosol) to clean 2 mL microfuge tubes. Add 1 mL IP buffer with 4% DβM to each for a final detergent concentration of 2% DβM.
7. Resuspend pellets (membranes) in 0.5 mL IP buffer (without detergent) in the polyallomer tubes, and transfer to Potter-Elvehjem tissue grinders on ice. Lightly homogenize the membrane pellets (15 strokes).
8. Add 0.5 mL IP buffer with 4% DβM to each membrane sample for a final detergent concentration of 2% DβM.
9. Solublize membranes by incubating at 4°C for 3 h on an end-over-end rocker (*see* **Note 10**). Incubate cytosol samples similarly for the same duration.
10. Pellet the insoluble material from membrane samples by high-speed centrifugation at 100,000 *g*, 4°C for 30 min.
11. Remove the supernatants (membrane extract) to clean microfuge tubes (*see* **Note 11**).

3.1.3. Immunoprecipitation of Labeled Protein, SDS-PAGE, and Fluorography (*see* **Note 12**)

1. Preblock membrane extracts and cytosol samples in 0.7 mg/mL BSA solution and pre-absorb with 50 µL Protein A Sepharose. Incubate with end-over-end rotation, 4°C from 30 min to 2 h.
2. Add 6–7 µL anti-EE antibody to each sample of membrane extracts and cytosol. Incubate at 4°C at least 3 h, or overnight if convenient, rotating end-over-end.
3. Collect sepharose beads and immunoprecipitated protein complexes by centrifugation: 200 *g*, 4°C for 1 min.
4. Aspirate supernatant, and resuspend sepharose beads in 1 mL IP buffer containing 0.2% DβM.

5. Repeat spin: 200 *g*, 4°C for 1 min. Wash sepharose beads two more times in the same fashion.
6. Suspend the washed beads in 60 µL 2X Laemmli sample buffer without DTT (*see* **Note 13**).
7. Boil samples 1 min, then spin 1 min in microcentrifuge at maximal speed. Load the supernatant samples on SDS-PAGE gels and run (*see* **Note 14**).
8. Stain gels with Coomassie blue stain, rocking, 30 min.
9. Incubate in several changes of destain solution, rocking, until proteins are visualized on the gel (*see* **Note 15**).
10. Soak gels in En^{3}Hance™ autoradiography enhancer solution, 60 min, with gentle rocking.
11. Wash gels thoroughly in a large volume of cold water for 30 min with gentle rocking.
12. Dry down the gels to completion on a vacuum dryer, 60°C.
13. Expose the gels to film in a cassette. Store the cassette at −80°C for at least 3 days to visualize the [^{35}S]-labeled bands. Replace with new film and expose for 1–4 weeks to visualize [^{3}H]-labeled bands (*see* **Note 16**).

3.2. Hydroxylamine Sensitivity of [^{3}H]palmitate-Labeled Proteins (*see* Note 17; Fig. 2)

1. Transfect cells, label and fractionate cells as in **steps 3.1.1** and **3.1.2** (*see* **Note 18**).
2. Immunoprecipitate EE-tagged protein from cells as outlined in 3.1.3, steps 1–6 above.
3. Boil samples 1 min, then spin 1 min in microcentrifuge at maximal speed. Divide each sample in half, and run duplicate gels of each.
4. Fix gels by incubating in destain solution for 30 min, rocking.

Fig. 2. Confirmation of thioester linkage of [3H]palmitate by hydroxylamine cleavage. Fluorography of the radiolabeled G16α N-terminus with and without neutral hydroxylamine treatment. A peptide representing the N-terminal domain of G16α (amino acids 1–41) was expressed in HEK_{293} cells as a FLAG-tagged GFP fusion protein. The fusion protein was immunoprecipitated (Anti-FLAG M2 Affinity Gel, Sigma, cat. no. A_{2220}) from transfected membranes of HEK_{293} cells metabolically radiolabeled with either [^{35}S]methionine or [^{3}H] palmitate. Immunoprecipitated proteins were treated with 0.5 M Tris, pH7.0 (left panel) or 0.5 M hydroxylamine, pH7.0 (NH_2OH, right panel) and prepared for fluorographic analysis. Exposure time was 2 days at −80°C for [^{35}S]-signals, 5 days for [^{3}H]-signals. (Reproduced from ***ref. 14*** with permission of American Society for Biochemistry and Molecular Biology.)

5. Soak one gel in fresh 0.5 *M* hydroxylamine solution (pH7.0) for 12–18 hours (overnight). As a control, soak the other gel in 0.5 *M* Tris (pH7.0) in 50% isopropanol. Replace the solutions at least once after approximately one h. The gels will shrink as they are dehydrated by the isopropanol.
6. Wash each gel 4 times in 50% isopropanol over a period of 48 h.
7. Soak gels in Coomassie stain, then destain solutions as above to visualize precipitated proteins. The gels will rehydrate and return to original size during this step.
8. Soak gels in En^{3}Hance™ autoradiography enhancer solution for 60 min with gentle rocking.
9. Dry down the gels on a vacuum dryer, 60°C, and expose to film at −80°C.

3.3. Identification of Fatty Acids on Labeled Protein

3.3.1. Base Hydrolysis and Extraction of Thioester-Linked Fatty Acids

1. Transfect cells, label, and fractionate cells as in **steps 3.1.1** and **3.1.2**.
2. Immunoprecipitate protein from cells as outlined in **Subheading 3.1.3, steps 1–6**.
3. Boil samples 1 min, then pellet for 1 min in microcentrifuge at maximal speed. Divide each sample in half and run duplicate SDS-PAGE gels.
4. Stain gels with Coomassie blue stain, rocking, 30 min.
5. Incubate in several changes of destain solution until proteins are visualized on the gel.
6. Excise the immunoprecipitated protein bands from membranes and cytosol with a razor blade or scalpel, keeping gel slices equal in size. Also excise three gel slices from unused portions of the gel to run with standards.
7. Place gel slices in air-tight, screw-cap 13 × 100 mm glass tubes. Wash gel slices overnight with five changes of 50% methanol.
8. Remove methanol with Pasteur pipet. To the blank gel slices, add [^{3}H]myristate, [^{3}H]stearate, or [^{3}H]palmitate standards, 25,000–50,000 dpm per sample. Dry gel slices under a nitrogen stream.
9. To hydrolyze thioester-linked lipids, resuspend gel slices in 0.7 mL 1.5 *M* NaOH. Flush tubes with nitrogen and cap. Incubate 3 h, 37°C, mixing periodically.
10. Acidify the solutions to pH1-2 by adding 6N (high-grade) HCl. This typically requires 100–200 µL of acid.
11. To extract the released fatty acids, add 3.75 volumes of chloroform:methanol (1:2 v/v) in a fume hood. This results in chloroform:methanol:aqueous 1.25:2.5:1 v/v/v. Incubate 10 min, room temperature with occasional mixing.
12. To separate the fatty acids from water-soluble components and gel slices, add 1.25 volumes (of original aqueous volume) of chloroform and 1.25 volumes of water.
13. Vortex tubes, then centrifuge at 1,000 rpm at room temperature. This will separate the mixture into an upper aqueous phase and a lower organic phase, with the gel slice in between.
14. Remove the bottom phase containing fatty acids by bubbling a Pasteur pipette through the aqueous phase to the bottom of the tube. Transfer to new screw-cap tubes.
15. To extract remaining fatty acids, add the same amount of chloroform as in **step 12**. Incubate 5 min, room temperature with occasional mixing. Centrifuge 1,000 rpm and remove bottom phase as before. Combine with first extracts.

16. Dry down extracts under nitrogen.
17. Add 0.5 mL chloroform and 40 µg cold palmitic acid as a carrier. Flush tubes with nitrogen and store at −20°C.

3.3.2. Thin-Layer Chromatographic Analysis of Hydrolyzed Lipids

1. Count a small volume of each sample (50 µL) in scintillation vials to determine how much sample to load. Let the chloroform dry before counting or it will quench.
2. Spot equivalent amounts of each sample (25,000–50,000 dpm) on a reverse-phase C:18 TLC plate. Also spot equivalent standards.
3. Resolve the extracts using 90% acetonitrile/10% acetic acid in a chromatography tank. This should take 20–30 min.
4. After the solvent has migrated to the top, remove plates and allow them to dry thoroughly in the hood.
5. Spray plates with En^{3}Hance™ spray. Let plates dry slightly and expose to film at −80°C for 5–10 h. Re-expose for 24–48 h if signal is undetectable.

4. Notes

1. The protocols for heterologous protein expression, cell lysis and fractionation (**Subheadings 3.1.1** and **3.1.2**) are described here specifically for mammalian cells. The remainder of the methods are performed the same independent of eukaryotic cell type used.
2. We use Midi- or Maxi-prep kits from Qiagen to produce DNA for transfections. Follow the manufacturer's protocols. Our G16α-EE DNA plasmid came from UMR cDNA Resource Center (www.cdna.org; cat. no. GNA1500000). Many other DNA constructs for mediators of G protein signaling (GPCRs, G proteins, RGS proteins) also are available from UMR in epitope-tagged and untagged forms.
3. [^{3}H]palmitate is supplied as a solution in ethanol and cannot be added directly to media. First, measure the appropriate amount into a glass tube and evaporate the ethanol under a nitrogen stream. When the palmitate is dry, it will appear as a light film on the bottom of the tube. Resuspend the palmitate first in DMSO (for final concentration of 1% in palmitate labeling media; volume will depend on final volume of labeling media), then add the fetal bovine serum (final concentration 2.5%). Add the remaining reagents to the dissolved [^{3}H]palmitate.
4. We have successfully used a homemade version of fluorographic reagent: 1 *M* sodium salicylate in 15% methanol. Store in a dark bottle.
5. Detailed instructions for optimizing transfection conditions with Lipofectamine™ 2000 Transfection Reagent are provided by the manufacturer. The amount of DNA and lipofectamine used per dish can vary depending on the protein to be expressed.

6. The optimal time to harvest transfected cells for peak protein expression may vary depending on the protein. In this protocol, cells are collected 48 h post-transfection. For shorter post-transfection incubations, labeling should be started at the appropriate time so that [^{35}S]methionine labeling media is incubated overnight and [^{3}H]palmitate media is incubated for 1–2 h.
7. Some proteins undergo turnover of the palmitate modification. For example, the half-life for palmitate on H-Ras has been measured as approximately 2.4 h; however, the half-life decreases to 90 min for ectopically expressed, activated H-Ras, suggesting that G protein activation is linked to palmitate turnover ***(15)***. The propensity for palmitate turnover should be considered when establishing a time period for metabolic labeling with [^{3}H]palmitate. A 1–2 h labeling period with high concentrations of [^{3}H]palmitate as suggested in this protocol is a good starting point. G protein alpha subunit palmitoylation has been detected with labeling periods as short as 15 min ***(16)***.
8. All solutions should be kept cold (4°C), and all samples should be kept on ice during the following steps in order to minimize protein degradation.
9. If using the same Potter-Elvehjem tissue grinder for both [^{35}S]- and [^{3}H]-labeled cells during an experiment, pass the [^{3}H]-labeled samples first to avoid accidental transfer of the higher energy [^{35}S]-signal into the [^{3}H]-labeled samples. Wash out the tissue grinder thoroughly with ethanol to remove trace [^{3}H]-residue. Alternatively, cells may be lysed by another convenient method (e.g. repeated cycles of snap-freezing and quick-thawing).
10. Other buffers may be used to solublize proteins successfully. We found this HEPES-based buffer formulation with 2% DβM detergent to work well for extraction and immunoprecipitation of our Gα proteins with the anti-EE antibody. If a different antibody is used, the buffer may need to be adjusted. Also, a shorter incubation period for membrane extraction may be sufficient for other proteins. Generally, a 1-h extraction period is sufficient to release proteins from membranes prepared at 1 mg/mL membrane protein concentration.
11. At this step, the membrane extracts and cytosol samples may be snap-frozen in liquid nitrogen and stored at −80°C until later use, as limited by the half-life of the [^{35}S]-signal. Frozen samples should be thawed quickly and kept on ice.
12. Immunoprecipitation protocols vary widely. For a review and guide to optimization of immunoprecipitation using different types of antibodies and solid support matrices, see reference ***(17)***. Other protocols may be easily substituted.
13. The thioester linkage for S-palmitoylation is vulnerable to reducing agents such as DTT. For this reason, we exclude DTT from our Laemmli sample buffer for [^{3}H]palmitate-labeled samples. This does not affect migration

of our G proteins on an SDS-polyacrylamide gel, but the same may not be true for other proteins. 20 m*M* DTT may be included in [^{3}H]palmitate-labeled samples if needed, but the lability of the thioester linkage should be considered. Laemmli sample buffer containing 20 m*M* DTT should be used for all other protein samples prepared for SDS-PAGE.

14. Avoid loading sepharose beads onto the SDS-PAGE gel. Thioester-linked fatty acid also is susceptible to prolonged heating. We have found that excluding DTT from the sample buffer and heating for 1 min is sufficient to obtain good resolution of Gα proteins on gels without a substantial loss of radioactive palmitate on the protein.
15. The gel can be left in destain solution overnight if desired.
16. Do not use plastic wrap to cover the gel during exposure as it will block the [^{3}H]-signal. Storage of the cassette at −80°C is essential for the En^{3}Hance™ fluorography reagent to work. Do not use a screen. The [^{35}S]-labeled samples may be visualized within a few days. The [^{3}H]-labeled bands may be detected after one week exposure, but it can take one month or longer, depending on the amount of protein on the gel. Exposure time must be determined empirically.
17. If the membrane-bound protein of interest incorporates [^{3}H]palmitate, further analysis should be done to confirm authentic thioester palmitate attachment. Treatment of the gel containing the [^{3}H]-labeled sample with neutral hydroxylamine should result in the reduction or disappearance of the labeled band. As a control, a duplicate gel is soaked in Tris buffer at the same pH. The [^{3}H]-labeled sample should be visible in this gel. Finally, [^{35}S]methionine-labeled proteins should be run in parallel to control for the loss of protein from the hydroxylamine- and Tris-treated gels during processing. A hydroxylamine-insensitive label can be analyzed as a potential amide-linkage by treating the gels with acid instead. Amide-linked acids are insensitive to hydroxylamine treatment, but are sensitive to acid hydrolysis.
18. The number of cells required for these experiments may vary depending on protein expression and stoichiometry of palmitoylation. Adjust the size and/or number of dishes transfected based on the autoradiograph in **Subheading 3.1**.

Incorporation of Radiolabeled Prenyl Alcohols and Their Analogs into Mammalian Cell Proteins

A Useful Tool for Studying Protein Prenylation

Alberto Corsini, Christopher C. Farnsworth, Paul McGeady, Michael H. Gelb, and John A. Glomset

1. Introduction

Prenylated proteins comprise a diverse family of proteins that are posttranslationally modified by either a farnesyl group or one or more geranylgeranyl groups ***(1–3)***. Recent studies suggest that members of this family are involved in a number of cellular processes, including cell signaling ***(4–6)***, differentiation ***(7–9)***, proliferation ***(10–12)***, cytoskeletal dynamics ***(13–15)***, and endocytic and exocytic transport ***(4,16,17)***. The authors' studies have focused on the role of prenylated proteins in the cell cycle ***(18)***. Exposure of cultured cells to competitive inhibitors (statins) of 3-hydroxy-3-methylglutaryl Coenzyme A (HMG-CoA) reductase not only blocks the biosynthesis of mevalonic acid (MVA), the biosynthetic precursor of both farnesyl and geranylgeranyl groups, but pleiotropically inhibits DNA replication and cell-cycle progression ***(10,18–20)***. Both phenomena can be prevented by the addition of exogenous MVA ***(10,18,19)***. The authors have observed that all-*trans*-geranylgeraniol (GGOH) and, in a few cases, all-*trans*-farnesol (FOH) can prevent the statin-induced inhibition of DNA synthesis ***(21)***. In an effort to understand the biochemical basis of these effects, the authors have developed methods for the labeling and two-dimensional gel analysis of prenylated proteins that should be widely applicable.

Because of the relative diversity of prenylated proteins, it is important to use analytical methods that differentiate between them. A useful approach discussed here is to selectively label farnesylated or geranylgeranylated proteins using [^{3}H] labeled FOH or GGOH ***(22–24)***, followed by one-dimensional

SDS-PAGE or high-resolution twodimensional gel electrophoresis (2DE) of the labeled proteins. Since the enzymes that transfer prenyl groups to proteins utilize the corresponding prenyl alcohol pyrophosphate (FPP or GGPP) as substrate, these prenols are thought to undergo two phosphorylation steps prior to their subsequent utilization ***(2,3)***. The discovery of a GGOH kinase and a geranylgeranyl phosphate kinase in eubacteria ***(25)***, together with the ability of rat liver microsomal and peroxisomal fractions to form FPP, provide additional evidence that these prenol pools serve as a source of lipid precursor for protein prenylation. When proteins are labeled in this way, and are subsequently analyzed by one-dimensional SDS-PAGE, it is possible to distinguish several major bands of radioactivity that correspond to two apparently distinct subsets of proteins: those that incorporate [^{3}H]-FOH and those that incorporate [^{3}H]-GGOH. But when the labeled proteins are analyzed by high-resolution 2DE, the number of radioactive proteins that are observed is at least fivefold greater, and three subsets of prenylated proteins can be identified: one subset of proteins that incorporates only farnesol, a second that incorporates only geranylgeraniol, and a third that can incorporate either prenol.

In this chapter, the advantages of using labeled prenols to dissect the differential effects of FOH and GGOH on cellular function will be presented in the context of studies of the role of prenylated proteins in cell-cycle progression. The ability of mammalian cells to incorporate natural and synthetic prenol analogs (**Fig. 1**) into specific proteins also will be discussed. In **Subheading 4,** some of the advantages and limitations of the methods will be discussed.

2. Materials

2.1. Prenols and Analogs: Synthesis and Labeling

1. All-*trans*-FOH, d^{20} 0.89 g/mL; mevalonic acid lactone; geraniol, d^{20} 0.89 g/mL (Sigma, St. Louis, MO).
2. Tetrahydrofarnesol was a gift from Hoffman la Roche (Basel, Switzerland). A racemic form can be made from farnesyl acetone following the procedure for hexahydro-GGOH (*see* **Subheading 3.1.1.**).
3. All-*trans*-GGOH, d^{20} 0.89 g/mL; all-*trans*-GGOH [1-^{3}H], 50–60 Ci/mmol; all-*trans*-FOH [1-^{3}H], 15–20 Ci/mmol; geraniol [1-^{3}H], 15–20 Ci/mmol (American Radiolabeled Chemicals, St. Louis, MO).
4. Mevalonolactone RS-[5-^{3}H(N)], 35.00 Ci/mmol (NEN, Boston, MA).
5. Charcoal; $LiAlH_4$ powder; MnO_2; $NaBH_4$ powder; triethyl phosphonoacetate; phosphonoacetone; sodium ethoxide (Aldrich, Milwaukee, WI).
6. [^{3}H]-$NaBH_4$ solid, 70 Ci/mmol (Amersham, Arlington Heights, IL).
7. Silica gel 60 (F254) (Merck, Gibbstown, NJ).
8. Aquamix liquid scintillation solution (ICN Radiochemicals, Irvine, CA).

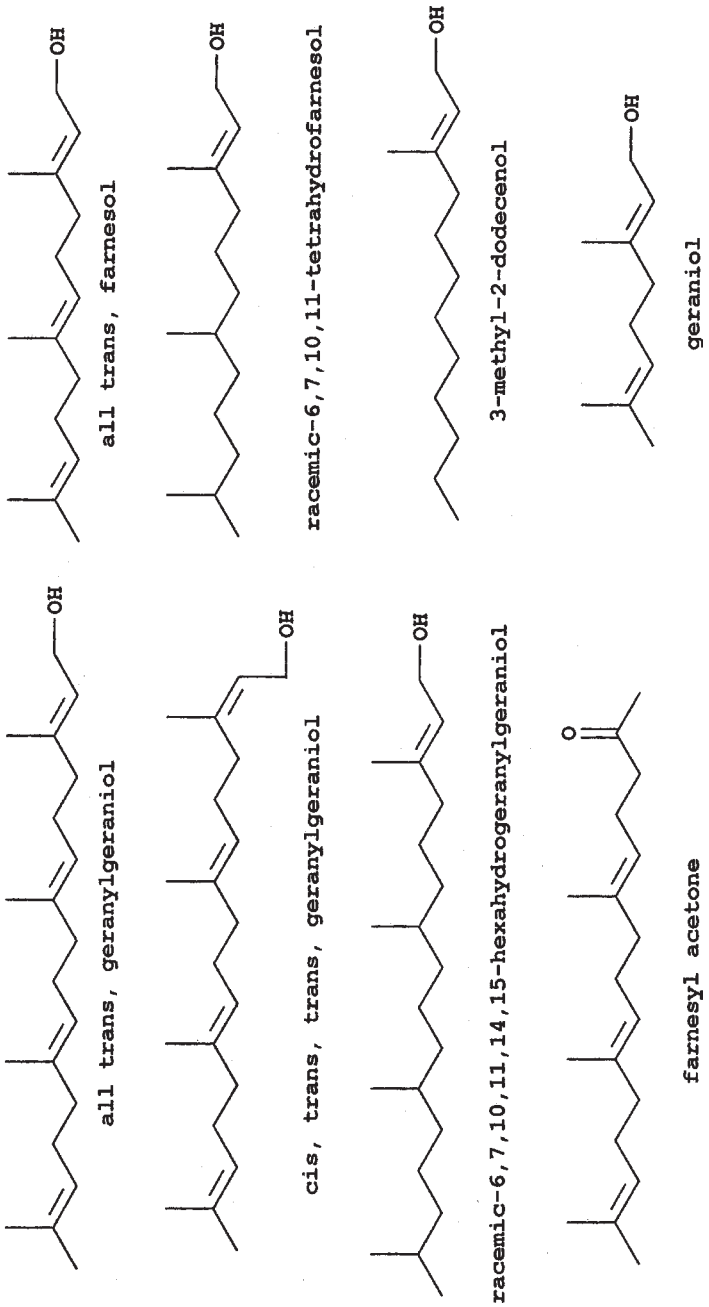

Fig. 1. Structure of the natural and synthetic prenol analogs used in these labeling studies.

2.2. Cell Culture Reagents

1. Dulbecco's modified Eagle media (DMEM) (glucose 4.5 g/L); penicillin (10,000 U/mL)–streptomycin (10 mg/mL); trypsin (0.25% w/v)–1 m*M* ethylenediaminetetraacetate (EDTA); nonessential amino acids (NEAA) solution 10 m*M*; phosphate-buffered saline (PBS) without Ca^{2+} and Mg^{2+}; fetal calf serum (FCS) (Gibco, Grand Island, NY).
2. Disposable culture Petri dishes (100 × 10 mm and 35 × 10 mm) (Corning Glass Works, Corning, NY).
3. Filters, 0.22 µm (Millipore, Bedford, MA).
4. Plasma-derived, bovine serum (PDS) (Irvine Scientific, Santa Ana, CA).
5. Aquasol scintillation cocktail; thymidine [methyl-^{3}H], 2 Ci/mmol] (NEN).
6. Trichloroacetic acid (TCA) (J. T. Baker, Phillipsburg, NJ).
7. Phenylmethylsulfonyl fluoride (PMSF), aprotinin, leupeptin, and pepstatin A (Sigma).
8. Simvastatin in its lactone form (gift from Merck, Sharp and Dohme; Rahway, NJ) is dissolved in 0.1 *M* NaOH (60°C, 3 h), to give the active form. Adjust the pH to 7.4 and the concentration to 50 m*M*, then sterilize by filtration.
9. Swiss 3T3-albino mouse cell line (3T3) were from American Type Culture Collection (ATCC), Rockville, MD.
10. Human skin fibroblasts (HSF) are grown from explants of skin biopsies obtained from healthy individuals. The cells are used between the fifth and fifteenth passages.

2.3. One-Dimensional and Two-Dimensional Gel Electrophoresis

1. SDS, TEMED, ammonium persulfate, mol wt protein standards, glycine, Bradford protein assay kit, heavyweight filter paper, and Bio Gel P6-DG (Bio-Rad, Hercules, CA).
2. Duracryl™ preblended acrylamide solution (30% T, 0.65% C, used for both one-dimensional and 2DE gels) and all other 2DE gel reagents, were obtained from ESA, Chelmsford, MA.
3. Ethylmaleimide, N-[ethyl-1,2-^{3}H] ([^{3}H]-NEM), 57 Ci/mmol (NEN).
4. N-ethylmaleimide (Aldrich).
5. Soybean trypsin inhibitor and SDS-7 mol wt standards used with 2DE gels (Sigma).
6. Amplify and Hyperfilm (Amersham).
7. Reacti-Vials™ (Pierce, Rockford, IL).
8. DNaseI and RNaseA (Worthington Biochem, Freehold, NJ).

3. Methods

3.1. Synthesis and Labeling of Prenols and Analogs

3.1.1. Synthesis of Racemic 6,7,10,11,14,15 Hexahydrogeranylgeraniol

1. This synthesis is outlined in **Fig. 2**. Weigh 10.4 g of farnesyl acetone and 500 mg 10% Pd on charcoal, dissolve in 100 mL methanol and hydrogenate at 50 psi in a Parr

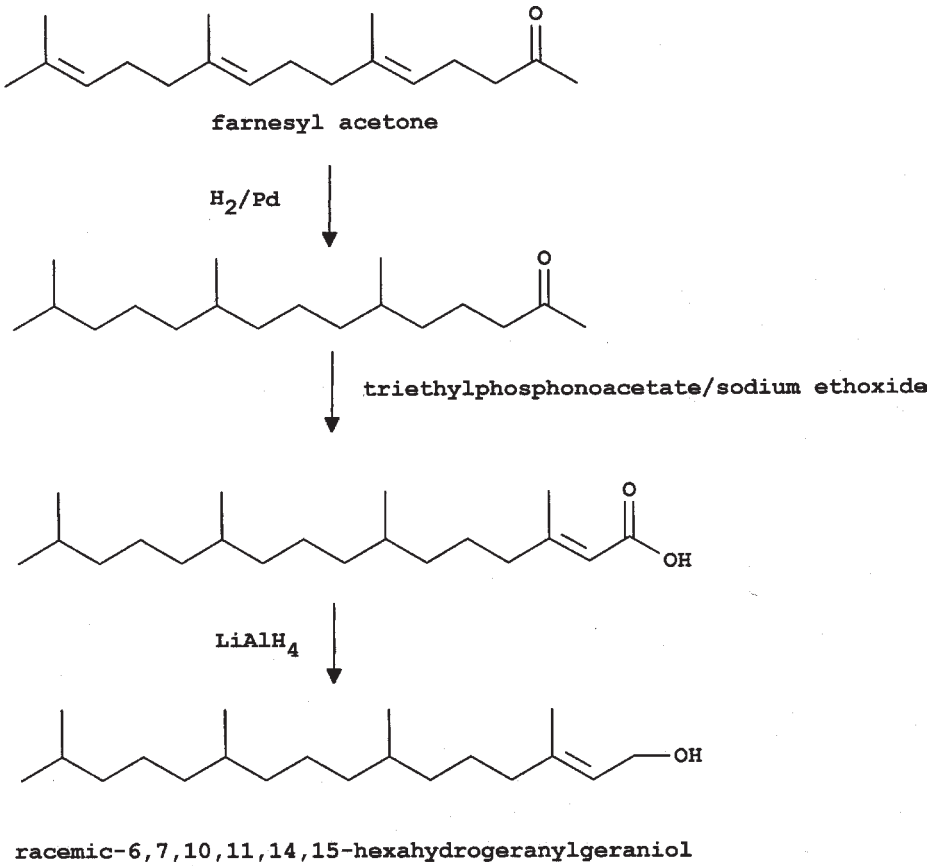

Fig. 2. Schematic for the synthesis of racemic 6,7,10,11,14,15 hexahydro-geranylgeraniol from farnesyl acetone.

hydrogenator for 2 d. Analysis by TLC (7:3 hexanes/diethyl ether) and GC-MS should indicate that the material is fully converted to the hexahydrofarnesyl acetone.

2. Filter the reaction mixture over filter paper, wash with ethanol, rotary-evaporate to dryness, and take up in a small volume of ethanol, then filter over Fluorosil to remove the last traces of catalyst. Concentrate the resultant oil to dryness with a rotary evaporator (yield 8.64 g, 81% recovery).
3. Dissolve 1.56 g hexahydrofarnesyl acetone in 10 g dry dimethylformamide in a round-bottom flask submerged in ice water and equipped with a dropping funnel containing 1.37 mL triethyl phosphonoacetone. Flush the entire apparatus with argon (Ar). Add triethyl phosphonoacetone over the course of 45 min, followed by 2.2 mL 21% (w/w) sodium ethoxide in ethanol, which is added over the course of 1 h.

4. Remove the mixture from the ice water bath and continue to stir for 48 h under Ar. Analysis by TLC (7:3 hexanes/diethyl ether) should show that the majority of the starting material (R_f 0.5) has reacted (final product R_f 0.6).
5. Transfer the reaction mixture to a separatory funnel with hexane, and wash 2× with a NaCl-saturated solution. Dry the organic layer with $MgS0_4$, pass through filter paper, and evaporate the solvent to dryness by rotary evaporation (yield 1.41 g, 72% recovery).
6. Dissolve 0.75 g of the product from the previous step in 10 mL anhydrous diethyl ether in a round-bottom flask equipped with a stir bar. Cool the apparatus by stirring in an ice-water bath.
7. Add 267 mg of $LiAlH_4$, and stir the reaction mixture overnight under Ar. The following day, add 25 mL saturated NH_4Cl and stir the reaction mixture overnight under Ar.
8. Transfer the reaction mixture to a separatory funnel with diethyl ether and wash with water and saturated NaCl solution. Dry the organic phase with $MgSO_4$, filter through filter paper and concentrate to dryness (yield 440 mg, 51% recovery).
9. Purify the material by TLC (7:3 hexanes–diethyl ether, R_f 0.25), or use in the crude state if proceeding on to make radiolabeled material.

3.1.2. Synthesis of cis-Isomers

1. Form the *cis*-isomers of the allylic alcohols from the respective *trans*-alcohols after oxidation to the aldehyde (*see* **Subheading 3.1.3.**). Allow the mixture of *cis*/*trans* isomers to come to equilibrium (approx 36 *cis*:65 *trans*) by standing at room temperature for several days.
2. Purify the *cis*-isomer by TLC (7:3 hexanes/diethyl ether).

3.1.3. Tritium Labeling of Prenols

1. The method for radiolabeling the prenols is outlined in **Fig. 3**. First, oxidize the alcohol to the aldehyde with an excess of MnO_2. Dissolve 44.7 mg of hexahydrogeranylgeraniol in 2 mL benzene, and add 517 mg of MnO_2. Mix the reaction by tissue culture rotator overnight.
2. The next day, allow the reaction mixture to settle, remove the liquid phase, and filter over glass wool to remove any remaining MnO_2. Add diethyl ether to the original reaction vessel, and repeat the process. Combine the two solutions, and concentrate to dryness under a stream of nitrogen.
3. Chromatograph the material by TLC (7:3 hexanes/diethyl ether, R_f 0.35). Two overlapping bands are present corresponding to the *cis*- and *trans*-double bond isomer, the upper band being the *cis*-isomer and the lower band being the *trans*.
4. Remove the lower one-third of the overlapping bands, elute with diethyl ether, dry with $MgSO_4$, and concentrate to dryness (yield 20%). If not used immediately, this material should be stored at −70°C to prevent isomerization of the *trans*-aldehyde to the equilibrium mixture (~30% *cis*).
5. Elute the remaining material, and rechromatograph if desired.
6. Reduce the aldehyde to the alcohol using [^{3}H]$NaBH_4$. Dissolve 2 mg of the aldehyde in 1 mL absolute ethanol, and add 5 µL 14 *N* NH_4OH. Dissolve the [^{3}H]$NaBH_4$

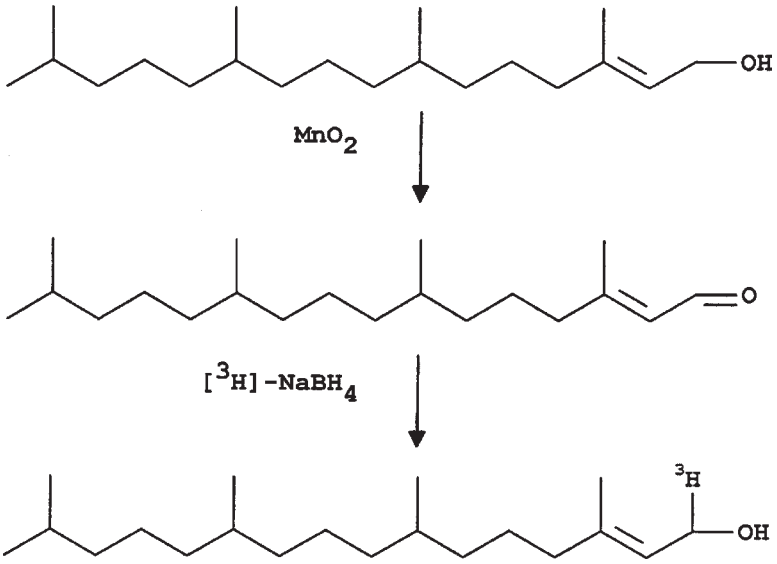

Fig. 3. Schematic for the tritium labeling of naturally occurring prenols.

in ethanol at a concentration of 100 mCi/mL. Add 200 µL of the [^{3}H]$NaBH_4$ to the aldehyde solution, shake the solution, and then leave it vented in the hood for at least 4 h.

7. Concentrate the material to dryness in a gentle stream of Ar, take up in diethyl ether, and place over a column of silica gel overlaid with $MgSO_4$. Purify the material by TLC (7:3 hexanes/diethyl ether) to remove unreacted starting material and the small amount of the *cis*-isomer that is generated during the reaction. Elute the labeled alcohols from the silica using diethyl ether. Dry using a stream of Ar.
8. Dissolve the product in ethanol, and bring to a final concentration of 2.1 m*M*, 2.6 m*M*, 6.5 m*M*, or 0.4 m*M* for labeled 2 *cis*-GGOH, hexahydrogeranylgeraniol, geraniol, and tetrahydrofarnesol, respectively.

3.2. Cell Culture Experiments

1. Grow HSF and 3T3 cells in monolayers, and maintain in 100-mm Petri dishes at 37°C in a humidified atmosphere of 95% air, 5% CO_2 in DMEM, pH 7.4, supplemented with 10% FCS v/v, 1% (v/v) NEAA, penicillin (100 U/mL), and streptomycin (0.1 mg/mL).
2. Dissociate confluent stock cultures with 0.05% trypsin-0.02% EDTA, and seed HSF cells (3×10^5 cells/35-mm Petri dish) or 3T3 cells (2×10^5 cells/35-mm Petri dish) in a medium containing 0.4% FCS or 1% PDS, respectively, to stop cell replication.
3. HSF cells become quiescent within 3 d and the experiments can begin on d 4. For 3T3 cells, change the medium on d 2 and 4; cells become quiescent within 5 d, and the experiments can begin on d 6.

4. At this time, stimulate the cells by replacing the medium with one containing 10% FCS, in the presence or absence of the tested compounds, and continue the incubation as needed at 37°C. Simvastatin is used at a final concentration of 40 µ*M*, when required.
5. Dissolve unlabeled prenols in absolute ethanol and prepare stock solutions as follows:
   a. 2 m*M* all-*trans*-GGOH (the density for this and all other prenols used in these studies is d^{20} 0.89 g/mL). Add 30 µL of the prenol to 49 mL ethanol and store in 1-mL aliquots at −20°C. On the day of the experiment, dilute an aliquot with ethanol (e.g., 300 µL of GGOH to 900 µL of ethanol) to obtain a working solution of 0.5 m*M*.
   b. 4 m*M* all-*trans*-FOH. Add 20 µL of the prenol to 20 mL of ethanol and store in 1-mL aliquots at −20°C. On the day of the experiment, dilute this 1:3 with ethanol to make 1 m*M* working stock solution.
   c. 4 m*M* geraniol. Add 20 µL of the prenol to 28.83 mL ethanol and store in 1-mL aliquots at −20°C. On the day of the experiment, dilute this 1:3 with ethanol to make 1 m*M* working stock solution.
6. Prenols are light-sensitive, so experiments should be performed under dim light, and incubation should be done with Petri dishes covered with foil. Be careful not to exceed 1% (v/v) ethanol in the culture medium.
7. For estimation of DNA synthesis after mitogenic stimulation, incubate cells for 22–24 h at 37°C then change the medium to one containing 10% FCS and 2 µCi/mL [^{3}H]-thymidine and incubate the cells for another 2 h at 37°C ***(19)***. Remove the medium and wash the monolayers once with PBS at room temperature, then add 2 mL of fresh, ice-cold 5% TCA (w/v), and keep the cells at 4°C on ice for at least 10 min. Remove TCA and wash once with 5% TCA, and dissolve the monolayers in 1 mL of 1 *N* NaOH for 15 min. Transfer 500 µL of the cell lysates to a liquid scintillation vial, add 150 µL glacial acetic acid and 5 mL Aquasol, and measure incorporated radioactivity in a liquid scintillation counter **(Table 1; Fig. 4)**.

3.3. Cell Labeling and Prenylated Protein Analysis

3.3.1. Labeling of Proteins with [^{3}H] Farnesol or [^{3}H] Geranylgeraniol and One-Dimensional SDS-PAGE Analysis

1. Dry 9 mCi [^{3}H]-MVA, 500 µCi[^{3}H]-GGOH, or 1 mCi [^{3}H]-FOH, and resuspend in 50 µL ethanol, to bring to the concentration of 4.2 m*M*, 166 µ*M*, or 1.1 m*M*, respectively.
2. Incubate the cells (3 × 35-mm Petri dishes/sample) (*see* **Notes 2–6**) for 20 h at 37°C, with the appropriate labeled isoprenoids. Incubation periods as short as 5 h are sufficient to label most proteins, making it possible to perform time course experiments.
3. To harvest the cells, place the Petri dishes on ice, remove the medium, and wash 3× with ice-cold PBS containing 1 m*M* PMSF. Scrape the cells into 1.5 mL PBS/PMSF per Petri dish, collect the resuspended cells, and centrifuge for 5 min at 200*g*.

Table 1
Mevalonate, Prenols, and Synthetic Analogs Vary in Their Ability to Prevent the Inhibitory Effect of Simvastatin on DNA Synthesisin Cultured Cellsas Measured by Incorporation of [^{3}H]-Thymidine

Cell type	HSF	3T3
Treatment Conditions:	(Reported as % control)	
Simvastatin (S) 40 µ*M*	30	30
S+ mevalonate 100 µ*M*	100	90
S+ all-*trans*-GGOH 5 µ*M*	85	96
S+ 2-*cis*-GGOH 5 µ*M*	29	30
S+ all-*trans*-FOH 10 µ*M*	37	33
S+ geraniol 5 m*M*	29	30
S+ 6,7,10,11,14,15-hexahydro-GGOH 5 µ*M*	34	46
S+ tetrahydro FOH 5 µ*M*	N.A.	36

Experimental conditions: *see* **Subheading 3.2.**
N.A., not assayed.
The mean value of control (100%) without inhibitor was $104 \times 10^3 \pm 3 \times 10^3$ dpm/plate and $187 \times 10^3 \pm 10 \times 10^3$ dpm/plate for HSF and 3T3 cells, respectively.

4. Aspirate the PBS, add 150 µL PBS/PMSF to the cell pellet, and sonicate in a bath sonicator to disrupt the cell pellet. Transfer the resuspended pellet to a 1.5-mL Eppendorf tube.
5. Add 1.3 mL of cold (−20°C) acetone, mix, sonicate, and allow to stand on ice for 15 min. Centrifuge for 5 min (13,000 g at 4°C) to sediment the delipidated proteins. Re-extract the protein pellet twice with 1 mL cold acetone.
6. Add 1 mL chloroform:methanol (2:1), mix, sonicate, and incubate for 30 min at 37°C. Centrifuge for 5 min (13,000 g, 4°C), and collect the lipid extracts.
7. Remove the residual organic solvent by evaporation, and solubilize the delipidated proteins overnight at room temperature in 100 µL 3% SDS, 62.5 m*M* Tris-HCl, pH 6.8.
8. Determine the protein content in 10 µL of sample, according to Lowry ***(27)***.
9. Transfer 10 µL of the sample to a liquid scintillation vial, add 5 mL Aquamix, and measure the incorporated radioactivity.
10. Add 80 µL of sample application buffer to the remainder, and analyze an aliquot (15–80 µg of protein) by one-dimensional SDS-PAGE, according to Laemmli ***(28)***, using a 12% gel.
11. After electrophoresis, wash the gel with destain (methanol–MilliQ water–acetic acid, 25:65:10) for 10 min, then stain the gel (0.1% Coomassie R250 in methanol–MilliQ–acetic acid, 40:50:10) for 20 min, and destain overnight.
12. Treat the gel with Amplify for 30 min in preparation for fluorography. Wash the gel twice with water, dry, and expose to Kodak XOMAT-AR film at −70°C (**Figs. 5** and **6**).

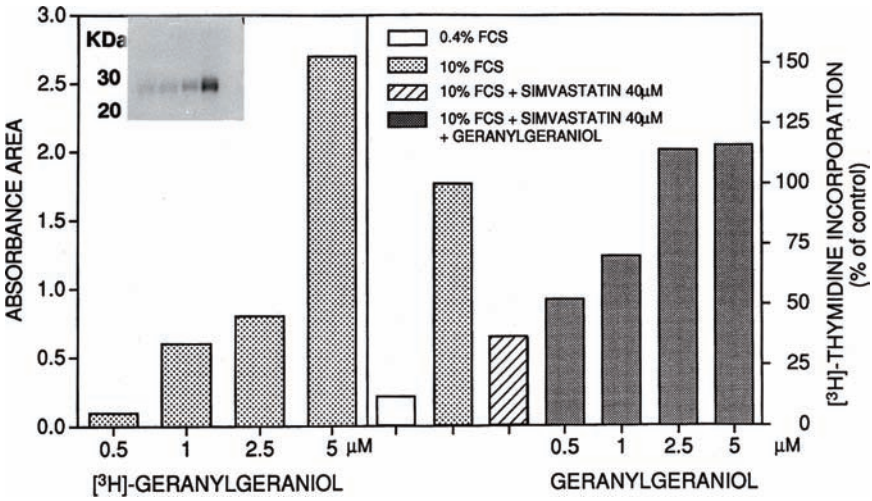

Fig. 4. The ability of simvastatin-treated HSF cells to synthesize DNA was used as a measure of their ability to traverse the cell cycle. HSF cells were seeded at a density of 3×10^5/35-mm dish in medium supplemented with 0.4% FCS, and the cultures were incubated for 72 h. Quiescent cells were incubated for 24 h in fresh medium containing 10% FCS, 40 μ*M* simvastatin, and the indicated concentrations of unlabeled GGOH or [^{3}H]-GGOH (15 Ci/mmol). Control cells received only 10% FCS. **(Left panel)** the labeled cell lysates from each treatment group were analyzed by SDS-PAGE (*see* **Subheading 3.3., step 1**), the gel was fluorographed, and the resulting films analyzed by densitometry. The optical density reported for each treatment group represents the sum of all protein bands between 20 and 30 kDa observed in the corresponding gel lane (*see insert*). An equal amount of cell lysate (15 μg cell protein/lane) was applied to each lane. In the experiment shown, 9×10^3, 12×10^3, 42×10^3, and 142×10^3 cpm/lane were analyzed for the 0.5, 1, 2.5, and 5 μ*M* [^{3}H]-GGOH samples, for lanes left to right respectively. **(Right panel)** In a parallel experiment, DNA synthesis was determined for each treatment group. Cells were incubated as above, but with a corresponding concentration of unlabeled GGOH. After 22 h, [^{3}H]-thymidine (2 μCi/mL) was added to treated and control samples, and the incubation was continued for another 2 h. Nuclear DNA was analyzed for incorporation of [^{3}H]-thymidine (*see* **Subheading 3.2., step 7**). The incorporation of [^{3}H]-thymidine for each treatment group is reported as a percentage of the control. The mean value of control (100%) was $114 \times 10^3 \pm 6 \times 10^3$ dpm/plate.

3.3.2. High-Resolution Two-Dimensional Gel Electrophoresis of Labeled Proteins

1. In 2DE analysis, proteins are first separated on the basis of pI, using isoelectric focusing (IEF), followed by separation on the basis of mol mass. Therefore, differentiation of closely related proteins with similar mol masses is facile ***(29,30)***. Two different IEF methods have been developed for use in high-resolution

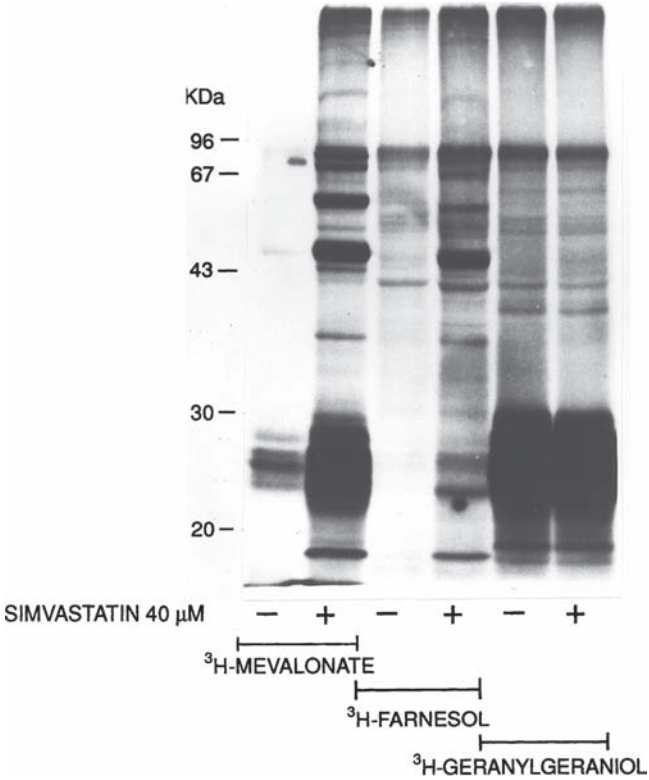

Fig. 5. Metabolic labeling of prenylated proteins in Swiss 3T3 cells after various treatments. Cells were seeded at a density of 2×10^5/dish in medium containing 1% PDS and the cultures incubated for 5 d. Quiescent cells were incubated for 20 h in fresh medium containing 10% FCS, 50 µ*M* [^{3}H]-MVA (35 Ci/mmol), 2.5 µ*M* [^{3}H]-FOH (15 Ci/mmol), or 1 µ*M* [^{3}H] GGOH (60 Ci/mmol), in the presence or absence of 40 µ*M* simvastatin. Cell pellets were delipidated, and equal amounts of cell extracts (80 µg cell protein/lane) were separated by 12% SDS-PAGE and fluorographed. In the experiment shown, 8×10^8, 2.7×10^7, 6×10^7 cpm/lane were analyzed for cells labeled with [^{3}H]-MVA, [^{3}H]-FOH or [^{3}H]-GGOH, respectively.

2DE. The one described here uses carrier ampholytes ***(31–33)*** to obtain the appropriate pH gradient in which sample proteins are focused. This system is available from Genomics Solutions, Chelmsford, MA. The second IEF method uses precast gel strips containing an immobilized pH gradient made by crosslinking ampholytes into a gel matrix ***(29,34)***. This system is available from Amersham Pharmacia, Piscataway, NJ (*see* **Notes 7–10** for additional comments).

2. Prior to analysis by 2DE, cells are labeled as described in **Subheading 3.3.1.**

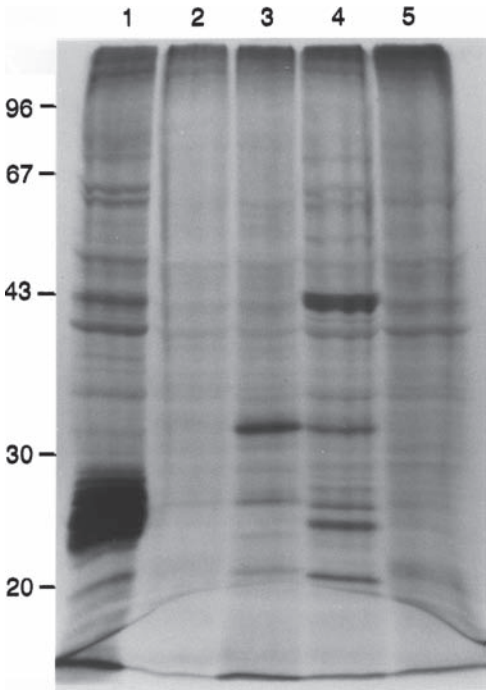

Fig. 6. Metabolic labeling of prenylated proteins in Swiss 3T3 cells after various treatments. Experimental conditions as in **Fig. 5**. Quiescent cells were incubated for 20 h in medium containing 10% FCS, 40 µ*M* simvastatin, and one of the following: lane 1, 5 µ*M* [^{3}H]-all *trans*-GGOH (20 Ci/mmol); lane 2, 5 µ*M* [^{3}H]-*cis, trans*-GGOH (17.5 Ci/mmol); lane 3, 5 µ*M* [^{3}H]-6,7,10,11,14,15 hexahydrogeranylgeraniol (17.5 Ci/mmol); lane 4, 5 µ*M* [^{3}H]-tetrahydrofarnesol (17.5 Ci/mmol); and lane 5, 5 µ*M* [^{3}H]-geraniol (17.5 Ci/mmol). Cell pellets were delipidated, and equal amounts of cell extract (60 µg cell protein/lane) were analyzed by SDS-PAGE on 12% gels, and gels were fluorographed. In the experiment shown, 334×10^3, 197×10^3, 247×10^3, 271×10^3, 285×10^3 cpm/lane were analyzed for lanes 1–5, respectively.

3. On ice, wash each 100-mm dish once with 10 mL PBS, then twice with a solution containing 10 m*M* Tris buffer, pH 7.5, 0.1 m*M* PMSF, and 1.0 µg/mL each of aprotinin, leupeptin, and pepstatin A. Drain for 45 s, and remove residual buffer.
4. Add 240 µL of boiling sample buffer (28 m*M* Tris-HCl, and 22 m*M* Tris base, 0.3% SDS, 200 m*M* DTT, pH 8.0), and collect cells with a cell scraper. Transfer lysate to a 1.5-mL microcentrifuge tube, boil for 5 min, and cool on ice. This and subsequent steps are a modification of methods previously described ***(32,33)***.
5. Add 30 µL (or one-tenth vol) of protein precipitation buffer (24 m*M* Tris base, 476 m*M* Tris-HCl, 50 m*M* $MgCl_2$, 1 mg/mL DNaseI, 0.25 mg/mL RNaseA, pH 8.0) to each cell lysate sample, and incubate on ice for 8 min. Subsequent steps are performed at room temperature, unless otherwise indicated.

6. Add ~6000 cpm of the internal standard, [^{3}H]NEM-labeled soybean trypsin inhibitor (preparation described in **Subheading 3.3.3.**), to each sample (*see* **Note 10**).
7. Add 4 vol of acetone at room temperature to each lysate, and let stand for 20 min. Centrifuge the protein precipitate for 10 min at 16,000 g.
8. Remove the acetone phase, resuspend the precipitate in 800 µL fresh acetone, using a bath sonicator, and centrifuge as above for 5 min. Repeat this wash step once.
9. Let the pellet air dry for 3 min (avoid overdrying), before adding 30 µL of a 1:4 mixture of the SDS buffer (from **Subheading 3.2.2., step 4**) and urea solution (9.9 *M* urea; 4% Triton X-100; 2.2% ampholytes, pH 3–10; 100 m*M* DTT). Warm the sample to 37°C, and bath-sonicate to solubilize the protein (avoid overheating the sample). Centrifuge for 5 min at 16,000 g. Set aside 1 µL for scintillation counting and 1 µL for Bradford protein assay.
10. Apply the sample (26 µL) onto a 1 × 180 mm-tube gel (4.1% T, 0.35% C; ampholyte pH range of 3.0–10.0). Focus for 17.5 h at 1000 V, then for 0.5 h at 2000 V.
11. Extrude the gel from the tube into equilibration buffer (300 m*M* Tris base, 75 m*M* Tris-HCl, 3% SDS, 50 m*M* DTT, and 0.01% bromophenol blue), and incubate it for 2 min before overlaying onto the second dimension SDS-PAGE gel (12.5% T, 0.27% C).
12. Perform SDS-PAGE on large format gels (220 × 240 × 1 mm) for 6 h, using the constant power mode (16 W/gel) in a prechilled tank equipped with Peltier cooling (Genomics Solutions). When five gels are used in this mode, the running buffer temperature will increase 14°C over the course of 6 h when started at 0°C.
13. Fix gels for 1 h in methanol:Milli Q:acetic acid (50:40:10), then stain overnight with a solution containing 0.001% Coomassie R250 in methanol:Milli Q:acetic acid (25:65:10).
14. Immerse each stained gel in 200 mL of Amplify, and incubate for 20 min, with rocking. Without rinsing, dry the treated gel onto heavyweight blotting paper and expose to preflashed Hyperfilm MP for 7–14 d at −70°C. Exposures of >10 wk may be needed to visualize low abundance labeled proteins (**Fig. 7A,B**).

3.3.3. Preparation of the Two-Dimensional Gel Internal Standard, [^{3}H]NEM-Labeled Soybean Trypsin Inhibitor

1. Transfer 100 µL of a freshly prepared solution of 22 m*M* N-ethylmaleimide (NEM) in acetonitrile to a 0.5-mL Reacti-Vial, and add 250 µL [^{3}H]NEM (1 µCi/µL in pentane; 56 Ci/mmol). Mix, and let stand for 2 h uncapped in a fume hood to evaporate the pentane. The final volume will be 110 µL, and the new specific activity will be 95.4 mCi/mmol.
2. Prepare 1 mg/mL solution of soybean trypsin inhibitor (STI) in 50 m*M* Tris, pH 8.5, and reduce the protein by adding DTT (2 m*M*, final concentration). Incubate overnight at 4°C.
3. Remove excess DTT by applying 300 µL of the reduced STI (in six 50-µL aliquots) to six SW rotor equibbed, spin columns, and centrifuge for 4 min at 1000 g in a preequilibrated countertop centrifuge. Prepare spin columns by placing 1 mL

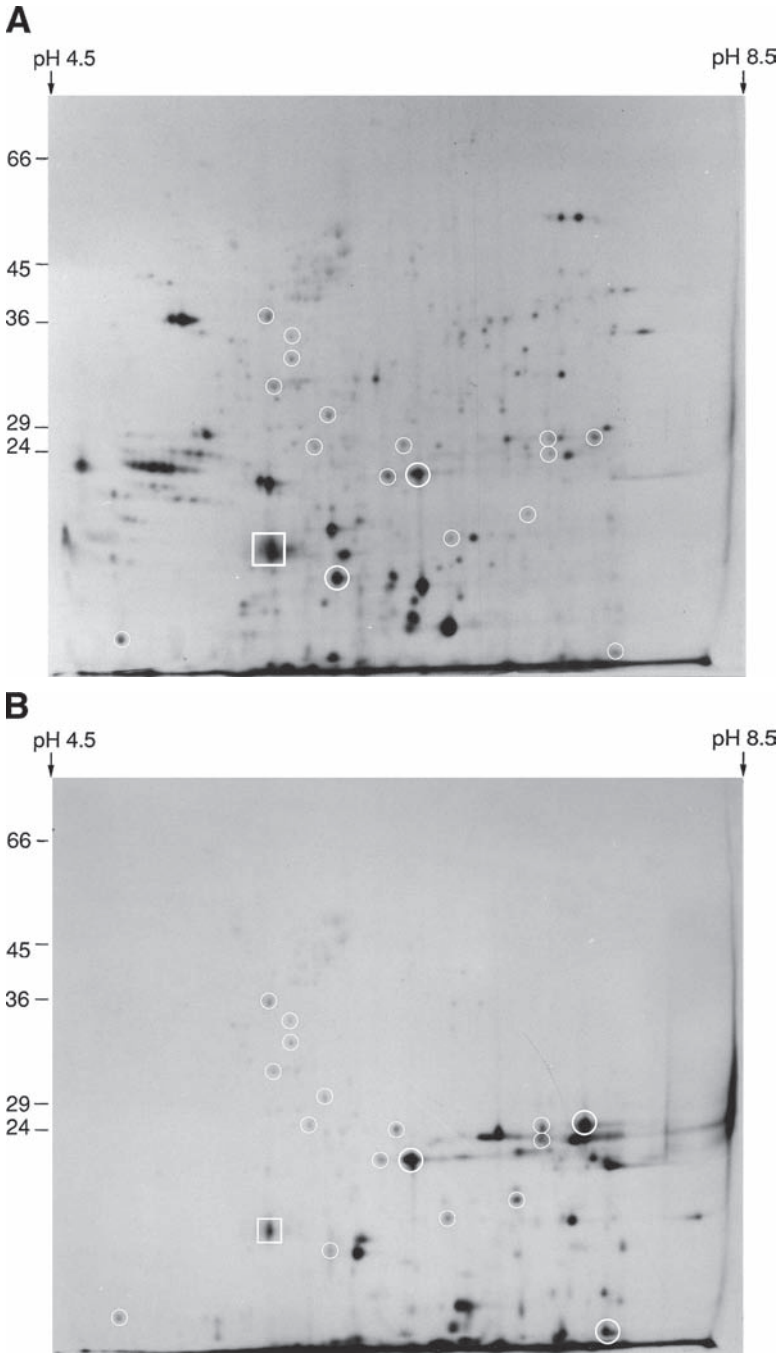

Fig. 7.

bed-volume of Bio Gel P6-DG (previously rehydrated in 50 m*M* Tris HCl, pH 7.5) into a 1-mL plastic tuberculinsyringe equipped with a plug of glass wool, followed by centrifugation for 2 min at 1000 g. (In addition to removing DTT, this step also permits buffer exchange to provide the proper pH required for the NEM reaction step which follows.)

4. Pool the six column eluates (250–300 µL total volume), and add 10–12 µL of the [^{3}H]NEM solution (24 µCi; *see* **Subheading 3.3.3., step 1**). Incubate for 6 h on ice.
5. Separate the [^{3}H]NEM-labeled STI from the unreacted [^{3}H]NEM using five or six fresh, preequibbelated spin columns (*see* **Subheading 3.3.3., step 3**). Pool the column eluates containing the purified [^{3}H]NEM-labeled STI (1 µCi/nmol protein), divide into 30-µL aliquots, and store at −70°C. To make up a working stock solution, dilute the eluate 1:39 with buffer (6000 cpm/5 µL), and use as an internal standard for 2DE gel fluorography (*see* **Subheading 3.3.2., step 6**; *see also* **Note 10**).

4. Notes

1. Since either all-*trans*-GGOH or MVA, but not all-*trans*-FOH, can completely prevent the inhibitory effect of simvastatin on DNA synthesis in cultured HSF and 3T3 cells (**Table 1**), it may be worthwhile to determine whether this effect is related to the cells' ability to incorporate labeled isoprenoid derivatives into specific proteins, or into other isoprenoid metabolites.
2. To maximize the incorporation of [^{3}H]-MVA into cellular proteins, it is necessary to block endogenous MVA synthesis with a statin such as simvastatin ***(35)***. One-dimensional SDS-PAGE reveals that whole-cell homogenates incorporated [^{3}H]-MVA into at least 10 major bands, with molecular masses ranging from 21 to 72 kDa (**Fig. 5**). Intense bands of radioactivity are seen in the 21–28 kDa range, corresponding to Ras and Ras-related small GTPases ***(2,3)***. In contrast, only a few protein bands are visible when simvastatin is omitted from the incubation.
3. It also is necessary to block endogenous MVA synthesis with simvastatin, for efficient incorporation of [^{3}H]-FOH into specific cellular proteins.

Fig. 7. Two-dimensional gel fluorographs of [^{3}H]-prenol-labeled cell-lysates. HSF cells were labeled with either 5 µm [^{3}H]-FOH or 5 µm [^{3}H]-GGOH (*see* **Subheading 3.3.1.**), lysed, delipidated and analyzed by 2DE and fluorography (*see* **Subheading 3.3.2.**). **(A)** Whole-cell lysate from [^{3}H]-FOH labeled cells that contained 385 µg protein and 170 × 10^3 cpm. Film was exposed for 23 wk **(B)** Whole-cell lysate from [^{3}H]-GGOH-labeled cells that contained 475 µg protein and 390 × 10^3 cpm. Film was exposed for 10 wk. The major proteins that incorporated both FOH and GGOH are circled. At least nine additional clusters of minor proteins display a similar ability to incorporate either prenol, but have not been circled (*see also* **Note 7**). The position of the internal standard, [^{3}H]-NEM-labeled soybean trypsin inhibitor (6250 cpm per gel; *see* **Subheading 3.3.3.**), is indicated by a square.

However, this is not the case for [^{3}H]-GGOH labeling, which proceeds equally well in the presence or absence of simvastatin (**Fig. 5**).

4. In investigations of the cellular uptake of MVA and its derivatives, the authors typically found uptake of less than 0.1% of the added [^{3}H]-MVA, 2% of the added [^{3}H]-FOH, and more than 10–15% of the added [^{3}H]-GGOH. The efficient uptake of GGOH by cells permits rapid labeling of geranylgeranylated proteins. Protein bands from one-dimensional SDS-PAGE are detectable after labeling the cells for only 1–2 h, and subsequent gels require only a few days of film exposure.
5. Both [^{3}H]-GGOH labeling of proteins and the GGOH-mediated prevention of simvastatin-induced inhibition of DNA synthesis show parallel dose-response sensitivities to a similar range of GGOH concentrations (up to 2.5 μ*M*; **Fig. 4**).
6. The labeling approach described here can also be utilized for investigating natural or synthetic isoprenoid analogs (**Fig. 6**). When cells were treated with [^{3}H]-2-*cis*-GGOH (precursor of dolichols), proteins are only weakly labeled, compared to all *trans*-GGOH. Under parallel conditions, the addition of unlabeled 2-*cis*-GGOH failed to prevent the inhibitory effect of simvastatin on DNA synthesis (**Table 1**).
7. When prenylated proteins are selectively labeled with [^{3}H]-FOH or [^{3}H]-GGOH, and analyzed by one-dimensional SDS-PAGE, two subsets of proteins can be identified: a subset of 17 protein bands that incorporate [^{3}H]-FOH, and a separate subset of 12 protein bands that incorporate [^{3}H]-GGOH (*see* **Fig. 5**). However, when similarly labeled proteins are analyzed by 2DE, which allows much greater resolution, a third subset of proteins is identified. Using this approach, 82 proteins are visualized that incorporate only [^{3}H]-FOH, 34 proteins that incorporate only [^{3}H]-GGOH, and 25 proteins that can incorporate either prenol (compare **Fig. 7A,B**), although with varying efficiencies. The presence of unlabeled GGOH in the media during [^{3}H]-FOH labeling experiments or unlabeled FOH during [^{3}H]-GGOH labeling experiments, does not affect the protein composition of these subsets.
8. As mentioned above (*see* **Subheading 3.3.2., step 1**), there are primarily two different methods of IEF available for use in 2DE: one that uses soluble carrier ampholytes ***(31,32)*** and one that uses immobilized ampholytes in Immobiline™ gel-strips, discussed in **Note 9** below ***(29,30,34)***. The analyses presented here were performed using the first method, which was, until recently, the only large format system commercially available. This system is especially convenient for small analytical samples, but can also be used reproducibly for large-sample analyses ***(33)***. When 2DE is coupled with immunoanalysis, this system permits the detection of some proteins that cannot be visualized on blots from Immobiline gels

(M. Aepfelbacker, personal communication; C. Farnsworth, unpublished results).

9. When large samples (>500 µg protein; e.g., cell lysates) are analyzed, the Immobiline system is currently preferable, because of advances in gel technology and sample-handling techniques. These gels are now commercially available in an extended format (0.5 × 3 × 180 mm) and come as dehydrated gel strips bonded to a rigid plastic support. This permits the gel to be rehydrated directly with dilute sample lysates. Additionally, samples containing up to 5 mg protein can be analyzed in this way ***(36)*** without the need for concentration by techniques such as protein precipitation. The gels can accommodate a relatively large sample volume (upper limit of 350 µL vs 26 µL for the carrier ampholyte system). Another advantage of immobilized ampholyte pH gradients is that they allow the use of very narrow pH gradients (e.g., pH 5.5–6.5). This permits the separation of charge-isoforms that differ by only pH 0.05 units ***(29)***. Lastly, when 2DE is coupled with immunoanalysis and overlay assays, detailed maps of multimember protein families can be constructed ***(37)***.
10. In control experiments using lysates of unlabeled cells, recovery of the labeled internal standard, [^{3}H]-NEM STI (*see* **Subheading 3.3.3.**), following complete sample workup (*see* **Subheading 3.3.2., steps 6–9**) was 91 ± 4%, $n = 3$.

The Metabolic Labeling and Analysis of Isoprenylated Proteins

Douglas A. Andres, Dean C. Crick, H. Peter Spielmann, and Charles J. Waechter

1. Introduction

1.1. Background

The posttranslational modification of proteins by the covalent attachment of farnesyl and geranylgeranyl groups to cysteine residues at or near the carboxyl-(C)-terminus via a thioether bond is now well established in mammalian cells ***(1–6)***. Most isoprenylated proteins are thought to serve as regulators of cell signaling and membrane trafficking. Farnesylation and geranylgeranylation of the cysteinyl residues has been shown to promote both protein–protein and protein–membrane interactions ***(3,7,8)***. Isoprenylation, and in some cases the subsequent palmitoylation, provide a mechanism for the membrane association of polypeptides that lack a transmembrane domain, and appear to be prerequisite for their in vivo activity ***(3,9,10)***.

Three distinct protein prenyltransferases catalyzing these modifications have been identified ***(1,2,4–6)***. Two geranylgeranyltransferases (GGTases) have been characterized and are known to modify distinct protein substrates. The CaaX GGTase (also known as GGTase-1) geranylgeranylates proteins that end in a CaaL(F) sequence, where C is cysteine, A is usually an aliphatic amino acid, and the C-terminal amino acyl group is leucine (L) or phenylalanine (F). Rab GGTase (also known as GGTase-2) catalyzes the attachment of two geranylgeranyl groups to paired C-terminal cysteines in most members of the Rab family of GTP-binding proteins ***(11)***. These proteins terminate in a Cys-Cys, Cys-X-Cys, or Cys-Cys-X-X motif where X is a small hydrophobic amino acid. Another set of regulatory proteins is modified by protein farnesyltransferase (FTase). All known farnesylated proteins terminate in a tetrapeptide CaaX box, wherein

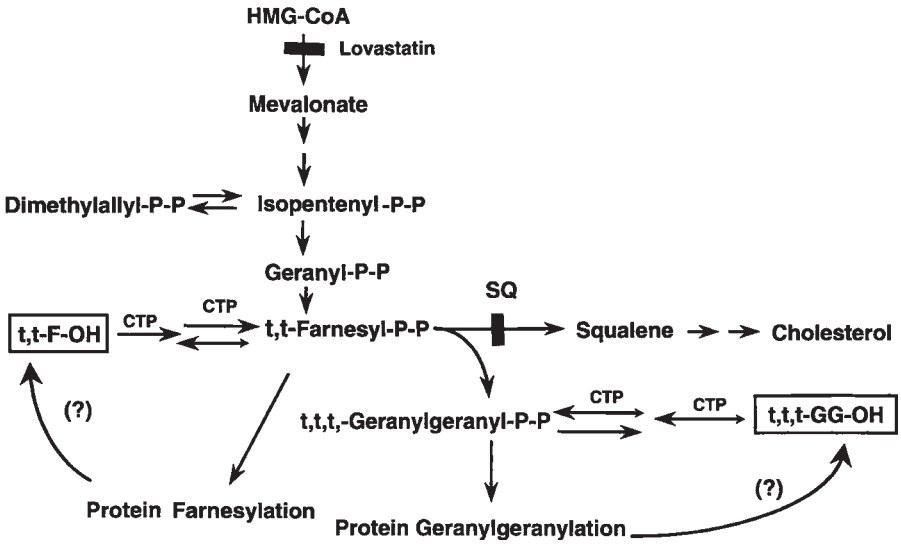

Fig. 1. Proposed "salvage" pathway for the utilization of F-OH and GG-OH for isoprenoid biosynthesis. Evidence for the presence of microsomal enzymes catalyzing the conversion of F-P-P and GG-P-P to the free isoprenols has been reported by Bansal and Vaidya ***(13)***.

C is cysteine, A is an aliphatic amino acid, and X has been shown to be a COOH-terminal methionine, serine, glutamine, cysteine, or alanine.

Isoprenylated proteins are commonly studied by metabolic labeling of cultured cells by incubation with [^{3}H]mevalonate which is enzymatically converted to [^{3}H]farnesyl pyrophosphate (F-P-P) and [^{3}H]geranylgeranyl pyrophosphate (GG-P-P) prior to being incorporated into protein (***ref. 12***; **Fig. 1**). Cellular proteins can then be analyzed by gel electrophoresis and autoradiography. However, [^{3}H]mevalonate labeling does not distinguish between farnesylated and geranylgeranylated proteins directly. Other methods for the identification of the isoprenyl group attached to protein that make use of [^{3}H]mevalonolactone labeling have been described. These methods generally require the isolation of large amounts of labeled protein, extensive proteolysis, a number of column chromatographic steps, and cleavage of the thioether bond with Raney nickel or methyl iodide, followed by gas chromatography or HPLC and mass spectrometry to identify the volatile cleavage products (*see* ***ref. 4*** and papers cited therein).

This chapter describes the use of either the natural free [^{3}H]farnesol (F-OH) and [^{3}H]geranylgeraniol (GG-OH) or the unnatural and non-radioactive anilinogeraniol (AGOH) in the selective metabolic labeling of farnesylated and geranylgeranylated proteins in cultured mammalian cells. In addition, the methods use materials and equipment readily available in most laboratories.

We have recently shown that mammalian cells can utilize the free isoprenols, GG-OH and F-OH, for the isoprenylation of cellular proteins ***(14,15)***. When C6

glioma cells were incubated with [^{3}H]F-OH, radioactivity was also incorporated into cholesterol ***(14)***. The observation that the incorporation of label into sterol was blocked by squalestatin 1 (SQ), a potent inhibitor of squalene synthetase ***(16–20)***, suggested that F-OH, and probably GG-OH, are utilized for isoprenoid biosynthesis after being converted to the corresponding activated allylic pyrophosphates, F-P-P and GG-P-P (**Fig. 1**). Preliminary studies have suggested the presence of enzyme systems in mammals and lower organisms that are capable of phosphorylating F-OH and GG-OH ***(21–23)***. More recently microsomal fractions from *N. tabacum* have been shown to contain CTP-mediated kinases that catalyze the conversion of F-OH and GG-OH to the respective allylic pyrophosphate intermediates by two successive monophosphorylation reactions (24). Further work is certainly warranted on the isolation and characterization of these enzymes. The early developments in understanding the mechanism and physiological significance of the salvage pathway for the utilization of F-OH and GG-OH have been reviewed ***(25)***.

A drawback to all metabolic labeling approaches to examine protein isoprenylation is the inherently low sensitivity of autoradiographic detection of [^{3}H]-labeled proteins and the limitation that incorporation of radiolabeled prenyl groups does not provide a convenient method for the isolation of the modified proteins. To address these limitations, incorporation of unnatural F-P-P analogues has been utilized to examine the prenylation status of cellular proteins. These methods provide a facile approach to both the detection and isolation of modified proteins ***(26–28)***. These methods include a tagging-via-substrate (TAS) approach using *in vivo* incorporation of 8-azido-farnesol ***(27)*** in conjunction with a biotinylated phosphine capture reagent to isolate modified proteins, which are then identified by mass spectroscopy. However, the TAS technology requires access to specialized equipment and thus does not lend itself to the routine detection of prenylated proteins. Here, we describe a more convenient method to simplify the detection of unnatural F-P-P modified proteins, making use of analogue-selective antibodies. In particular, recent studies have shown that the unnatural F-P-P analogue anilinogeranyl diphosphate (AG-P-P) is transferred by FTase to protein substrates with kinetics similar to F-P-P, that AG-OH is effectively utilized in a wide range of cells for the *in vivo* labeling of farnesylated proteins, and does not resemble any known natural protein modification ***(27,29,30)***. More importantly, anilinogeranyl modified proteins can be readily detected with anti-anilinogeranyl antibodies ***(28)***. Thus, the unnatural FPP analog and corresponding antibodies provide a simple and rapid method for monitoring FTase activity in cells and detection of cellular proteins modified by AG-OH.

1.2. Experimental Strategy

Utilizing free F-OH or GG-OH as the isotopic precursors of F-P-P and GG-P-P, or AG-OH as an unnatural alternative FTase substrate, has several experimental advantages over metabolic labeling of isoprenylated proteins with

mevalonate. First, isoprenoid alcohols are more hydrophobic and rapidly enter cultured mammalian cells. They are efficiently utilized in a range of mammalian cell lines, and obviate the need to include HMG-CoA reductase inhibitors to lower endogenous pools of mevalonate. The experimental strategy is illustrated in **Fig. 1**. A key advantage of the strategy is that F-OH, AGOH and GG-OH are selectively incorporated into distinct subsets of isoprenylated proteins, providing a simple and convenient approach to specifically label farnesylated or geranylgeranylated proteins (**Figs. 2** and **8**).

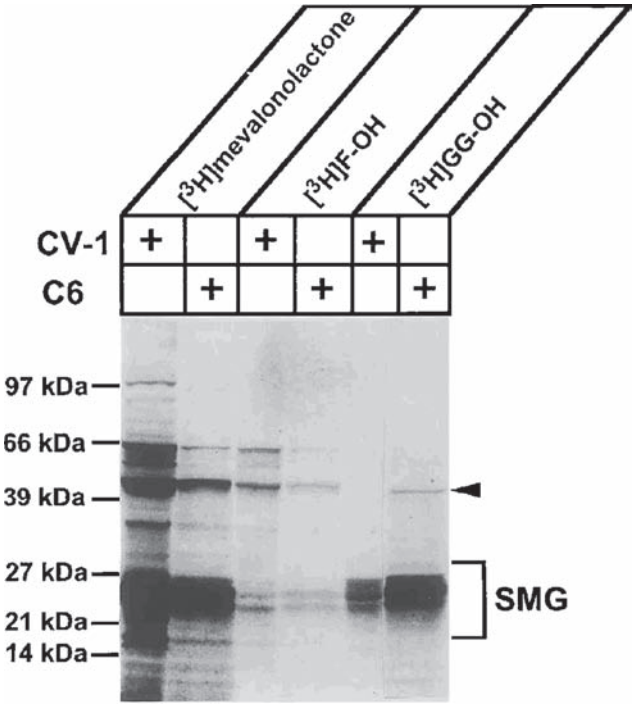

Fig. 2. SDS-PAGE analysis of proteins labeled by incubating C6 glioma cells and CV-1 cells with [^{3}H]mevalonate, [^{3}H]F-OH, or [^{3}H]GG-OH. The details of the metabolic labeling procedure and SDS-PAGE analysis are described in **Subheadings 3.1.–3.3.** For these analyses proteins were metabolically labeled by incubating the indicated cultured cells with [^{3}H]F-OH in the presence of lovastatin (5 µg/mL) because it increased the amount of radioactivity incorporated into protein during long-term incubations, presumably by reducing the size of the endogenous pool of F-P-P. The gel patterns reveal that distinctly different sets of proteins are labeled by each precursor in C6 and CV-1 cells. Consistent with selective labeling by [^{3}H]F-OH and [^{3}H]GG-OH, the labeling pattern for [^{3}H]mevalonate, which can be converted to ^{3}H-labeled F-P-P and GG-P-P, appears to be a composite of the patterns seen with the individual [^{3}H]isoprenols. SMG = proteins in the size range (19–27 kDa) of small GTP-binding proteins. (Figure reprinted with permission from ***ref. 14***).

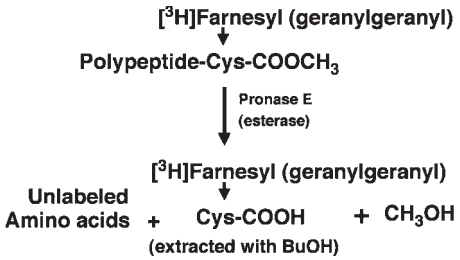

Fig. 3. Experimental scheme for the rapid analysis of metabolically labeled isoprenylated cysteine residues labeled by various isotopic precursors. The experimental details of this procedure are described in **Subheading 3.4.**

Following metabolic labeling using [^{3}H]F-OH, [^{3}H]GG-OH, or [^{3}H]mevalonolactone, the metabolically labeled proteins are exhaustively digested with Pronase E to liberate the specific isoprenyl-cysteine residues (**Fig. 3**). The identity of the isoprenylated cysteine residue can then be readily identified by normal or reverse-phase thin layer chromatography (TLC). **Figs. 4** and **5** show representative TLC analysis of isoprenyl-cysteines released from metabolically labeled cellular proteins and from recombinant proteins that were isoprenylated in vitro. Alternatively, once the non-radioactive AG-OH is incorporated in cellular proteins, total cell lysates can be directly subjected to immunoblotting with anti-AG antibodies to detect AG-modified endogenous proteins (**Fig. 8**). The anilinogeranyl moiety is structurally unrelated to any other known cellular components or protein modifications making it an excellent epitope for selective antibody recognition (Troutman Bioconj Chem 2005REF). The AG-P-P prodrug anilinogeraniol (AG-OH) is incorporated into cellular protein in the presence of the endogenous F-P-P pool without the requirement for blocking endogenous FPP formation and is remarkably non-toxic ***(28)***. Thus, AG-OH and the corresponding antibodies provide a simple, rapid, and nonradioactive method for monitoring FTase activity and detection of cellular proteins modified by AG-OH.

The isoprenol labeling and Pronase E methods may also be applied to the analysis of individual metabolically labeled proteins. These methods provide a simple and convenient approach for the identification of the isoprenyl group found on a specific protein. Two experimental approaches are available. In the first, separate cell cultures are incubated with [^{3}H]mevalonate, [^{3}H]F-OH, or [^{3}H]GG-OH the metabolically labeled protein of interest is then purified and subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis. The specificity of the F-OH and GG-OH incorporation allows the identity of the prenyl group to be directly assessed (**Fig. 6**). In the second, the cells are metabolically labeled with [^{3}H]mevalonolactone and the isolated protein of interest is subjected to Pronase E treatment followed

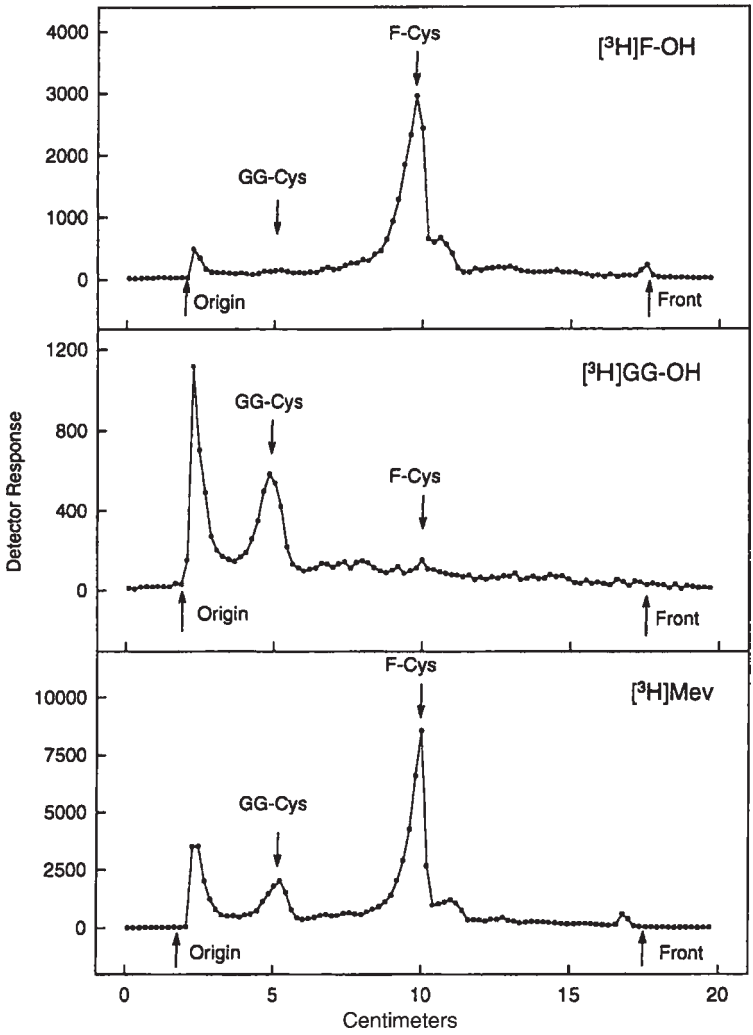

Fig. 4. Chromatographic analysis of isoprenyl-cysteine residues metabolically labeled by incubating C6 glioma cells with, [^{3}H]F-OH (*upper panel*), [^{3}H]GG-OH (*middle panel*) or [^{3}H]mevalonate (*lower panel*). From the traces illustrated, it can be seen that F-Cys and GG-Cys are both metabolically labeled when C6 cells are incubated with [^{3}H]mevalonate, but only F-Cys or GG-Cys are labeled when C6 cells are incubated with [^{3}H]F-OH or [^{3}H] GG-OH, respectively. Virtually identical results were obtained by chromatographic analysis of the Pronase E digests of CV-1 proteins metabolically labeled by each isotopic precursor. Radiolabeled products are also observed at the origin of the TLC which could be incompletely digested isoprenylated peptides, or in the case of [^{3}H]mevalonate and [^{3}H]GG-OH, possibly mono- or digeranylgeranylated Cys-Cys or Cys-X-Cys sequences reprinted with permission ***(14)*** (*see* **Fig. 5**).

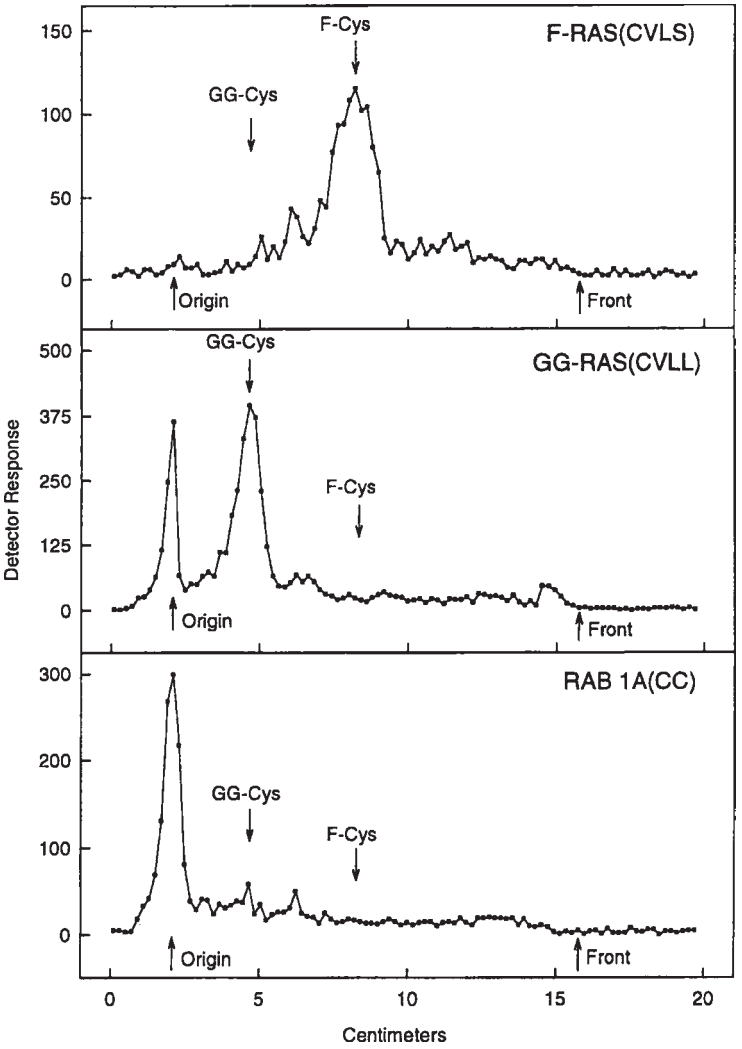

Fig. 5. Chromatographic analyses of isoprenyl-cysteine residues liberated by Pronase E digestion of recombinant protein substrates enzymatically labeled in vitro by [^{3}H]F-P-P or [^{3}H]GG-P-P. The recombinant proteins were labeled by incubation with recombinant FTase (*upper panel*), GGTase I (*upper panel*) or GGTase II (*lower panel*), essentially under the conditions described previously ***(18)***.

by TLC analysis of the butanol-soluble products. In this case analysis the chromatogram reveals the nature of the isoprenyl group (**Fig. 7**). The experimental methods for these analytical procedures are presented in detail in this chapter.

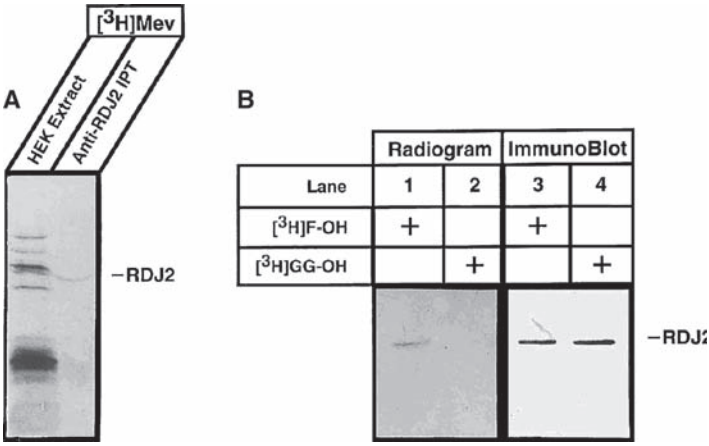

Fig. 6. Specific metabolic labeling of RDJ2-transfected HEK cells. **(A)** Monolayers of human embryonic kidney HEK cells transfected with pRDJ2 (an expression plasmid that contained the RDJ2 cDNA under the control of a CMV promoter) were radiolabeled with [^{3}H]mevalonate and the expressed RDJ2 immunoprecipitated from detergent-solubilized cell extracts using a RDJ2-specific antibody. A portion of the resulting immunoprecipitate as well as a portion of the cell extract were subjected to SDS-PAGE. The gel was treated with Amplify, dried, and exposed to film for 14 d. **(B)** Immunoprecipitated RDJ2 after metabolic labeling of transfected HEK cells with [^{3}H]F-OH (*lane 1*) or [^{3}H]GG-OH (*lane 2*) was subjected to SDS-PAGE analysis and fluorography. The remaining immunoprecipitated protein fractions isolated from HEK cells after metabolic labeling with [^{3}H]F-OH (*lane 3*) or [^{3}H]GG-OH (*lane 4*) were immunoblotted using anti-RDJ2 IgG and subjected to chemiluminescence detection.

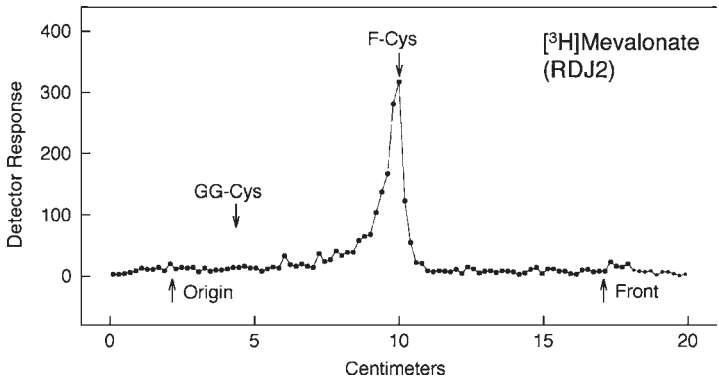

Fig. 7. Chromatographic analysis of butanol-soluble products released by Pronase E digestion of RDJ2 protein metabolically labeled by incubation with [^{3}H]mevalonolactone. Immunoprecipitated RDJ2, isolated from [^{3}H]mevalonolactone-labeled HEK cells, was subjected to Pronase E digestion. The labeled products were extracted with 1-butanol, and analyzed by reverse-phase chromatography using C18 reverse-phase TLC plates, and developed in acetonitrile–water–acetic acid (75:25:1). Radioactive zones were located with a Bioscan Imaging System 200-IBM. The *arrows* indicate the position of authentic F-Cys and GG-Cys.

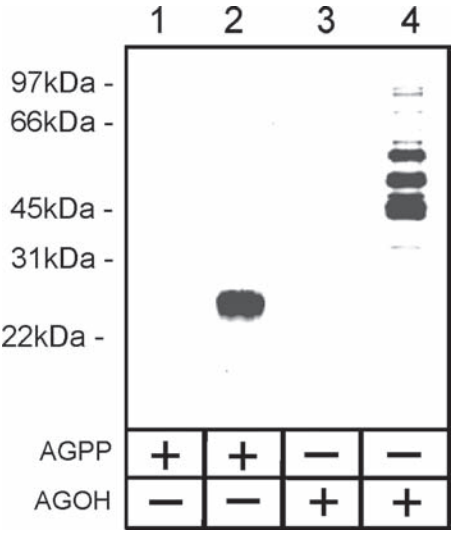

Fig. 8. Incorporation and detection of anilinogeranyl modified proteins by immunoblotting. *In vitro* prenylation reactions were performed using recombinant farnesyltransferase and AGPP in the absence (*lane 1*) or presence (*lane 2*) of H-Ras. The reactions were resolved by SDS-PAGE, transferred to nitrocellulose, and subjected to immunoblotting with anti-AG polyclonal antibody ***(28, 33)***. *In vivo* prenylation reactions (*lanes 3* and *4*) were performed on HEK-293 cells preincubated with 30 μ*M* lovostatin and 10 μ*M* GGOH for 24 h. The media was removed and replenished with media containing either 3 μ*M* FTI-277 (*lane 3*) or no inhibitor (*lane 4*) for 1 h. AGOH (100 μ*M*) was then added directly to the cultures and cells incubated for an additional 2 h. Cells were harvested and total cell lysates (50 μg) resolved by SDS-PAGE and anilinogeranyl modified endogenous proteins detected by immunoblotting using anti-AG polyclonal antibody.

2. Materials

2.1. Metabolic Radiolabeling of Mammalian Cells in Culture with [^{3}H]Farnesol, [^{3}H]Geranylgeraniol, and [^{3}H]Mevalonolactone

1. ω,*t*,*t*-[1-^{3}H]Farnesol (20 Ci/mmol, American Radiolabeled Chemicals, Inc., St. Louis, MO).
2. ω,*t*,*t*,*t*-[^{3}H]Geranylgeraniol (60 Ci/mmol, American Radiolabeled Chemicals, Inc., St. Louis, MO).
3. [^{3}H]Mevalonolactone (60 Ci/mmol, American Radiolabeled Chemicals, Inc., St. Louis, MO).
4. Appropriate cell culture media, plastic ware, and cell incubator.
5. 95% Ethanol.
6. Serum Supreme (SS), an inexpensive fetal bovine serum (FBS) substitute obtained from BioWhittaker, has been successfully used with C6 glioma, Chinese hamster ovary (CHO) clone UT-2 and green monkey kidney (CV-1) cells in this laboratory.
7. Bath sonicator.

2.2. Delipidation of Labeled Proteins

1. Phosphate-buffered saline (PBS).
2. PBS containing 2 m*M* EDTA.
3. Methanol.
4. Chloroform–methanol (2:1, v/v).
5. 12-mL Disposable conical screw-capped glass centrifuge tubes.
6. Benchtop centrifuge.
7. Probe sonicator.

2.3. SDS-PAGE Analysis of Metabolically Labeled Proteins

1. SDS-PAGE apparatus.
2. Western blot transfer apparatus.
3. Nitrocellulose membrane (Schleicher and Schuell, Protran BA83).
4. 2% SDS, 5 m*M* 2-mercaptoethanol.
5. Ponceau S: 0.2% Ponceau S, 3% trichloracetic acid (TCA), 3% sulfosalicylic acid (Sigma, S 3147).
6. Fluorographic reagent (Amplify, Amersham Corp.).
7. Sheets of stiff plastic (such as previously exposed X-ray film).

2.4. Pronase E Digestion and Chromatographic Analysis of Radiolabeled Proteins

1. *N*-[2-hydroxyethyl]piperazine-*N′*-[2′ -ethanesulfonic acid] Hepes, pH 7.4.
2. Calcium acetate.
3. Bath sonicator.
4. Pronase E (Sigma, St. Louis, MO).
5. 37°C water bath.
6. *n*-Butanol saturated with water.
7. Bench centrifuge.
8. Oxygen-free nitrogen gas.
9. Chloroform:methanol:H_2O (10:10:3, by vol).
10. Farnesyl-cysteine (F-Cys) was synthesized as described by Kamiya et al. ***(31)***.
11. Geranylgeranyl-cysteine (GG-Cys) was synthesized as described by Kamiya et al. ***(31)*** except that isopropanol is substituted for methanol in the reaction solvent to improve the yield of the synthetic reaction.
12. Silica Gel G 60 TLC plates (Sigma, St. Louis, MO).
13. Chloroform:methanol:7 *N* ammonia hydroxide (45:50:5).
14. Si*C_{18} reverse-phase plates (J. T. Baker Inc., Phillipsburg, NJ).
15. Acetonitrile:H_2O:acetic acid (75:25:1, by vol).
16. Conical glass tubes.
17. Anisaldehyde spray reagent (32) (*see* **Note 1**).
18. Ninhydrin spray reagent (*see* **Note 2**).

2.5. Immunoprecipitation of Specific Radiolabeled Protein

1. Protein-specific immunoprecipitating antibody.
2. Protein A-Sepharose (Pharmacia).

3. Wash buffer A: 20 m*M* Tris-HCl, pH 7.5, 150 m*M* NaCl, 0.2% Nonidet P-40 (NP-40).
4. Wash buffer B: 20 m*M* Tris-HCl, pH 7.5, 500 m*M* NaCl, 0.2% NP-40.
5. Wash buffer C: 20 m*M* Tris-HCl, pH 7.5, 150 m*M* NaCl.
6. *n*-Butanol saturated with water.
7. Tabletop ultracentrifuge (Beckman).

2.6. Immunodetection of AG-Modified Cellular Proteins

1. Anilinogeraniol (30 µ*M*, AG-OH) (Contact Drs. H. P. Spielmann and D. A. Andres, Univ. Kentucky, Lexington, KY) ***(28,33,34)***.
2. Appropriate cell culture media, plastic ware, and cell incubator.
3. Cell lysis buffer: 20 m*M* Tris-HCl, pH 7.5, 150 m*M* NaCl, 1 mM EDTA, 1% Nonidet P-40 (NP-40), 1 m*M* phenylmethyl+sulfonyl fluoride (PMSF) (add fresh PMSF solution and lysis is carried out at 4°C). Bradford reagent protein concentration kit (Pierce).
4. AG-specific antibody (Contact Drs. H. P. Spielmann and D. A. Andres, Univ. Kentucky, Lexington, KY) ***(28,33)***.
5. SDS-PAGE apparatus.
6. Western blot transfer apparatus.
7. Nitrocellulose membrane (Schleicher and Schuell, Protran BA83).
8. Blocking buffer PCT: 1 × phosphate buffered saline (PBS), 0.1 % Tween 20, 1% casein
9. Shaker platform.
10. Wash buffer PT: 1× PBS and 0.1% Tween 20.
11. Wash buffer PTE: 1× PBS and 0.3% Tween 20.
12. horseradish peroxidase-conjugated secondary antibody (Zymed).
13. Enhanced chemiluminescent detection reagent (Pierce).

3. Methods

3.1. Procedure for the Selective Metabolic Labeling of Farnesylated and Geranylgeranylated Proteins

Procedures are described for the metabolic labeling of mammalian cells grown to near-confluence in Falcon 3001 tissue culture dishes. These protocols can be scaled up or down as appropriate. The incorporation of [^{3}H]F-OH or [^{3}H]GG-OH into protein was linear with respect to time and the concentration of [^{3}H]isoprenol in tissue culture dishes ranging from 10 to 35 mm in diameter under the conditions described here ***(14,15,25)*** (*see* **Note 3**).

1. For metabolic labeling experiments with either [^{3}H]F-OH or [^{3}H]GG-OH, a disposable conical glass centrifuge tube (screw capped) and Teflon-lined cap are flame sterilized. The labeled isoprenol dissolved in ethanol is added to the tube and the ethanol is evaporated under a sterile stream of air.
2. An appropriate volume of sterile SS is added to yield a final concentration of 0.5–1 mCi/mL. The labeled isoprenols are dispersed in the SS by sonication in a Branson bath sonicator for 10 min. After sonication an aliquot is taken for liquid scintillation counting to verify that the ^{3}H-labeled isoprenol has been quantitatively dispersed in SS.

3. The growth medium is removed from the cultured cells by aspiration and 500 µL of labeling medium, consisting of an appropriate medium and SS (final concentration = 3–5%) containing [^{3}H]GG-OH or [^{3}H]F-OH, is added.
4. Cell cultures are typically incubated at 37°C under 5% CO_2 for 6–24 h. Actual culture media and incubation conditions will vary depending on the specific cell type being studied.

3.2. Recovery of Metabolically Labeled Proteins from Adherent Cell Lines

1. The labeling medium is removed by gentle aspiration.
2. The metabolically labeled cells are washed with 1–2 mL of ice-cold PBS, to remove unincorporated isotopic precursor.
3. One milliliter of PBS containing 2 m*M* EDTA is added, and cells are incubated for 5 min at room temperature. The washed cells are gently scraped from the dish with a disposable cell scraper, and transferred to a 12-mL conical glass centrifuge tube.
4. The metabolically labeled cells are sedimented by centrifugation (500*g*, 5 min), and the PBS–EDTA is removed by aspiration (avoid disrupting the cell pellet).
5. The cells are resuspended in PBS (1–2 mL) and the PBS is removed by aspiration after the cells are sedimented by centrifugation.
6. Two milliliters of methanol (CH_3OH) is added to the cell pellet, and the pellet is disrupted by sonication using a probe sonicator.
7. The suspension is sedimented by centrifugation (1500 *g* for 5 min).
8. The CH_3OH extract is carefully removed, to avoid disturbing the partially delipidated pellet, and transferred to a glass conical tube (*see* **Note 4**).
9. The protein pellet is reextraced twice with 2 mL of $CHCl_3$–CH_3OH (2:1), and the extracts are pooled with the CH_3OH extract (*see* **Note 4**).
10. Residual organic solvent is removed from the delipidated protein pellet by evaporation under a stream of nitrogen. The delipidated protein fractions are then subjected to Pronase E digestion for analysis of isoprenyl-cysteine analysis by TLC (*see* **Subheading 3.4**), or dissolved in 2% SDS, 5 m*M* 2-mercaptoethanol for SDS-PAGE analysis.

3.3. SDS-PAGE Analysis of Metabolically Labeled Proteins

To examine the molecular weight and number of proteins metabolically labeled by incubation with [^{3}H]F-OH or [^{3}H]GG-OH, the delipidated protein fractions can be analyzed by SDS-PAGE. Because these experiments rely on the detection of low-energy ^{3}H-labeled compounds, two procedures are described for the use of fluorography to increase the sensitivity of detection (*see* **Note 5** before proceeding).

1. The delipidated protein fractions are solubilized in 2% SDS, 5 m*M* β-mercaptoethanol. An aliquot is used to determine the amount of labeled precursor incorporated into protein.
2. The radiolabeled polypeptides (20–60 µg of protein) were analyzed by SDS-PAGE using an appropriate percentage polyacrylamide resolving gel (4–20%) for the proteins of interest.

3. Following SDS-PAGE, gels can be analyzed using two distinct methods. In the first, the gel is directly soaked in the fluorographic reagent, Amplify (Amersham), according to the manufacturer's protocol, dried, and exposed to X-ray film as described in **step 5**. In a second approach, proteins were electrophoretically transferred to nitrocellulose filters and stained with Ponceau S to determine the efficiency of transfer. The nitrocellulose filters are destained by brief washing in distilled water and allowed to air-dry. (*See* **Note 5** for a discussion of the merits of each method before continuing.)
4. The filters were then dipped briefly in the fluorographic reagent, Amplify (Amersham), placed on a sheet of plastic backing, and dried for 1 h at 50°C. It is important that a thin and even film of Amplify reagent remain on the filter and that it be placed protein side up to dry.
5. Fluorograms were produced by exposing preflashed X-ray film to the nitrocellulose filter, or dried SDS-PAGE gel, for 5–30 d at −80°C.

3.4. Methods for the Identification of Cysteine-Linked Isoprenyl Group

These simple methods are inexpensive, rapid, and allow the identification of the isoprenyl-cysteine residue(s) from isoprenylated protein(s). Examples of this method for the identification of isoprenyl-cysteine groups from metabolically labeled cells and recombinant proteins labeled in vitro are shown in **Figs. 4** and **5**. As expected, [^{3}H]F-Cys and [^{3}H]GG-Cys were liberated from RAS(CVLS) and RAS(CVLL), respectively. A radioactive peak is also seen at the origin in the analysis of the Pronase digest of radiolabeled RAS(CVLL) (**Fig. 5**, *middle panel*). This radiolabeled product(s) is probably incompletely digested [^{3}H]geranylgeranylated peptides. Rab 1A terminates in two cysteine residues, both of which are isoprenylated (35). **Fig. 5** (*lower panel*) indicates that Pronase E is incapable of cleaving between the two cysteine residues.

1. To liberate the labeled isoprenyl-cysteine residues for analysis, the delipidated protein fractions (50–100 µg) are incubated with 2 mg of Pronase E; 50 m*M* HEPES, pH 7.4; and 2 m*M* calcium acetate in a total volume of 0.1 mL at 37°C for approx 16 h. The experimental scheme for this analysis is illustrated in **Fig. 3** (*see* **Note 6**).
2. Proteolysis is terminated by the addition of 1 mL of *n*-butanol saturated with H_2O and mixing vigorously.
3. Centrifuge the mixture for 5 min in a benchtop centrifuge at 1500*g*. Two phases will form, and the upper phase should be clear (*see* **Note 7**).
4. Transfer the upper phase, containing *n*-butanol, to a separate conical glass centrifuge tube.
5. Add 1 mL of H_2O to the butanol extract and mix vigorously. Centrifuge at 1500*g* for 5 min, to effect a phase separation. Remove the lower aqueous phase with a Pasteur pipet (*see* **Note 8**). Evaporate the *n*-butanol under a stream of nitrogen at 30–40°C (*see* **Note 9**).

6. The labeled isoprenyl-cysteines are dissolved in 250 µL of $CHCl_3$:CH_3OH:H_2O (10:10:3, by vol) by mixing vigorously, and an aliquot (10 µL) is taken to determine the amount of radioactivity.
7. The radiolabeled products are analyzed chromatographically on a normal-phase system, using silica gel G 60 TLC plates developed in $CHCl_3$:CH_3OH:7 *N* NH_4OH (45:50:5, by vol) or by reverse-phase chromatography using silica gel Si*C18 reverse-phase plates developed with acetonitrile–H_2O–acetic acid (75:25:1, by vol) (*see* **Note 10**).
8. The desired developing solvent mixture is added to the chromatography tank to a depth of 0.5–1.0 cm and allowed to equilibrate.
9. Dry entire sample under nitrogen stream. Redissolve in chloroform–methanol–water (10:10:3, by vol).
10. Apply an aliquot (approx 10,000 dpm containing 10–12 µg of authentic F-Cys and GG-Cys) to the origin on the TLC plate, using a fine glass capillary or a Hamilton syringe. The addition of the unlabeled standards improves the resolution of the metabolically labeled isoprenylated cysteines.
11. Allow the sample to dry (this can be facilitated with a stream of warm air). Complete application of the labeled isoprenyl-cysteine extract to the plate in 5-µL aliquots, allowing time for the spot to dry between applications.
12. Place the plate(s) in the preequilibrated chromatography tank, and after the solvent has reached the top of each plate (1–2 h) remove and allow to air-dry in a fume hood.
13. When the plates are thoroughly dried, the radioactive zones are located with a Bioscan Imaging Scanner System 200-IBM or autoradiography (*see* **Note 11**).
14. Standard compounds are localized by exposure of the plate to the anisaldehyde spray reagent ***(32)*** or a ninhydrin spray reagent (*see* **Note 12**).

3.5. Application of These Methods to the Analysis of Individual Proteins

To illustrate the utility of this approach for individual isoprenylated proteins, these methods are applied to the analysis of a recently isolated farnesylated protein, RDJ2 (rat DnaJ homologue 2). The cDNA clone of this DnaJ-related protein was recently identified ***(36)***. The predicted amino acid sequence is found to terminate with the tetrapeptide Cys-Ala-His-Gln, which conforms to the consensus sequence for recognition by protein farnesyltransferase, and was shown to undergo farnesylation *in vivo*.

To perform this analysis, a means of specifically identifying the protein of interest must be available. In this example, a protein-specific immunoprecipitating antibody was used to isolate the protein from isotopically radiolabeled mammalian cells. However, other experimental approaches are available. (*See* **Note 13** for a discussion of these stategies.)

1. Mammalian cells are grown to near confluence and metabolically labeled with either [^{3}H]mevalonate, [^{3}H]F-OH, or [^{3}H]GG-OH as described in **Subheading 3.1**.

If a recombinant protein is to be analyzed, the mammalian cells should be transfected either stably or transiently with the expression vector prior to labeling ***(37)***.

2. The metabolically labeled cells are washed with 1–2 mL of ice-cold PBS to remove unincorporated isotopic precursor.
3. One milliliter of PBS containing 2 m*M* EDTA is added, and the cells are incubated for 5 min at room temperature. The washed cells are gently scraped from the dish with a disposable cell scraper and transferred to a 12-mL conical glass centrifuge tube.
4. The metabolically labeled cells are sedimented by centrifugation (500 *g*, 5 min), and the PBS–EDTA is removed by aspiration (avoid disrupting the cell pellet).
5. The cells are resuspended in lysis buffer (2 mL), disrupted by passage through a 20-gauge needle (3–4×), and centrifuged for 15 min at 100,000 *g* in a Beckman table top ultracentrifuge.
6. For immunoprecipitation of recombinant RDJ2, 20 µg of rabbit anti–RDJ2 antibody was added to the cleared supernatant and the mixture was incubated for 12 h at 4°C with gentle rocking (*see* **Note 14**).
7. Immune complexes were then precipitated by addition of 100 µL of a 50% slurry of protein A-Sepharose for 2 h at 4°C with gentle rocking.
8. Protein A beads were collected by centrifugation (1 min in a tabletop microfuge at 10,000 rpm). The pellet was washed 3× by resuspending in 1 mL of wash buffer A, 1 mL of wash buffer B, and 1 mL of wash buffer C, sequentially.
9. The protein is dissolved in 2% SDS, 5 m*M* β-mercaptoethanol for SDS-PAGE analysis (*see* **Subheading 3.3.** and **Fig. 6**). Alternatively, the protein A beads are subjected to pronase E digestion for analysis of isoprenyl-cysteine analysis by TLC (*see* **Subheading 3.4**, **Fig. 7**, and **Note 15**).

3.6. Immunodetection of AG-labeled Cellular Proteins

A recent advance in the detection of cellular isoprenylated proteins was been the generation of the unnatural F-P-P analogue AG-P-P and anti-AG antibodies ***(28)***. These reagents have been utilized to examine the prenylation status of both general cellular proteins (**Fig. 8**) and specific prenylated proteins ***(33)***. The combined use of an unnatural FPP analog and specific antibody provides a simple, inexpensive, and rapid method for monitoring both FTase activity in cells and detection of cellular prenylated proteins using non-radioactive methods (**Fig. 8**).

1. Mammalian cells are grown to near confluence and metabolically labeled with AG-OH. This can either be performed on cells treated with lovastatin (30 µ*M*) to reduce the intracellular F-P-P/GG-P-P pool and 100 m*M* AG-OH for 24 h, or cells with no lovastatin block can be incubated with 30–100 µ*M* AG-OH from 6–72 h ***(28, 33)*** (*see* **Note 16**). If a recombinant protein is to be analyzed, the mammalian cells should be transfected either stably or transiently with the expression vector prior to labeling ***(37)***.
2. The AG-OH labeled cells are washed with 1–2 mL of ice-cold PBS to remove unincorporated AG-OH, the PBS removed by aspiration, and the cells resuspended

in cell lysis buffer (300–500 µl for a 10-cm dish). The cells are disrupted by brief sonication, and protein concentration determined using Bradford reagent.

3. The AG-modified polypeptides (50–100 µg of total cell protein) can be analyzed by SDS-PAGE using an appropriate percentage polyacrylamide resolving gel (4–20%) for the proteins of interest and electrophoretically transferred to nitrocellulose membrane.
4. The membranes are incubated in PCT for 1 h at room temperature, after which the following sequential steps are performed at room temperature: incubate with polyAG-Ab (1; 5,000 dilution) in PCT for 1 h; 3 × 15 min washes with shaking in PT buffer; incubation for 1 h in PCT with goat-anti-rabbit horseradish peroxidase-conjugated secondary antibody (dilution of 1: 20,000); 2 × 10 min washes with PT; 1 × 10 min wash with PTT; and a final 2 × 10 min wash with PT.
5. The membranes are then subjected to enhanced chemiluminescence detection by being placed in 10 mL of detection buffer (Pierce Supersignal) for 1 min and exposed to x-ray film.

4. Notes

1. Anisaldehyde spray reagent contains 10 mL of anisaldehyde, 180 mL of 95% ethanol, and 10 mL of conc. sulfuric acid, added in that order.
2. Ninhydrin spray reagent contains 0.2% ninhydrin in 95% ethanol.
3. All mammalian cells tested (CHO, C6 glioma cells and green monkey kidney [CV-1] cells) utilized F-OH and GG-OH for protein isoprenylation except murine B cells before or after activation by lipopolysaccharide (LPS). Thus, it is possible that the "salvage" pathway for F-OH and GG-OH (**Fig. 1**) may not be ubiquitous in mammalian cells.
4. The pooled organic extracts can be used for analysis of lipid products metabolically labeled by [^{3}H]F-OH (*see **ref. 14***). The organic solvent is evaporated under a stream of nitrogen, and the lipid residue redissolved in $CHCl_3$:CH_3OH (2:1) containing 20 µg each of authentic cholesterol and squalene. An aliquot is taken to determine the amount of radioactivity incorporated into the lipid extracts. The lipid products are analyzed on Merck silica gel G 60 TLC plates (Sigma) by developing with hexane–diethyl ether–acetic acid (65:35:1) or chloroform. Radioactive zones were located with a Bioscan Imaging Scanner System 200-IBM. Standard compounds are located with iodine vapor or anisaldehyde spray reagent (32).
5. Western transfer is preferred because transferring labeled proteins to nitrocellulose membrane appears to give a gain of 2–10-fold in sensitivity. One suspects that the polyacrylamide gel acts to quench the signal from radiolabeled protein. The transfer step serves to collect proteins in a single plane, and eliminates this problem. However, care should be taken with the intrepretation of these experiments. It is possible that some radiolabeled proteins, particularly those of either small (<10 kDa) or very large

(>100 kDa) molecular mass, may be inefficiently transferred. The properties of the protein, percentage of acrylamide, transfer buffer components, and transfer time will each influence the transfer efficiency. Direct analysis of the gel will be less sensitive, requiring more labeled protein and longer exposure times, but material will not be lost during transfer.

6. Pronase E will completely dissolve over a period of 30 min at 37°C, and these protease preparations contain sufficient esterase activity to hydrolyze the carboxymethyl esters at the C-termini of isoprenylated proteins ***(38).***
7. The lower aqueous phase remains cloudy, and contains precipitated proteins and peptides.
8. The addition of H_2O will significantly reduce the volume of the *n*-butanol phase at this step (reducing the time required for the following steps).
9. The addition of an equal volume of *n*-hexane to the *n*-butanol will speed this evaporation, by forming an azeotrope. The addition of the hexane will cause the solution to become cloudy and biphasic. The upper (butanol–hexane phase) evaporates quite rapidly, and the subsequent addition of 1 mL of 100% ethanol speeds the evaporation of the lower aqueous phase.
10. The resolution of GG-Cys and F-Cys is better in the reverse–phase chromatography system. If the normal phase system is used, the plates should be activated by heating in a 100°C oven for at least 1 h.
11. At least 5000 dpm are required for good detection using a Bioscan Imaging System, but analysis will be better (and faster) with 10,000 dpm or more. The entire sample from the digestion of 100 µg of labeled protein can usually be loaded on the TLC plates without any significant loss of chromatographic resolution.
12. Spray until plate is moist, and heat in 100°C oven until spots appear. The plates are scanned prior to spraying to avoid the reagent vapors, and because the spray reagents quench the detection of radioactivity.
13. A consideration before beginning these experiments is the abundance of the protein of interest. The analysis of a very low abundance protein will require a large number of radiolabeled tissue culture cells. Therefore, the overproduction of the protein using a mammalian expression vector may present a distinct experimental advantage. This approach also allows the cDNA to be modified to contain a unique epitope or affinity sequence at the N-terminus. In this way, proteins for which specific antibodies are not available may be studied.
14. Optimal immunoprecipitation conditions must be established for each protein-antibodyc omplex.
15. Pronase E digestion can be carried out directly on the protein A beads without further processing. Follow directions given in **Subheading 3.4**, scaling up the volume of the proteolysis reaction mixture to provide sufficient

liquid to amply cover the protein A beads. Follow **steps 2–15** as directed. Initially, proteins should be labeled with mevalonate and both free isoprenols, to ensure correct interpretation of the results. Although a variety of proteins have been tested (*see* **Figs. 2**, **4**, and **7**) using [^{3}H]isoprenol labeling, the list of individual proteins is quite limited. It will be necessary to analyze a wide variety of defined isoprenylated proteins to further establish the reliability and limitations of this method.

16. Optimal AG-OH labeling conditions must be established for each cell culture system. Thus, pilot studies varying both the concentration (within the limits of 10–100 µM to avoid potential toxicity) and time of AG-OH labeling, in the presence or absence of lovastatin, should be performed ***(28).*** This will be particularly important if examining a specific cellular protein (*see* **Note 13**). Finally, it must be remembered that AGPP is a FTase substrate and that this approach can not be used to analyze geranylgeranylated proteins.

Acknowledgments

The methods described in this chapter were developed with support from NIH grants NINDS04103 and HL072936 (D.A.A.) and GM36065 (C.J.W.).

Antibody Production

Robert Burns

1. Introduction

Antibodies are proteins that are produced by the immune systems of animals in response to foreign substances. The immune system has the ability to recognize material as nonself or foreign and mount a response to them. Substances that elicit this are known as immunogens or antigens, and one of the outcomes of the immune response is the production of antibodies that will recognize and bind to the eliciting substance.

The immune response results in the degradation and processing of the antigen by cells called macrophages and its presentation in fragments to B lymphocytes that are found in the lymphatic tissues of the animal. On presentation of the antigen fragments the B lymphocytes mature and "learn" to produce antibody molecules that have a specific affinity to the antigen fragment that they have been presented with. This process gives rise to populations of B lymphocyte clones each of which produces antibody molecules to different locations known as epitopes on the target antigen ***(1)***. As individual clones produce the antibody molecules and there are many of them, the resulting antibody mix in the blood is known as polyclonal and the fluid derived from the clotted blood is known as polyclonal antiserum.

Deliberate exposure to antigens producing antibodies in animals is known as immunization, and repeated exposure leads to a condition known as hyperimmunity, in which a significantly large proportion of the circulating antibodies in the animals blood will be directed toward the antigen of interest. When exposure to the antigen ceases a stable but quiescent populations of B lymphocytes known as memory cells remain that will respond to the presence of the antigen by dividing to increase their number and the level of circulating antibody in the blood.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

The primary exposure to an antigen gives rise to a pentameric form of antibody known as immunoglobulin M (IgM). Subsequent exposure to the antigen causes maturation of the cells and a shift in the antibody type to the more stable dimeric immunoglobulin G (IgG). This shift in antibody type happens as affinity maturation of the B lymphocyte clones occurs.

Some antigens, particularly highly glycosylated proteins, do not elicit the production of memory B lymphocytes and also may not give rise to IgG antibodies even after repeated immunization. These are known as anamnestic antigens, and as no memory B lymphocytes are produced, the immune system always interprets exposure to them as a primary one and mounts an IgM response. It is possible to produce IgG to anamnestic antigens by treating them to remove the carbohydrate moieties prior to immunization, but in some cases this may lead to antibodies that do not recognize the native protein structure.

Antibodies have two qualities known as avidity and affinity. Affinity is a measure of how well the binding site on the antibody molecule fits the epitope, and antibodies, which have high affinity also, have high specificity to the target epitope. Avidity is a measure of how strong the interaction between the epitope and the antibody molecule is.

For research purposes, antibodies to the antigen of interest should be expressed at fairly high levels in the sera of donor animals, should be of high affinity, and should predominantly be composed of IgG molecules, which are stable and easily purified. This can be achieved for most antigens providing they are not too highly glycosylated, have a molecular weight >5000, and are not toxic or induce immuneparesis in the donor animal. The ability of species to respond to antigens is variable and it may be necessary to investigate which animal would be the most suitable prior to embarking on a large scale immunization project.

Monoclonal antibodies are used very successfully in many areas of research and can either replace, complement, or be used in conjunction with immunoglobulins obtained from donor serum. Monoclonal antibodies are produced by hybridoma cell lines and can be grown in tissue culture in the laboratory. Hybridomas are recombinant cell lines produced from the fusion of B cells derived from the lymphatic tissue of donor animals and myeloma cell lines that imparts immortality to the cells ***(2,3)***. As each hybridoma is descended from a single B cell clone the antibody expressed by it is of a single specificity and immunoglobulin type, and is thus termed a monoclonal antibody.

Each monoclonal antibody is monospecific and will recognize only one epitope on the antigen to which it has been raised. This may lead to practical problems if the epitope is not highly conserved on the native protein or where conformational changes may occur in the because of to shifts in pH or other environmental factors. Monoclonal antibodies are highly specific and will rarely if ever produce cross-reactions with other proteins. Polyclonal antibodies may cross-react with other closely related proteins where there are shared epitopes.

Polyclonal antisera contain a heterogeneic mixture of antibody molecules, many of which will recognize different epitopes on the protein, and their binding is much less likely to be affected by poorly conserved epitopes or changes in the protein shape.

Antisera are derived from individual animal bleeds and because of this are subject to batch variation. Individual animals can have very different immune responses to the same antigen, and individual bleeds from the same animal may vary in antibody content quite markedly. Monoclonal antibodies are produced from highly cloned cell lines that are stable and reliably produce a defined antibody product.

Polyclonal antibodies are generally less specific than monoclonals, which can be a disadvantage, as cross-reactivity may occur with nontarget proteins. Monoclonal antibodies can be too specific, as they will recognize only a single epitope that may vary on the protein of interest.

Both antibody types have their place in the research laboratory, and a careful evaluation of the required use should be undertaken before deciding which would be most applicable.

In recent years the use of non-animal-based systems have been reported and in particular the use of phage display technology for antibody production appears to be promising. Phage display libraries expressing single chain antibodies can be screened using the antigen to isolate antibodies of interest which are then expressed using vector systems such as M13 ***(4)***. These systems allow the generation of antibodies without the use of animal donors and also allow the generation of antibodies to "difficult" antigens. There are limitations in that the antibodies produced are actually antibody fragments and there may be restrictions on how they may be used in assays due to molecule size and stability. Antibodies derived by phage display technology may be transfected into cell lines such as Chinese Hamster Ovary (CHO) if large quantities of product are required. Fully human antibodies can be generated using this methodology without the use of human donor tissue and its attendant ethical concerns.

1.1. Donor Animals

Most polyclonal antibodies for research purposes are produced in domestic rabbits unless very large quantities are required, and then sheep, goats, donkeys, and even horses are used. Antibodies can also be produced in chickens; the antibodies are conveniently produced in the eggs. Rats and mice can also be used to produce antiserum but yield much smaller quantities of antibody owing to their relatively small size. Immunized mice can be used to produce 5–10 mL of polyclonal ascitic fluid by induction of ascites. Ascites is induced by the introduction of a nonsecretory myeloma cell line into the peritoneal cavity after priming with Pristane. Polyclonal antibodies are secreted into the peritoneum from the blood plasma of the animal and can achieve levels of 2–5 mg/mL. Fluid isaspirated

from the peritoneum of the mouse when ascites has developed, indicated by bloating of the abdomen. The UK Home Office and other regulatory authorities now regard induction of ascites in mice as a moderate/severe procedure and this method is not normally used unless no alternative methods are available.

1.2. Adjuvants

Adjuvants are substances that increase the immune response to antigen by an animal. They may be simple chemicals such as alum, which adsorbs and aggregates proteins, increasing their effective molecular weight, or they may be specific immunestimulators such as derivatives of bacterial cell walls ***(5)***. Saponins such as Quil-A derived from the tree *Quillaja saponaria* may also be used to increase the effective immunogenicity of the antigen. Ideally an adjuvant should not induce too great an antibody response to itself to ensure that antibodies generated are specific to the antigen of interest.

The most popular adjuvant, which has been used very successfully for many years, is Freund's adjuvant. It has two formulations, complete and incomplete, which are used for the primary and subsequent immunizations, respectively. Freund's incomplete formulation is a mixture of 85% paraffin oil and 15% mannide monooleate. The complete formulation additionally contains 1 mg/mL of heat-killed *Mycobacterium tuberculosis*. In recent years the use of Freund's adjuvant has declined owing to animal welfare concerns and also the risk that it poses to workers, as it can cause localized soft tissue damage following accidental needlestick injuries. Injection preparations that contain Freund's adjuvant are also difficult to work with, as the resultant emulsion can be too thick to administer easily and it interacts with plastic syringes, preventing easy depression of the plunger.

Several adjuvant formulations are available that contain cell wall derivatives of bacteria without the intact organisms; they are much easier to administer and will achieve a similar immunostimulatory effect to Freund's without its attendant problems.

1.3. Legislation

Most countries have legislation governing the use of animals for all experimental work, and antibody production is no exception. Although the methods used are usually mild in terms of severity they must be undertaken with appropriate documentation and always by trained, authorized staff.

The legislation in terms of animal housing, immunization procedures, bleeding regimens, and choice of adjuvant vary widely according to local legislation, and it is imperative that advice be taken from the appropriate authorities prior to undertaking any antibody production work.

1.4. Antigens

The antigen chosen for an immunization program should be as close in structure and chemical identity to the target protein as possible. An exception to this is when synthetic peptides are produced to mimic parts of the native protein, an approach that is invaluable when the native antigen may be toxic to animals or nonimmunogenic.

The antigen should be soluble, stable at dilutions of approx 1 mg/mL, and capable of being administered in a liquid of close to physiological pH (6.5–7.5). The antigen should also be in as pure a form as practically possible to avoid the generation of antibodies to contaminating materials.

Many proteins are highly immunogenic in donor animals, particularly when the antigen is derived from a different species (*see* **Note 1**). Raising antibodies in the same species from which the antigen is derived from can be extremely difficult but can be overcome by conjugating the antigen to a carrier protein from another species prior to immunization. Carrier proteins such as hemoglobin, thyroglobulin, and keyole limpet hemocyanin (KLH) are commonly used. Animals immunized with the conjugated form of the antigen will produce antibodies to both the protein of interest and the carrier protein. Apart from a lower specific antibody titer in the serum there should be no interference from the carrier protein antibodies as it will not be present in the final testing system.

1.5. Test Protocol

Ideally antiserum should be tested using the procedure in which it is to be used, as antibodies may perform well using one assay but not with another. This, however, is not always practical and so a number of tests can be carried out on antiserum to test its suitability for final use. The affinity of the antiserum to the antigen can be assayed by plate-trapped double-antibody sandwich enzyme-linked immunosorbent assay (DAS ELISA) ***(6)***. The antigen is bound to a microtiter plate and then challenged with dilutions of the test antiserum. A secondary antispecies antibody enzyme conjugate is then added to the plate and will bind to any antibody molecules present. A chromogenic enzyme substrate is then added and the degree of color development indicates the quantity of antibody bound by the antigen.

Ouchterlony double-immunodiffusion can be used to observe the ability of the antiserum to produce immune complexes with the antigen in a semisolid gel matrix. This method can also be used to test cross-reactivity of the antiserum to other proteins closely related to the antigen. Radioimmunoassay and other related techniques can also be used to test the avidity of the antiserum to the antigen and will also give a measure of antibody titer.

In all the above tests preimmune antisera should be included to ensure that results obtained are a true reflection of antibodies produced by immunization and not due to nonspecific interactions.

2. Materials

1. At least two rabbits should be used for each polyclonal antibody production project, as they may have different immune responses to the antigen. They should be purchased from a reputable source and be parasite and disease free. New Zealand whites are often used but any of the domestic breeds can be used (*see* **Note 2**).
2. The antigen should be in a buffer of pH 6.5–7.5 and be free of toxic additives (sodium azide is often added as a preservative). A concentration of 1 mg/mL is desirable but anything above 100 µg/mL is acceptable.
3. Complete and incomplete Freund's adjuvant or any of the propriety preparations containing purified bacterial cell wall components such as Titermax and RIBI.

3. Method

1. Prior to a course of immunizations a test bleed should be taken from the rabbits to provide a source of preimmune antiserum for each animal (*see* **step 5** below). It is usual to take only 2–3 mL for the test bleeds, which will yield 1–1.5 mL of serum. The blood should be allowed to clot at 4°C for 12 h and the serum gently aspirated from the tube.
2. The antigen should be mixed with the appropriate adjuvant according to the manufacturer's instructions to achieve a final volume of 0.5 mL/injection containing 50–500 µg of antigen (*see* **Note 3**). If Freund's adjuvant is to be used, the first injection only should contain the complete formulation and the incomplete one should be used for all subsequent immunizations.
3. The rabbit should be gently restrained and the antigen–adjuvant mixture injected into the thigh muscle. Alternate legs should be used for each injection (*see* **Note 4**).
4. The immunization should be repeated 14 d after the primary one and a test bleed taken 28 d after that.
5. If the antiserum shows that the desired immune status and antibody quality has been achieved then donor bleeds can be taken. The volume of blood collected and frequency of bleeding depends on animal welfare legislation and must be adhered to. Each bleed should be assayed individually, and once the antibody titer has started to fall a further immunization can be given, followed by donor bleeds, or the animal can be terminally anesthetized and exsanguinated by cardiac puncture or by severing the carotid artery.
6. Antiserum collected from rabbits can be stored for extended periods of time at 4°C but the addition of 0.02% sodium azide is recommended to prevent adventitious bacterial growth. Antiserum quite commonly has functional antibodies even after years of refrigerated storage, but storage at −20°C is recommended for long-term preservation.
7. Antiserum will often yield in excess of 5 mg/mL of antibody and can be purified to give the immunoglobulin fraction. This can be achieved with ammonium sulfate

precipitation or by affinity chromatography using either the immobilized antigen or protein A or G. The antibody fraction can then be adjusted to 1 mg/mL, which is an ideal concentration both for its stability and for many practical applications. Purified antibody should have 0.02% sodium azide or some other preservative added to prevent the growth of adventitious organisms. Sodium azide can interfere with enzyme reactions and with photometric measurement, and this should be taken into account with regard to the final assay. Purified antibodies diluted to 1 mg/mL can be stored for long periods at 4°C with no loss of activity but for extended storage −20°C is recommended.

4. Notes

1. Some antigens will consistently fail to induce an antibody response in certain animals, and other species should be investigated as potential donors. In very rare occasions antigens will not elicit an immune response in a range of species and the nature of the antigen will then have to be investigated with a view to modifying it to increase its immunogenicity.
2. Female rabbits are less aggressive, and although smaller and yielding smaller quantities of antiserum are preferable to male rabbits for antiserum production. Many biomedical facilities use communal floor pens for donor animals and female rabbits adapt better to this form of housing.
3. The use of excessive amounts of antigen in immunizations should be avoided, as this can lead to a poor immunological response. Overloading the immune system can lead to selective deletion of the B cell clones of interest and a reduction in the specific antibody titer. High doses of antigen in the secondary and subsequent immunizations can cause anaphylactic shock and death of the donor animal.
4. It has been reported that increased stress levels in animals can depress the immune response, and appropriate measures should be taken to ensure that immunizations and bleeds are performed with the minimum of stress to the animals. General husbandry in terms of housing, noise levels, and other environmental factors should also be examined to ensure that animals for polyclonal production are maintained under suitable conditions.

Production of Antibodies Using Proteins in Gel Bands

Sally Ann Amero, Tharappel C. James, and Sarah C. R. Elgin

1. Introduction

A number of methods for preparing proteins as antigens have been described ***(1)***. These include solubilization of protein samples in buffered solutions (**ref. *2*** and *see* Chapter 169), solubilization of nitrocellulose filters to which proteins have been adsorbed (**ref. *3*** and *see* Chapter 171), and emulsification of protein bands in polyacrylamide gels for direct injections ***(4–8)***. The latter technique can be used to immunize mice or rabbits for production of antisera or to immunize mice for production of monoclonal antibodies ***(9–11)***. This approach is particularly advantageous when protein purification by other means is not practical, as in the case of proteins insoluble without detergent. A further advantage of this method is an enhancement of the immune response, since polyacrylamide helps to retain the antigen in the animal and so acts as an adjuvant ***(7)***. The use of the protein directly in the gel band (without elution) is also helpful when only small amounts of protein are available. For instance, in this laboratory, we routinely immunize mice with 5–10 μg total protein using this method; we have not determined the lower limit of total protein that can be used to immunize rabbits. Since polyacrylamide is also highly immunogenic, however, it is necessary in some cases to affinity-purify the desired antibodies from the resulting antiserum or to produce hybridomas that can be screened selectively for the production of specific antibodies, to obtain the desired reagent.

2. Materials

1. Gel electrophoresis apparatus; acid-urea polyacrylamide gel or SDS-polyacrylamide gel.
2. Staining solution: 0.1% Coomassie brilliant blue-R (Sigma, St. Louis, MO, B-7920) in 50% (v/v) methanol/10% (v/v) acetic acid.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Destaining solution: 5%-(v/v) methanol/7% (v/v) acetic acid.
4. 2% (v/v) glutaraldehyde (Sigma G-6257).
5. Transilluminator.
6. Sharp razor blades.
7. Conical plastic centrifuge tubes and ethanol.
8. Lyophilizer and dry ice.
9. Plastic, disposable syringes (3- and 1-mL).
10. 18-gage needles.
11. Spatula and weighing paper.
12. Freund's complete and Freund's incomplete adjuvants (Gibco Laboratories, Grand Island, NY).
13. Phosphate-buffered saline solution (PBS): 50 m*M* sodium phosphate, pH 7.25/150 m*M* sodium chloride.
14. Microemulsifying needle, 18-g.
15. Female Balb-c mice, 7–8 wk old, or New Zealand white rabbits.

3. Method

1. Following electrophoresis (*see* **Note 1**), the gel is stained by gentle agitation in several volumes of staining solution for 30 min. The gel is partially destained by gentle agitation in several changes of destaining solution for 30–45 min. Proteins in the gel are then cross-linked by immersing the gel with gentle shaking in 2% glutaraldehyde for 45–60 min ***(12)***. This step minimizes loss of proteins during subsequent destaining steps and enhances the immunological response by polymerizing the proteins. The gel is then completely destained, usually overnight (*see* **Note 2**).
2. The gel is viewed on a transilluminator, and the bands of interest are cut out with a razor blade. The gel pieces are pushed to the bottom of a conical plastic centrifuge tube with a spatula and pulverized. The samples in the tubes are frozen in dry ice and lyophilized.
3. To prepare the dried polyacrylamide pieces for injection, a small portion of the dried material is lifted out of the tube with a spatula and placed on a small square of weighing paper. In dry climates it is useful to first wipe the outside of the tube with ethanol to reduce static electricity. The material is then gently tapped into the top of a 3-mL syringe to which is attached the microemulsifying needle (**Fig. 1A**). Keeping the syringe horizontal, 200 µL of PBS solution is carefully introduced to the barrel of the syringe, and the plunger is inserted. Next, 200 µL of Freund's adjuvant is drawn into a 1-mL tuberculin syringe and transferred into the needle end of a second 3-mL syringe (**Fig. 1B**). This syringe is then attached to the free end of the microemulsifying needle. The two plungers are pushed alternatively to mix the components of the two syringes (**Fig. 1C**). These will form an emulsion within 15 min; it is generally extremely difficult to mix the material any further.
4. This mixture is injected intraperitoneally or subcutaneously into a female Balb-c mouse, or subcutaneously into the back of the neck of a rabbit (*see* **refs. *13*** and ***14***). Since the emulsion is very viscous, it is best to use 18–g needles and to anesthesize the animals. For mice, subsequent injections are administered after 2 wk and after

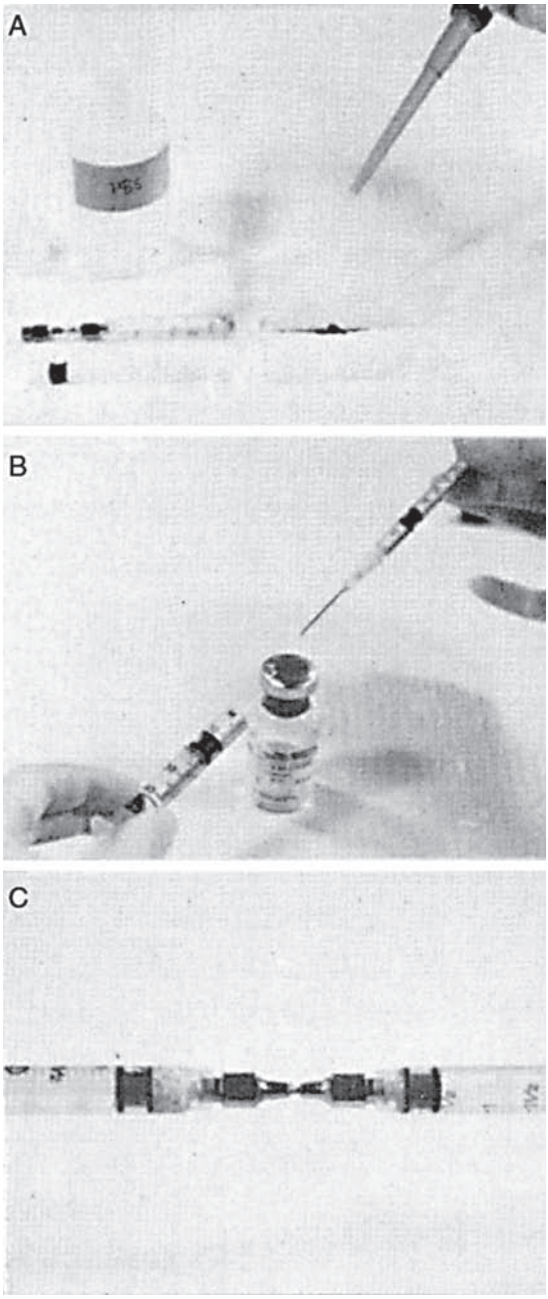

Fig. 1. Preparation of emulsion for immunizations. To prepare proteins in gel bands for injections, an emulsion of Freund's adjuvant and dried polyacrylamide pieces is prepared. **(A)** Dried polyacrylamide is resuspended in 200 µL of PBS solution in the barrel of a 3-mL syringe to which is attached a microemulsifying needle. **(B)** Freund's adjuvant is transferred into the barrel of a second 3-mL syringe. **(C)** An emulsion is formed by mixing the contents of the two syringes through the microemulsifying needle.

3 more wk. If monoclonal antibodies are desired, the animals are sacrificed 3–4 d later, and the spleen cells are fused with myeloma cells (**ref. *13***). The immunization schedule for rabbits calls for subsequent injections after 1 mo or when serum titers start to diminish. Antiserum is obtained from either tail bleeds or eye bleeds from the immunized mice, or from ear bleeds from immunized rabbits. The antibodies are assayed by any of the standard techniques (*see* Chapters 204 and 205).

4. Notes

1. We have produced antisera to protein bands in acetic acid–urea gels (*see* Chapter 27), Triton–acetic acid–urea gels ***(15, 16)*** (*see* Chapter 28), or SDS–polyacrylamide gels (*see* Chapter 21). In our experience, antibodies produced to proteins in one denaturing gel system will crossreact to those same proteins fractionated in another denaturing gel system and will usually crossreact with the native protein. We have consistently obtained antibodies from animals immunized by these procedures.
2. It is extremely important that all glutaraldehyde be removed from the gel during the destaining washes, since any residual glutaraldehyde will be toxic to the animal. Residual glutaraldehyde can easily be detected by smell. It is equally important to remove all acetic acid during lyophilization. Monoacrylamide is also toxic, whereas polyacrylamide is not. We do observe, however, that approx 50 mm^2 of polyacrylamide per injection is the maximum that a mouse can tolerate.
3. Freund's complete adjuvant is used for the initial immunization; Freund's incomplete adjuvant is used for all subsequent injections. The mycobacteria in complete adjuvant enhance the immune response by provoking a local inflammation. Additional doses of mycobacteria may be toxic.
4. High-titer antibodies have been produced from proteins in polyacrylamide gel by injecting the gel/protein mixture into the lumen of a perforated plastic golf ball implanted subcutaneously in rabbits ***(17)***. This approach places less stress on the animal, as complete adjuvants need not be used, and bleeding is eliminated. The technique has also been used in rats.

Raising Highly Specific Polyclonal Antibodies Using Biocompatible Support-Bound Antigens

Monique Diano and André Le Bivic

1. Introduction

Highly specific antibodies directed against minor proteins, present in small amounts in biological fluids, or against insoluble cytoplasmic or membraneous proteins, are often difficult to obtain. The main reasons for this are the small amounts of protein available after the various classical purification processes and the low purity of the proteins.

In general, a crude or partially purified extract is electrophoresed on an SDS-polyacrylamide (SDS-PAGE) gel; then the protein band is lightly stained and cut out. In the simplest method, the acrylamide gel band is reduced to a pulp, mixed with Freund's adjuvant, and injected. Unfortunately, this technique is not always successful. Its failure can probably be attributed to factors such as the difficulty of disaggregating the acrylamide, the difficulty with which the protein diffuses from the gel, the presence of SDS in large quantities resulting in extensive tissue and cell damage, and finally, the toxicity of the acrylamide.

An alternative technique is to extract and concentrate the proteins from the gel by electroelution but this can lead to loss of material and low amounts of purified protein. Another technique is to transfer the separated protein from an SDS-PAGE gel to nitrocellulose. The protein-bearing nitrocellulose can be solubilized with dimethyl sulfoxide (DMSO), mixed with Freund's adjuvant, and injected into a rabbit. However, although rabbits readily tolerate DMSO, mice do not, thus making this method unsuitable for raising monoclonal antibodies.

To obtain highly specific antibodies the monoclonal approach has been considered as the best technique starting from a crude or partially purified immunogen. However, experiments have regularly demonstrated that the use of highly heterogeneous material for immunization never results in the isolation of

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

clones producing antibodies directed against all the components of the mixture. Moreover, the restricted specificity of a monoclonal antibody that usually binds to a single epitope of the antigenic molecule is not always an advantage. For example, if the epitope is altered or modified (i.e., by fixative, Lowicryl embedding, or detergent), the binding of the monoclonal antibody might be compromised, or even abolished.

Because conventional polyclonal antisera are complex mixtures of a considerable number of clonal products, they are capable of binding to multiple antigenic determinants. Thus, the binding of polyclonal antisera is usually not altered by slight denaturation, structural changes, or microheterogeneity, making them suitable for a wide range of applications. However, to be effective, a polyclonal antiserum must be of the highest specificity and free of irrelevant antibodies directed against contaminating proteins, copurified with the protein of interest and/or the proteins of the bacterial cell wall present in the Freund's adjuvant. In some cases, the background generated by such irrelevant antibodies severely limits the use of polyclonal antibodies.

A simple technique for raising highly specific polyclonal antisera against minor or insoluble proteins would be of considerable value.

Here, we describe a method for producing polyclonal antibodies, which avoids both prolonged purification of antigenic proteins (with possible proteolytic degradation) and the addition of Freund's adjuvant and DMSO. Two-dimensional gel electrophoresis leads to the purification of the chosen protein in one single, short step. The resolution of this technique results in a very pure antigen, and consequently, in a very high specificity of the antibody obtained. It is a simple, rapid, and reproducible technique. Two-dimensional (2D) electrophoresis with ampholines for the isoelectric focusing (IEF) is still considered by most as time consuming and technically demanding. The introduction, however, of precast horizontal Ampholines or Immobilines IEF gels has greatly reduced this objection. Moreover, the development of 2D gel databases and the possibility to link it to DNA databases (Swiss-2D PAGE database) ***(1)*** further increases the value of using 2D electrophoresis to purify proteins of interest. Our technique was tested using two kinds of supports, nitrocellulose and polyvinylidene fluoride (PVDF), for the transfer of the protein. Both supports were tested for biocompatibility in rats and rabbits and were readily tolerated by the animals. Because PVDF is now used routinely for the analysis of proteins and peptides by mass spectrometry, it was of primary importance to test this as a prerequisite.

Even if 2D electrophoresis is a time-consuming technique it actually allows one to isolate several antigens in the same experiment, which is very important for applications such as maps of protein expression between wild-type and mutant cells or organisms or identification of proteins belonging to an isolated functional complex.

A polyclonal antibody, which by nature cannot be monospecific, can, if its titer is very high, behave like a monospecific antibody in comparison with the low titers of irrelevant antibodies in the same serum. Thus, this method is faster and performs better than other polyclonal antibody techniques while retaining all the advantages of polyclonal antibodies.

2. Materials

1. For 2D gels, materials are those described by O'Farrell ***(2,3)*** and Laemmli ***(4)***. It should be noted that for IEF, acrylamide and *bis*-acrylamide must be of the highest level of purity, and urea must be ultrapure (enzyme grade) and stirred with Servolit MB-1 from Serva (0.5 g of Servolit for 30 g of urea dissolved in 50 mL of deionized water) as recommended by Görg ***(5)***.
2. Ampholines with an appropriate pH range, for example, 5–8 or 3–9.
3. Transfer membranes: 0.45-µm BA 85 nitrocellulose membrane filters (Schleicher and Schull GmBH, Kassel, Germany); 0.22-µm membranes can be used for low molecular weight antigenic proteins.
4. Transfer buffer: 20% methanol, 150 m*M* glycine, and 20 m*M* Tris, pH 8.3.
5. Phosphate-buffered saline (PBS), sterilized by passage through a 0.22-µm filter.
6. Ponceau red: 0.2% in 3% trichloroacetic acid.
7. Small scissors.
8. Sterile blood-collecting tubes, with 0.1 *M* sodium citrate, pH 6, at a final concentration of 3.2%.
9. Ultrasonication apparatus, with 100 W minimum output. We used a IOO-W ultrasonic disintegrator with a titanium exponential microprobe with a tip diameter of 3 mm (1/8 in.). The nominal frequency of the system is 20 kc/s, and the amplitude used is 12 p.

3. Methods

This is an immunization method in which nitrocellulose-bound protein purified by 2D electrophoresis is employed and in which *neither DMSO nor Freund's adjuvant* is used, in contrast to the method described by Knudsen ***(6)***. It is equally applicable for soluble and membrane proteins.

3.1. Purification of Antigen

In brief, subcellular fractionation of the tissue is carried out to obtain the fraction containing the protein of interest. This is then subjected to separation in the first dimension by IEF with Ampholines according to O'Farrell's technique or by covalently bound Immobilines gradients. Immobilines allow a better resolution by generating narrow pH gradients (<1 pH unit), a larger loading capacity, and a greater tolerance to salt and buffer concentrations. At this point, it is important to obtain complete solubilization of the protein (*see* **Note 1**).

Separation in the second dimension is achieved by using an SDS polyacrylamide gradient gel.

The proteins are then transferred from the gel to nitrocellulose (*7*, and *see* Chapters 58–60). It is important to work with gloves when handling nitrocellulose to avoid contamination with skin keratins.

3.2. Preparation of Antigen for Immunization

1. Immerse the nitrocellulose sheet in Ponceau red solution for 1–2 min, until deep staining is obtained, then destain the sheet slightly in running distilled water for easier detection of the spots. **Never let the nitrocellulose dry out.**
2. Carefully excise the spot corresponding to the antigenic protein. Excise inside the circumference of the spot to avoid contamination by contiguous proteins (*see* **Fig. 1**).
3. Immerse the nitrocellulose spot in PBS in an Eppendorf tube (1 mL size). The PBS bath should be repeated several times until the nitrocellulose is thoroughly destained. The last bath should have a volume of about 0.5 mL, adequate for the next step.
4. Cut the nitrocellulose into very small pieces with scissors. Then rinse the scissors into the tube with PBS to avoid any loss (*see* **Fig. 2**).
5. Macerate the nitrocellulose suspension by sonication. The volume of PBS must be proportional to the surface of nitrocellulose to be sonicated. For example, 70–80 µL of PBS is adequate for about 0.4 cm^2 of nitrocellulose (*see* **Notes 3** and **4**).

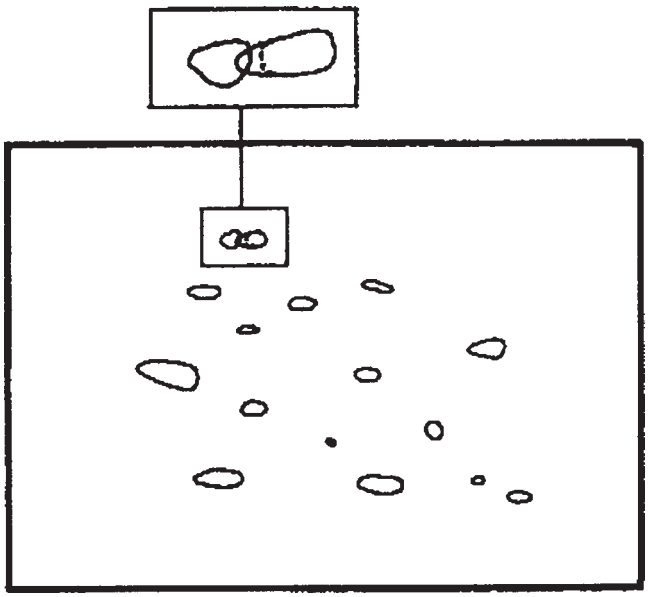

Fig. 1. Excision of the spot containing the antigen. Cut inside the circumference, for instance, along the dotted line for the right spot.

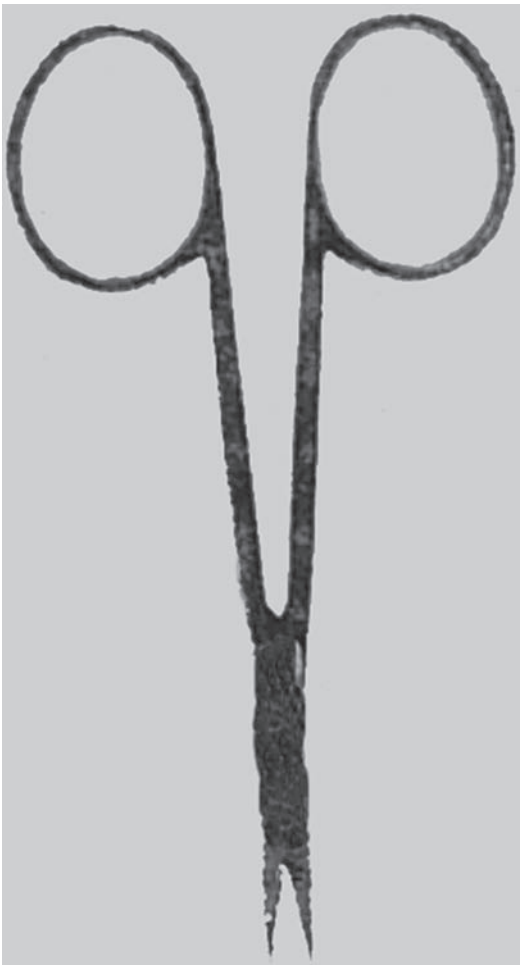

Fig. 2. Maceration of nitrocellulose.

6. After sonication, add about 1 mL of PBS to the nitrocellulose powder to dilute the mixture, and aliquot it in 500-, 350-, and 250-µL fractions and freeze these fractions at −80°C until use. Under these storage conditions, the aliquots may be used for immunization for up to 1 yr, or perhaps longer. Never store the nitrocellulose without buffer. Never use sodium azide because of its toxicity.

3.3. Immunization

1. Shave the backs of the rabbits or rats. Routinely inject two rabbits or two rats with the same antigen.
2. Thaw the 500-µL fraction for the first immunization and add 1.5–2 mL of PBS to reduce the concentration of nitrocellulose powder.

3. Inoculate the antigen, according to Vaitukaitis ***(8)***, into 20 or more sites (Vaitukaitis injects at up to 40 sites). Inject subcutaneously, holding the skin between the thumb and forefinger. Inject between 50 and 100 µL (a light swelling appears at the site of injection). As the needle is withdrawn, compress the skin gently. An 18-gauge hypodermic needle is routinely used, though a finer needle (e.g., 20- or 22-gauge) may also be used (*see* **Note 5**). Care should be taken over the last injection; generally, a little powder remains in the head of the needle. Thus, after the last injection, draw up 1 mL of PBS to rinse the needle, resuspend the remaining powder in the syringe, and position the syringe vertically to inject it.
4. At 3 or 4 wk after the first immunization, the first booster inoculation is given in the same way. The amount of protein injected is generally less, corresponding to two thirds of that of the first immunization.
5. At 10 d after the second immunization, bleed the rabbit (*see* **Note 6**). A few milliliters of blood is enough to check the immune response against a crude preparation of the injected antigenic protein. The antigen is revealed on a Western blot with the specific serum diluted at 1:500 and a horseradish peroxidase-conjugated or alkaline phosphatase-conjugated second antibody. We used 3,3′ -diaminobenzidine tetrahydrochloride (DAB) for color development of peroxidase activity or the NBC-BCIP or the Western blue stabilizer (from Promega) for color development of phosphatase activity. If the protein is highly antigenic, the beginning of the immunological response is detectable.
6. At wk 2 after the second immunization, administer a third immunization in the same way as the first two, even if a positive response has been detected. If there was a positive response after the second immunization, one half of the amount of protein used for the original immunization is sufficient.
7. Bleed the rabbits 10 d after the third immunization and every week thereafter. At each bleeding, check the serum as after the second immunization, but the serum should be diluted at 1:4000 or 1:6000. Bleeding can be continued for as long as the antibody titer remains high (*see* **Note 7**). Another booster should be given when the antibody titer begins to decrease if it is necessary to obtain a very large volume of antiserum (*see* **Note 7**).
8. After bleeding, keep the blood at room temperature until it clots. Then collect the serum and centrifuge for 10 min at 3000*g* to eliminate microclots and lipids. Store aliquots at –22°C.

4. Notes

1. To ensure solubilization, the following techniques are useful:
   a. The concentration of urea in the mixture should be 9–9.5 *M*, that is, close to saturation.
   b. The protein mixture should be frozen and thawed at least 6×. Ampholines should be added only after the last thawing because freezing renders them inoperative.

c. If the antigenic protein is very basic and outside the pH range of the Ampholines, it is always possible to carry out NEPHGE (nonequilibrium pH gradient electrophoresis) for the first dimension ***(9)***.
d. A significant improvement using horizontal IEF is the possibility to load the sample at any place on the gel allowing to carry out in a single experiment both NEPHGE and IEF.

2. If the antigenic protein is present in small amounts in the homogenate, it is possible to save time by cutting out the part of the IEF gel where the protein is located and depositing several pieces of the first-dimension gel side by side on the second-dimension gel slab (*see* **Fig. 3**).
3. Careful attention should be paid to temperature during preparation of the antigen; always work between 2 and 4°C. Be particularly careful during sonication; wait 2–3 min between consecutive sonications. It helps to dip the eppendorf tube containing the nitrocellulose in liquid nitrogen until it is frozen and then to thaw it between each cycle of sonication.
4. This is a crucial point in the procedure. If too much PBS is added, the pieces of nitrocellulose will swirl around the probe and disintegration does not occur. In this case, the nitrocellulose pieces should be allowed to settle to the bottom of the tube before sonication and the excess buffer drawn off with a syringe or other suitable instrument (70–80 µL of PBS is sufficient for about 0.4 cm^2 of nitrocellulose). For these quantities, one or two 10-s cycles suffice to get powdered nitrocellulose. We mention the volume as a reference since the surface of nitrocellulose-bound antigen may vary.

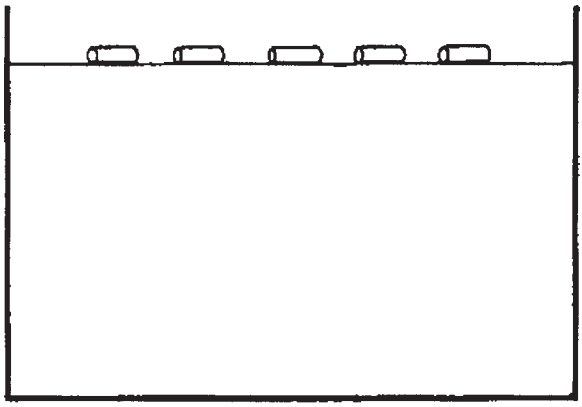

Fig. 3. Second dimension with several IEF gels. Several IEF gels are cut, 0.5 cm above and 0.5 cm below the isoelectric point of the protein of interest. They are placed side by side at the top of the second dimension slab gel. Thus, only one SDS gel is needed to collect several spots of interest.

In every case the volume of PBS must be adjusted. We experienced that PVDF is more resistant to sonication than nitrocellulose and thus several cycles of freezing and thawing are necessary.

5. What is an appropriate amount of antigenic protein to inject? There is no absolute answer to this question. It depends both on the molecular weight of the protein and also on its antigenicity. It is well known that if the amount of antigen is very low (0.5–1 µg for the classic method with Freund's adjuvant), there is no antibody production; if the amount of antigen is very high (e.g., several hundred micrograms of highly antigenic protein), antibody production might also be blocked.

   It would appear that in our method, a lower amount of antigen is required for immunization; the nitrocellulose and PVDF act as if they progressively release the bound protein, and thus, the entire amount of protein is used progressively by the cellular machinery.

   Our experiments show that a range of 10–40 µg for the first immunization generally gives good results, although, in some cases, 5 µg of material is sufficient. The nitrocellulose powder has the additional effect of triggering an inflammatory process at the sites of injection, thus enhancing the immune response, as does Freund's adjuvant by means of the emulsion of the antigenic protein with the tubercular bacillus; macrophages abound in the inflamed areas.
6. It is perhaps worth noting that careful attention should be paid to the condition of the rabbit at time of bleeding. We bleed the rabbits at the lateral ear artery. When the rabbit is calm, 80–100 mL of blood may be taken. The best time for bleeding is early in the morning, and after the rabbit has drunk. Under these conditions, the serum is very clear. It is essential to operate in a quiet atmosphere. If the rabbit is nervous or under stress, the arteries are constricted so strongly that only a few drops of blood can be obtained. Note that to avoid clotting, the needle is impregnated with a sterile sodium citrate solution by drawing the solution into the syringe 3×. The atmosphere in the animal room should be also stressless for the rats to obtain enough blood.
7. When the effective concentration required corresponds to a dilution of 1:2000, the titer is decreasing. Serum has a high titer if one can employ a dilution >1:2000 and if there is a strong specific signal without any background.
8. We have also immunized mice with nitrocellulose-bound protein by intraperitoneal injection of the powder. This is convenient when time and material are very limited, since very little protein is needed to induce a response (3–5× less than for a rabbit) and since the time lag for the response is shorter (the second immunization was 2 wk after the first, and the third

immunization, 10 d after the second). Mice have a high tolerance for the nitrocellulose powder. Unfortunately, the small amount of serum available is a limiting factor. This technique for immunizing mice can, of course, be used for the preparation of monoclonal antibodies. For people who need to raise antibodies against *Drosophila melanogaster* proteins, rats are better hosts than rabbits (mice too with the above restrictions). Nitrocellulose is injected on the top of the shoulder of the rats. The foot pad is also adequate as a site of priming injection for small quantities. Blood is collected from the tail.

9. Utilization of serum. The proper dilutions are determined. We routinely use 1:4000 for blots, 1:300–1:200 for immunofluorescence, and 1:50 for immunogold staining. Serum continues to recognize epitopes on tissue proteins after Lowicryl embedding. Labeling is highly specific, and gives a sharp image of *in situ* protein localization. *There is no need to purify the serum*. IgG purified from serum by whatever means usually gives poorer results than those obtained with diluted serum. Purification procedures often give rise to aggregates and denaturation, always increase the background, and result in loss of specific staining.
10. Bacterial antigenic protein. When antibodies are used in screening cDNA libraries in which the host is *Escherichia coli*, the antibodies produced against bacterial components of Freund's adjuvant may also recognize some *E. coli* components. An advantage of our technique is that it avoids the risk of producing antibodies against such extraneous components.
11. Is nitrocellulose antigenic? Some workers have been unable to achieve good results by immunization with nitrocellulose-bound protein. They reproducibly obtain antibodies directed against nitrocellulose. We found out that it is the result from injecting powdered nitrocellulose in Freund's adjuvant; using adjuvant actually increases the production of low-affinity IgM that binds nonspecifically to nitrocellulose. We have never observed this effect in our experiments when the technique described here was followed strictly. The same observations applied to PVDF membranes.
12. The purification step by 2D electrophoresis implies the use of denaturing conditions (SDS), and thus is not appropriate for obtaining antibodies directed against native structures. For that purpose, the protein should be transferred onto nitrocellulose after purification by classical nondenaturing methods and gel electrophoresis under nondenaturing conditions. However, it should be pointed out that, following the method of Dunn ***(10)***, it is possible partially to renature proteins with modifications of the composition of the transfer buffer.
13. Second dimension electrophoresis can be carried out with a first electrophoresis under native conditions, followed by a second electrophoresis

under denaturing conditions, that is, with SDS. Because the resolution provided by a gradient is better, it should always be used in the 2D electrophoresis. Agarose may also be used as an electrophoresis support.

14. If only a limited amount of protein is available, and/or if the antigen is weakly immunogenic, another procedure may be used. The first immunization is given as a single injection, of up to 0.8 mL, into the popliteal Iymphatic ganglion ***(10)***, using a 22-gauge needle, that is, the finest that can be used to inject nitrocellulose powder. In this case, the antigen is delivered immediately into the immune system. If necessary, both ganglions can receive an injection. The small size of the ganglions limits the injected volume. The eventual excess of antigen solution is then injected into the back of the rabbit, as described in Methods. The boosters are given in the classic manner, that is, in several subcutaneous injections into the rabbit's back. If the amount of protein available is even more limited, a guinea pig may be immunized (first immunization in the Iymphatic ganglion, and boosters, as usual).
15. The advantage of getting a high titer for the antibody of interest is that the amount of irrelevant antibodies is, by comparison, very low and, consequently, does not generate any background. Another advantage of using a crude serum with a high antibody titer is that this serum may be used without further purification to screen a cDNA expression library ***(12)***.
16. The time required for transfer and the intensity used are dependent on the molecular weight and the nature of the protein to be transferred (hydrophilic or hydrophobic). During transfer, the electrophoresis tank may be cooled with tap water. We, however, prefer semidry transfer, which is time and buffer saving and cooling is not necessary.

Production of Antisera Using Peptide Conjugates

Thomas E. Adrian

1. Introduction

Because an immunogen requires both an antigenic site and a T-cell receptor binding site, a minimum size is necessary ***(1)***. Natural immunogens have a molecular weight >5000. Synthetic fragments of proteins may be able to bind to the surface of B cells, but do not stimulate an immune response. Such molecules are known as haptens. A hapten is an incomplete immunogen but can be made immunogenic by coupling to a suitable carrier molecule. A variety of different cross-linking agents are utilized for coupling of peptides to carrier proteins; examples of each type are covered in this chapter. In the case of larger fragments (approximately 40 amino acids), it may be possible to stimulate an immune response by presenting the peptide together with a carrier such as polyvinylpyrrolidone without the need for conjugation. This method, which is also described in this chapter, has proven to be useful for the author for a number of different peptides. Unfortunately, however, the success of this method compared with the responses to conjugated peptides is largely a matter of trial and error, and peptide fragments of this size are expensive to produce.

2. Materials

2.1. Synthetic Peptides as Haptens

There is considerable advantage to be gained by using synthetic peptides as haptens. First, it is possible to raise region-specific antibodies directed perhaps to one end, or the active site of a protein. Second, it is possible to insert particular amino acids with specific side chains for coupling. For example, a peptide can be synthesized with an extra cysteine residue at one end of the molecule to enable coupling using sulfo-SMCC ***(2)***. Alternatively, a tyrosine residue can be inserted that will enable specific coupling through the *bis*-diazotized benzidine reaction ***(3)***.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

This latter approach is valuable because the same synthetic peptide can then serve as a radioligand for metabolic studies, for receptor binding, or for a radioimmunoassay, with the assurance that the antibodies raised will not be directed toward the tyrosine residue that will be iodinated ***(3)***.

2.2. Protein Carriers

Factors governing the choice of the carrier include immunogenicity, solubility, and availability of functional groups for cross-linking. Although substances such as mucopolysaccharides, poly-L-lysine, and polyvinylpyrrolidone have been used as carriers, proteins are more widely used. Common protein carriers include serum albumin, ovalbumin, hemocyanin, and thyroglobulin. To find the very best immunogen it would be ideal to prepare conjugates with several different carriers with a range of hapten to carrier coupling ratios (*see* **Note 1**). The cost and time involved will usually make this impractical, however, and it is therefore necessary to carefully select the carrier most suitable for a particular antigen. In the classical hapten carrier system T lymphocytes recognize processed carrier determinates and cooperate with B cells which produce hapten-specific antibody response. Note that the amounts of carrier and peptide for conjugation are given in molar terms in the following conjugation protocols. This is necessary because of the wide variation in the molecular weights of potential carriers and neuropeptides to be coupled. The carrier protein represented by 100 nmol is approx 7 mg of bovine albumin, 4.5 mg of ovalbumin, 15 mg of γ-globulin, and 70 mg of thyroglobulin.

2.2.1. Bovine Serum Albumin

Because of its wide availability, high solubility, and relatively high number of coupling sites albumin is a popular choice as a carrier for weakly antigenic compounds. Albumin has a molecular weight of 67,000 and has 59 lysine residues providing primary amines useful for conjugation. A drawback in the use of albumin for conjugation is that it is frequently used in immunoassays as a non-specific blocking protein. Anti-albumin antibodies induced by its use as a carrier protein can result in false positive results in such systems.

2.2.2. Ovalbumin

Ovalbumin (egg albumin) also has wide availability, as it is the primary protein constituent of egg white. This protein is smaller than serum albumin with a molecular weight of 45,000, but contains 20 lysine residues, 14 aspartic acid, and 33 glutamic acid residues for conjugation ***(4)***. Ovalbumin exists as a single polypeptide chain with an isoelectric point of 4.6. Half of its 400 residues are hydrophobic. Caution should be exercised in handling of albumin, as it is denatured at temperatures above 56°C or even by vigorous shaking.

2.2.3. Hemocyanin

Keyhole limpit hemocyanin (KLH) is a copper-containing protein that belongs to a family of nonheme proteins found in arthropods and mollusca. KLH exists in five different aggregate states at neutral pH that will dissociate into subunits above pH 9.0 ***(5)***. KLH is a valuable carrier protein because of its large molecular mass (approx 1×10^6 to 1×10^7) and numerous lysine groups for coupling. This property of dissociation at high pH can be utilized because it increases the availability of angiogenic sites, and this can produce improved antigenic responses ***(5)***. The disadvantage of using KLH as a carrier protein is its poor water solubility. Although this makes the protein difficult to handle, it does not impair its immunogenicity.

2.2.4. Thyroglobulin

Thyroglobulin is another large molecular weight protein with a limited solubility. The advantage of thyroglobulin as a carrier comes from its large content of tyrosine residues which can be used for conjugation using the diazo reaction. The molecular weight of thyroglobulin is 670,000.

2.3. Coupling Agents

Chemical coupling agents or cross-linkers are used to conjugate small peptide haptens to large protein carriers. The most commonly used cross-linking agents have functional groups that couple to amino acid side chains of peptides (*see* **Table 1**). A host of different cross-linkers are commercially available, each with different characteristics regarding chemical groups that they are reactive toward, pH of coupling, solubility, and ability to be cleaved. The most comprehensive listing of coupling reagents is found in the Pierce catalog (Pierce, Rockford, IL; http://www.piercenet.com). This user friendly website now includes a table of all the available cross-linking agents (called: "Crosslinkers at a Glance") and a crosslinker selection guide to identify suitable coupling agents for specific linkage sites. Several things need to be taken into consideration when selecting a bifunctional coupling reagent. First is the selection of functional groups; this can be used to produce a specific type of conjugate. For example, if the only primary amine available is in the amino-(N)-terminal end of a peptide, then a coupling agent can be selected to specifically couple in this position, leaving the carboxyl (C)-terminal end of the peptide free and available as an antigenic site. Of course, a synthetic peptide can be engineered to contain an amino acid with a specific side chain available for coupling. This is usually placed at one end of the peptide, again making the other end available as an antigenic site. Second is the length of the cross bridge; the presence of a spacer arm may make the hapten more available and therefore produce a better immune response. Third is whether the cross-linking groups are the same (homobifunctional) or different

(heterobifunctional). Once again this can alter the specificity of the coupling reaction. The last consideration is whether the coupling reaction is chemical or photochemical. For a good antigenic response it is necessary to maintain the native structure of the protein complex, and this can be achieved only using mild buffer conditions and near neutral pH. The reactive groups that can be targeted using cross-linkers include primary amines, sulfhydryls, carbonyl, and carboxylic acids (*see* **Note 2**). It is difficult to predict the proximity of protein–peptide interactions. The use of bifunctional reagents with spacer arms can prevent steric hindrance and make the hapten more available for producing a good immune response.

2.3.1. Carbodiimide

Carbodiimide condenses any free carboxyl group (nonamidated C-terminal aspartate or glutamate residue) or primary amino group (N-terminal or lysyl residue), to form a peptide bond (CO–NH). The most commonly used water-soluble carbodiimide is 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (CDI or EDC). This coupling agent is very efficient and easy to use and usually couples at several alternative points on a peptide, giving rise to a variety of antigenic responses ***(6)***. Because of the unpredictable nature of the antibody responses, using this bifunctional agent the process has been termed "shotgun immunization." If it is necessary to raise antisera to a particular region of the peptide then this is not the method of choice. Furthermore, because the peptide bond linking the hapten to the carrier cannot rotate and holds the hapten physically close, steric hindrance is considerable.

Carbodiimide reacts with available carboxyl groups to form an active *O*-acylurea intermediate, which is unstable in aqueous solution, making it ineffective in two-step conjugation procedures. This intermediate then reacts with the primary amine to form an amide derivative. Failure to immediately react with an amine results with hydrolysis of the intermediate. Furthermore, hydrolysis of CDI itself is a competing reaction during the coupling and is dependent on temperature 4-morphylinoethansulfonic acid (MES) can be used as an effective carbodiimide reaction buffer in place of water. Phosphate buffers reduce the efficiency of the CDI reaction, although this can be overcome by increasing the amount of CDI used to compensate for the reduction and efficiency. Loss of efficiency of the CDI reaction is even greater with Tris, glycine, and acetate buffers, and therefore use of these these should be avoided.

2.3.2. Glutaraldehyde

Glutaraldehyde links primary amino groups (either the N-terminal or lysyl residues) on both the peptide hapten and the carrier. This linkage allows free

rotation of the hapten, which reduces possible steric hindrance which may otherwise block access to the immune system by the large carrier molecule.

2.3.3. Sulfo-Succinimidyl 4-(N-maleimidomethyl) Cyclohexane-1-Carboxylate (Sulfo-SMCC)

A peptide with a free sulfhydryl group, such as a synthetic peptide with a terminal cysteine residue, provides a highly specific conjugation site for reacting with sulfo-SMCC. This cross-linker contains a maleimide group that reacts with free sulfhydryl groups, along with an *N*-hydroxysuccinimidyl ester group that reacts with primary amines ***(2)***. All peptide molecules coupled using this chemistry display the same basic antigenic conformation. They have a known and predictable orientation leaving the molecule free to interact with the immune system. This method can preserve the major epitopes on a peptide while enhancing the immune response. The water solubility of sulfo-SMCC, along with its enhanced maleimide stability, makes it a favorite for hapten carrier conjugation.

2.3.4. Bis-diazotized Benzidine

Bis-diazonium salts bridge tyrosyl or hystidyl residues between the hapten and carrier. Overnight treatment of benzidine at 4°C with nitrous acid (hydrochloric acid and sodium nitrite) results in the two amino groups being diazotized. These two diazonium groups allow coupling at both ends of the molecule. Although limited in coupling points, diazotized benzidine provides a spacer arm holding the hapten away from the carrier and usually results in an excellent antigenic response.

2.4. Adjuvants

The adjuvant is important for inducing an inflammatory response. The author has had continuous success over two decades using Freund's adjuvant. Various synthetic adjuvants are available such as AdjuPrime (Pierce) and Ribi Adjuvant System (Ribi Immunochemicals) ***(7)***. The author has had very limited success with the latter adjuvant, when used to immunize with several different small peptides. In contrast, responses with Freund's adjuvant run in parallel have always been good.

The conjugate is injected in the form of an emulsion made with Freund's adjuvant, which is a mixture of one part of detergent (Arlacel A, Sigma Chemicals) with four parts of *n*-hexadecane. This permits slow release of the coupled hapten into the circulation and may serve to protect labile antigens from degradation. Freund's adjuvant alone ("incomplete") causes an inflammatory response that stimulates antibody formation, and when made "complete" by addition of 1 mg/mL of heat-killed *Mycobacterium butyricum*, this response is further enhanced. It is convenient to purchase complete and incomplete Freund's adjuvant ready mixed (Sigma Chemicals or Calbiochem).

When preparing the emulsion, care should be taken to ensure that the oil remains in the continuous phase. Injection of aliquots of the aqueous conjugate solution into the oil via a fine bore needle, followed by repeated aspiration and ejection of the crude emulsion, will produce the required result. An alternative for making the emulsion is to use a homogenizer, although the generator should be retained specifically for this purpose to avoid subsequent peptide contamination. A simple test for the success of the preparation is to add a drop of the emulsion to the surface of water in a tube. The emulsion should stay in a single droplet without dispersing; confirming that it is immiscible and thus oil-phasec ontinuous.

2.5. Choice of Animal for Immunization

Several factors need to be considered when choosing animal species for an immunization program, including cost, ease of handling and the volumes of antisera required (*see* **Note 3**). Small animals (such as rats and mice) have low blood volumes and present difficulties with bleeding. Large animals such as sheep or goats are expensive to house particularly over long periods. Rabbits or guinea pigs provide a near optimal solution, as they are relatively cheap to house and bleeding an ear vein or cardiac puncture in guinea pigs can provide between 10 and 30 mL of plasma from each bleed. For production of monoclonal antibodies immunization of mice is required.

3. Methods

3.1. Carbodiimide Procedure

1. Dissolve the peptide to be coupled (400 nmol) and protein carrier (100 nmol) in a small volume of water (<1 mL if possible) (*see* **Note 4**).
2. Add carbodiimide (200 mmol, 50 mg) to this solution.
3. Incubate the mixture overnight at 4°C (*see* **Notes 5** and **6**).

3.2. Glutaraldehyde Procedure

1. Dissolve the peptide (400 nmol) and carrier protein (100 nmol) in 1 mL of 0.1 *M* phosphate buffer, pH 7.5 (*see* **Note 4**).
2. Add glutaraldehyde (30 mmol, 1.5 mL of a 0.02 M solution) dropwise for 15 min.
3. Incubate the mixture overnight at 4°C (*see* **Notes 5** and **6**).

3.3. Sulfo-SMCC Procedure

1. Activate the carrier (100 nmol) by conjugating the active ester of sulfo-SMCC (2 µmol) via an amino group, in phosphate-buffered saline (PBS), pH 7.2 (with 5 m*M* EDTA) for 60 min at room temperature. This reaction results in the formation of an amide bond between the protein and the cross-linker with the release of sulfo-N-hydroxysuccinimidyl ester as a by product.

2. If desired the carrier protein can then isolated by gel filtration to remove excess reagent using a gel such as Sephadex G25 (*see* **Note 5**). Desalt by eluting the column with PBS, collecting 0.5-mL fractions. Locate the protein peak using a protein assay (Bio-Rad micro method).
3. At this stage the purified carrier possesses modifications generated by the cross-linker, resulting in a number of maleimide groups projecting from its surface. The maleimide group of sulfo-SMCC is stable for several hours in solution at physiological pH. Therefore, even after activation and purification the greatest possible activity will still be left for conjugation with the peptide.
4. The maleimide group of sulfo-SMCC reacts at pH 7.0 with free sulfhydryls on the peptide to form a stable thioether bond. The peptide (100 nmol) with a free sulfhydryl group is incubated with the maleimide-activated carrier in 1 mL of PBS (with 5 m*M* EDTA) for 2 h (or overnight if more convenient) at 4°C (*see* **Note 6**).
5. Keep sulfo-SMCC away from moisture since it is subject to hydrolysis.

3.4. Diazo Procedure

1. Freshly prepare *bis*-diazotized benzidine on each occasion in the following manner: dissolve benzidine hydrochloride (80 mmol, 20.5 mg) in 10 mL of 0.18 *M* HCl and gently mix overnight with 1 mL of 0.16 *M* $NaNO_2$ (11 mg). This reaction should take place in an ice bath inside a cold room, and the temperature should never be allowed to rise above 4°C.
2. Dissolve the peptide (400 nmol) in 130 µL (1 µmol) of fresh *bis*-diazotized benzedine solution.
3. Add $NaHCO_3$ (40 µmol, 3.4 mg) followed immediately by the addition of the carrier predissolved in a minimal volume of aqueous solution (carrier protein 100 nmol) at 4°C.
4. Adjust the pH to 9.8 with NaOH using a microelectrode.
5. Incubate the mixture overnight at 4°C (*see* **Notes 5** and **6**).

3.5. Immunization Without Conjugation to Carrier Protein

1. This procedure, using polyvinylpyrrolidone as a noncovalent carrier, can be very valuable for peptide antigens with more than 40 amino acid residues. Good results have been obtained with 30–40 amino acid peptides, but it is unlikely to produce useful antisera with smaller antigens. As well as being quick and easy, it has the added advantage of retaining tertiary peptide structure.
2. Dissolve the peptide in aqueous solution containing a 100 *M* excess of polyvinylpyrrolidone (with respect to peptide concentration).
3. Emulsify the solution in Freund's adjuvant in the same manner as with peptide conjugates.

3.6. Making an Emulsion in Freund's Adjuvant

1. Dissolve conjugate in water (between 10 and 100 nmol of conjugated peptide/mL, 1 mL for each rabbit being immunized).

2. Make Freund's adjuvant by mixing one part of Arlacel A with four parts of *n*-hexadecane (allowing a little more than 1 mL per rabbit).
3. For primary injections only "complete" Freund's adjuvant is used. This is made by addition of 1 mg/mL of heat-killed mycobacteria. (Boosts are given in incomplete Freund's.)
4. When preparing the emulsion, care should be taken to ensure that the oil remains in the continuous phase. Injection of aliquots of the aqueous conjugate solution into the oil via a fine bore needle, followed by repeated aspiration and ejection of the crude emulsion, will produce the required result.
5. A simple test for the success of the preparation is to add a drop of the emulsion to the surface of water in a tube. The emulsion should stay in a single droplet without dispersing, confirming that it is immiscible and thus oil-phase continuous.

3.7. Immunization Procedure

The emulsified conjugate can be administered in a variety of ways. For rabbits, the most frequently used are multiple (30–50) intradermal injections in the neck or back region, by four subcutaneous injections into each groin and axilla (0.5) ***(8)***. The latter is the method we have successfully adopted for more than 20 yr. Injection into the footpads, which was at one time commonly employed, provides no advantage in terms of antibody response and should be avoided to prevent distress to the animals.

The procedure is as follows:

1. Bleed the animals and collect preimmune serum for later comparison with antisera produced by the immunization procedure.
2. Primary inoculations are given in complete Freund's adjuvant, 0.5 mL of emulsion into each groin and axilla.
3. Booster injections are given at 2–4-wk intervals, in the same manner but with incomplete Freund's adjuvant. The optimum is probably about 4 wk, but time constraints and cost may necessitate a shorter immunization schedule. With small synthetic haptens three to five, or even more boosts may be required to produce the desired high titer or high avidity antibody (*see* **Notes 7** and **8**).
4. After the first and subsequent boosts blood should be collected from an ear vein to test for the antibody titer and avidity.

3.8. Antibody Characterization for Radioimmunoassay

1. Serial dilutions of antisera are incubated with radiolabeled peptide under routine assay conditions to determine a working dilution.
2. The maximum displacement of radioactively labeled hormone from the antibody by the minimum amount of unlabeled peptide (the maximum displacement slope) is one of the main criteria for radioimmunoassay sensitivity.
3. Rapid screening for slope can be achieved by the addition of small amounts (usually about 10 fmol) of standard peptide to one set of a series of replicate antiserum dilutions set up to determine the antiserum titer. The amount of standard used should reflect the useful range (e.g., the concentration at which a hormone circulates).

4. Antibody heterogeneity may be due to use of nonhomogeneous antigens for immunization, polymerization or degradation of the hapten or carrier after coupling, or individual differences in the lymphocytic response to the antigen ***(9)***.
5. Existence of heterogeneity can be revealed by Scatchard analysis. However, for high titer antisera there is frequently effectively only a single class of antibody that predominates in the reaction. Other populations of lower concentrations and avidities make insignificant contributions.
6. Specificity should be tested using related peptides.

4. Notes

1. The ratio of hapten reactive with protein is usually arranged to be in excess of 4?1 to achieve better antigenicity with respect to the hapten. Some authorities prefer ratios as high as 40?1 but in our experience this gives a lower affinity antibody response. This is presumably due to conjugation between hapten molecules rather between hapten and carrier. The hapten and protein carriers should be both present in high concentration to increase the efficiency of the cross-linking between the molecules.
2. Coupling of a hapten at a specific site gives more chance of governing which part of the peptide becomes the antigenic determinant for the antibody, as the particular area of peptide where coupling occurs is likely to be hidden from immune surveyance.
3. Success in raising antisera is to some extent a hit and miss affair. Some workers have needed to immunize many animals to produce useful antisera, whereas three or four rabbits may produce the desired product in another immunization program. This depends, in part, on the antigenicity of the peptide and on the goals set for sensitivity and specificity. Some peptides are particularly susceptible to proteolysis (such as members of the vasoactive intestinal polypeptide family) or oxidation (such as cholecystokinin). In general, these less stable peptides make relatively poor antigens.
4. Usually the coupling agent is added after the hapten and carrier have been mixed together to minimize self-polymerization of either component.
5. Although not usually necessary, excess unreacted hapten and toxic byproducts may be removed by dialysis or gel permeation chromatography.
6. Quantification of the success of the coupling reaction is conveniently obtained by addition of a small amount of radioactively labeled hapten to the mixture prior to adding the coupling agent. Thus before and after the reaction small aliquots are removed and chromatographed. Small disposable columns contain Sephadex G-25 (Pharmacia) are ideal for this purpose. Proportion of radiation diluting in the high molecular weight position, together with the carrier, indicates the amount of coupling achieved.

7. If a particular animal has been boosted three or four times without producing detectable antibody, then the likelihood of it subsequently doing so is small and further effort is unprofitable.
8. On other occasions when animals do show a response but further boosting results in little improvement in avidity or titer, then variation in the coupling method for subsequent boosts can help. Changes including a different carrier protein or the cross-linking agent, or both, may result in production of a higher titer or more avid antisera.

Small-Molecule–Protein Conjugation Procedures

Stephen Thompson

1. Introduction

The conjugation of small molecules (SM) to proteins is required in many areas of medical diagnostics and research. Many molecules are simply too small to elucidate an immune response, and they have to be coupled to a carrier protein such as bovine serum albumin (BSA) or keyhole limpet hemocyanin (KLH) in order to form antigenic conjugates. Even after polyclonal (or monoclonal) antibodies have been raised to the small molecule, similar SM–enzyme conjugates are required for competitive immunoassays in which the antibodies are used to coat an enzyme-linked immunosorbent assay (ELISA) plate. Alternatively, the SM–protein conjugates can be used to coat the ELISA plate, but then the detecting antibody has to be labeled. Indeed, labeled antibodies and antigens are required in the vast majority of the diagnostic techniques discussed in this book.

It is often impossible or extremely expensive to obtain the required conjugates. This chapter therefore concentrates on the general procedures (**Subheading 3**) that can be used to couple SM carboxyl (**Subheading 3.1.1**), hydroxyl (**Subheading 3.1.2**), and amine (**Subheading 3.1.3**) residues to proteins and the analysis of the resulting conjugates. The coupling of biotin to proteins is specifically demonstrated in **Subheading 3.1.1**. Biotinylated antigens and antibodies are often used in medical diagnosis, as biotin can easily be further complexed with commercial avidin and streptavidin conjugates.

Protein–protein conjugation is sometimes required to elucidate an effective immune response. A large diagnostic antibody, marker, or protein may not be immunogeneic, as it is a natural product. However, KLH can be conjugated to it to increase its immunogenicity. Protein–protein coupling is also required to make antibody–enzyme conjugates and bispecific antibodies. A second section is therefore included that discusses antibody–KLH (**Subheading 3.2.1**),

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

antibody–enzyme (**Subheading 3.2.2**), and antibody–antibody (**Subheading 3.2.3**) conjugations for the sake of completeness. Although many of the principles discussed in **Subheadings 3.1.1–3.1.3** are equally applicable to the formation of protein–protein conjugates, all such protein–protein conjugations have to be carried out in aqueous solutions to prevent denaturization/deactivation of the proteins. This second section is therefore also highly relevant in the conjugation of SM, which are only soluble in aqueous solutions to proteins.

2. Materials

1. Dry organic solvents: dioxan, dimethylformamide (DMF), and dimethyl sulfoxide (DMSO). These are all bought over molecular sieves to minimize their water content.
2. Proteins: BSA, alkaline phosphatase (AP), KLH. (mc-KLH from Pierce is both very soluble and has a well-defined molecular weight.)
3. 1-Ethyl-3-(3-dimethylamino-propyl)carbodiimide (EDC).
4. N-hydroxysuccinamide (NHS).
5. 1,3-Dicyclohexylcarbodiimide (DCC).
6. Biotin.
7. Carbonyldiimidazole (CDI).
8. Phosgene (Fluka).
9. p-Maleimidophenyl isocyanate (PMPI).
10. P10 desalting column (Pharmacia).
11. N-(maleimidocaproyloxy)succinimide ester (EMCS).
12. Vitamin B12.
13. Sodium dodecyl sulfate (SDS).
14. S-acetylthioglycolic acid NHS-ester (SATA).
15. 3-(2-Pyridyldithio)propionic acid NHS-ester (SPDP).

3. Methods

3.1. Small Molecule Coupling to Proteins

3.1.1. Small Molecule Carboxyl Residues

Carboxylic acid groups are normally coupled to protein amine groups using carbodiimide condensation reagents. These react with carboxylic acids to form highly reactive mixed anhydride and isourea esters ***(1,2)***. There are two major practical problems. The first is that carbodiimides are quite unstable, especially in the presence of water. The second is that the activated derivatives they form with acid groups ***(1,2)*** are even less stable, hydrolyzing in fractions of a second ***(3)***, often before you have time to add the activated SM to the protein. Luckily, most SMs (vitamins, dyes, and so on) and carbodiimides are soluble in dry organic solvents, which gets us round the first problem. The second problem can be overcome by adding NHS to the SM before the carbodiimide is added. This reacts with the SM–isourea acid derivatives as they are formed to give

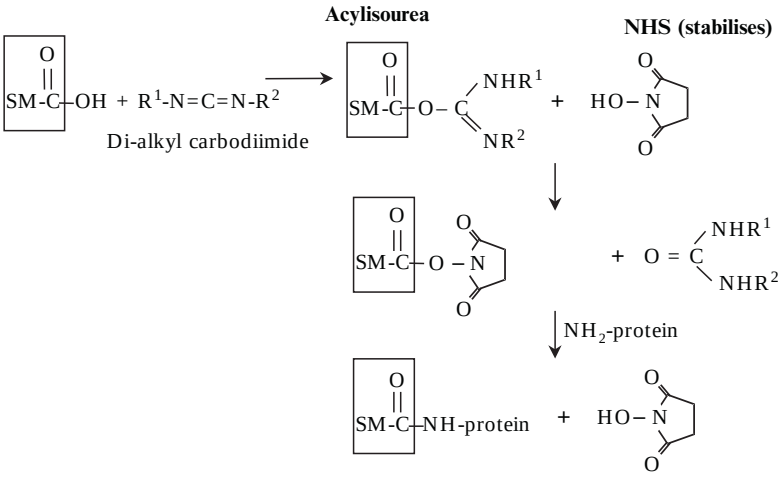

Fig. 1. The reactions involved in coupling a SM-carboxylic acid residue to a protein.

rise to activated NHS esters. These intermediates are stable indefinitely in dry conditions and have a half-life of approx 40 min in aqueous solutions ***(3)***. These activated esters can then be added to proteins in aqueous solutions and react with protein amine groups to form SM–protein amide bonds and free NHS (**Fig. 1**). If the SM is only soluble in water, the water soluble carbodiimide EDC has to be used, (normally added at twice the concentration of the SM), with the NHS added before the EDC.

A typical example of the conjugation procedure is given below using biotin, BSA, and two different carbodiimides.

3.1.1.1. Biotin-BSA Conjugation

1. Suspend 10 mg biotin in 1 mL of dry dioxan or DMF.
2. Divide into two halves and add 250 µL of NHS (10 mg/mL) to each 500-µL aliquot.
3. Add 250 µL of either EDC or DCC (both at 16 mg/mL) to each aliquot and leave for 1 h to react. As the NHS and carbodiimides are dissolved in the same dry organic solvent, this solution of activated biotin–NHS esters is stable indefinitely if kept in dry solution (*see* **Note 1**).
4. Add varying amounts of either the EDC or DCC NHS-activated biotin solutions (20, 50, or 100 µL) to 1-mL aliquots of BSA (10 mg/mL in 0.1 *M* sodium bicarbonate) and leave for 16 h to react (*see* **Note 2**).
5. Dialyze the biotin-BSA conjugates exhaustively against phosphate-buffered saline to remove uncoupled reaction products.

The formation of biotin–BSA conjugates can be confirmed by nondenaturing electrophoresis of the conjugates in 8% polyacrylamide gels (**Fig. 2, lane 4**)

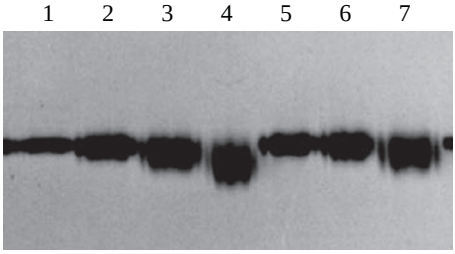

Fig. 2. The migration of BSA-Biotin conjugates in an 8% polyacrylamide gel.

All lanes contain 5 ug BSA. Lane 1 contains unconjugated BSA. Lanes 2–4 contain BSA-Biotin conjugates made when 20, 50 and 100 ul of EDC activated Biotin-NHS were added to BSA. Lanes 5–7 contain BSA-Biotin conjugates made by the addition of the same amounts of DCC activated Biotin.

using the discontinuous buffer system of Laemmli ***(5)*** without SDS. As more biotin is bound, the negative charge on the BSA increases (owing to loss of the positively charged NH_2 groups), and the conjugates migrate faster. Slightly more conjugation can be obtained with EDC than DCC with approx one, four, and eight residues of biotin bound to BSA in each conjugate.

It is normally fairly easy to determine how many SM residues are conjugated to a protein by comparing the OD of the substituted protein with the OD of the unsubstituted protein (**Fig. 3**). Unfortunately, biotin has no easily measured absorbance value. This is why the formation of conjugates was verified by electrophoresis. ELISA assays with labeled avidin were also used to confirm the presence of conjugates.

It is very easy to couple an SM to a protein residue via a spacer arm using this technique (*see* **Note 3**).

3.1.2. Small-Molecule Hydroxyl Residues

3.1.2.1. Using Carbonyldiimidazole

It is generally accepted that carbonyldiimidazole (CDI) can be used to couple hydroxyl residues to proteins in a manner similar to that discussed above for carboxylic acid residues. The CDI is added as above at an equimolar concentration to the SM in dry solvent for 2 h, and then aliquots are added to protein in 0.1 *M* sodium bicarbonate for up to 16 h. For example, dioxigenin can be bound to BSA using CDI, and it is possible to couple the light-sensitive protecting group 2-nitrobenzylalcohol to BSA ***(6)***. However, the secondary alcohol, 2-nitrobenzyl ethanol, cannot be coupled to proteins by this method ***(6)***. As this is a simple and cheap procedure, it should be attempted, but it will not always work.

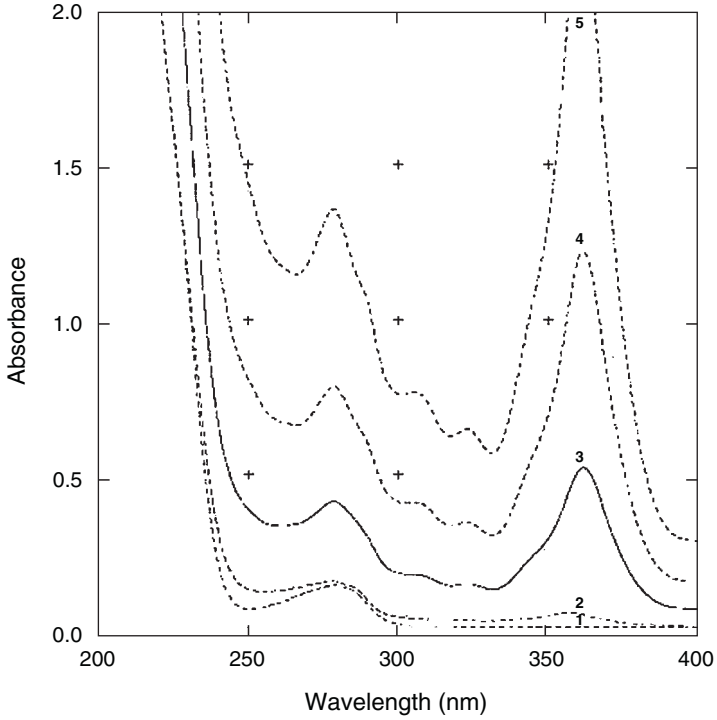

Fig. 3. Spectrophotometric scans (1–5) of Vitamin B_{12}-BSA conjugates (at 0.2 mg/ml) made by the addition of increasing amounts of Vitamin B_{12}-chloroformate (0, 1, 8, 25 and 50 mg) to 10 mg BSA.

3.1.2.2. Prederivitization of the Hydroxyl Residue

It is much easier to conjugate a hydroxyl group to proteins if it is first chemically modified prior to conjugation. This can easily be done by converting the hydroxyl groups to highly reactive chloroformates by treating them with equimolar amounts of diphosgene in dry dioxan in the presence of pyridine as a catalyst. The resulting chloroformates are highly reactive and spontaneously couple to protein amine groups at pH >7.5 ***(6)***. Although the chloroformates are highly reactive toward protein amine groups, they also hydrolyze rapidly in aqueous solutions. Therefore, they are normally added in large excess to the protein. A typical example of this procedure is given below in which vitamin B_{12} is coupled to BSA:

1. Suspend 84 mg of vitamin B12 in 250 µL of dry dioxan with 6 µL of pyridine and 8 µL of diphosgene. The vitamin immediately changes color from red to purple (*see* **Note 4**).

2. Leave the mixture for 15 min to react.
3. Evaporate unreacted materials.
4. Resuspend the chloroformates in 250 µL of dry solvent.
5. Add approx 1, 8, 25, and 50 mg of the B12–chloroformate to 2 mL aliquots of BSA (5 mg/mL in 0.1 *M* bicarbonate) and leave for 4 h to react.
6. Dialyze the B12–BSA conjugates for 2 d against PBS to remove uncoupled B12 and unwanted reaction products.

The pink solutions can then be measured by scanning spectrophotometry (**Fig. 3**), and the amount of vitamin coupled can be measured by the increase in absorbance at 280 nm, or more accurately by measuring the absorbance at 360 nm that was only due to B_{12}. In this case, the four conjugates were found to contain 0.1, 1.1, 2.8, and 5.2 mg of B_{12}, which represented approx 0.5, 7, 22, and 30 molecules of B_{12} bound to each BSA molecule. The covalent bonding of the vitamin groups can be confirmed by using the conjugates in competitive ELISA assays.

3.1.2.3. Utilizing a Commercial Linker Containing a Hydroxyl-Specific Isocyanate Group

There is one commercial linker, PMPI, which can be used to couple hydroxyl residues to protein sulfhydryl groups *(7)*. One end of the linker consists of an isocyanate group, which is normally first coupled at equimolar concentrations to the SM hydroxyl residue in dry organic solvents. The other end is a maleimide residue, which couples to free protein sulfhydryl groups in aqueous buffers between pH 6.5 and 7.5.

3.1.3. Small Molecule Amine Residues

SMs containing an amine residue can be coupled to proteins by simply reversing the above carbodiimide reaction. NHS is added to the protein, and it is then treated with a large excess of the water-soluble carbodiimide (EDC) to generate NHS activated carboxylic acid residues in the proteins. The NHS maintains the protein solution at around pH4.5 hence preventing the protein crosslinking to its own amine groups as they are protonated. This procedure is discussed in much greater practical detail in **Subheading 3.2.1**. The SM (dissolved in 0.1 *M* bicarbonate) is then added and left to couple for 2–16 h. After extensive dialysis, conjugation can be confirmed by spectrophotometry or non-denaturing electrophoresis. Here, however, conjugated proteins would migrate more slowly due to their loss of carboxylic acid residues.

If the SM is insoluble in water, then it can be coupled to a commercial crosslinker, which contains an NHS-activated ester at one end. This is done by simply adding the SM to the linker at an equimolar ratio for 24 h in dry DMF or DMSO. This type of linkage is also required when the protein (antibody

or enzyme) loses its activity after it is treated with EDC. I have found this to happen with AP. This type of crosslinker can also be used to create a spacer arm between the SM and the protein, but as they are more commonly used to couple antibodies and enzymes together, their practical use is described below in **Subheadings 3.2.2** and **3.2.3**.

3.2. The Formation of Protein-Protein Conjugates

Protein–protein conjugates can be made by most of the procedures already discussed. However, there is one critical difference. Proteins have to be coupled in aqueous solutions in order to prevent their denaturization, precipitation, and loss of functional activity. In practical terms, this means that the organic solvents often needed to dissolve the carbodiimides and commercial linkers should never exceed 10% of the final reaction volumes.

3.2.1. Antibody–KLH Conjugates

Antibody–KLH conjugates can be used to increase the murine–murine immune response to an antibody above and beyond that obtained solely by changing the mouse strains ***(8)***. The simplest way to prepare such conjugates is to use the water-soluble carbodiimide EDC at a large molar excess to allow for the rapid hydrolysis of both the EDC and its reactive intermediates. It is now absolutely essential to include NHS in reaction mixtures prior to the addition of the carbodiimide ***(3)***. I normally treat the antibody with the carbodiimide for 15 min to activate its carboxylic acid groups and then add the activated antibody to the KLH to enable it to bind to the KLH amine groups as described below.

1. Dialyze 1 mg (0.5–3 mL) of monoclonal antibody against distilled water for at least 4 h at 0°C. This is done to remove all preservatives (e.g., azide), and buffers containing carboxylic acid and amine groups.
2. Prepare one vial of mcKLH (20 mg in 5 mL) by dialysis against 0.1 *M* bicarbonate for the same length of time.
3. Add 5 mg of NHS to the antibody followed by 2 mg EDC. Leave for 15 min to activate carboxylic acid groups.
4. Add 800 µL (approx 3 mg) of the KLH solution to the above and leave this antibody/KLH mixture to conjugate overnight. This should result in a roughly 1:1 complex given the molecular weights of IgG and KLH as 165 and 480 K, respectively.
5. Dialyze the conjugate against 0.9% saline for 24 h.

Conjugation can be confirmed by electrophoresis in SDS in 5% polyacrylamide gels (**Fig. 4**). The complexes (b and c) are at a much higher molecular weight than the KLH (a) and the monoclonal antibody (d and e; note: probably two antibodies!) starting components. Given the low intensity of staining of b and c, most of the complexes do not even penetrate the gel.

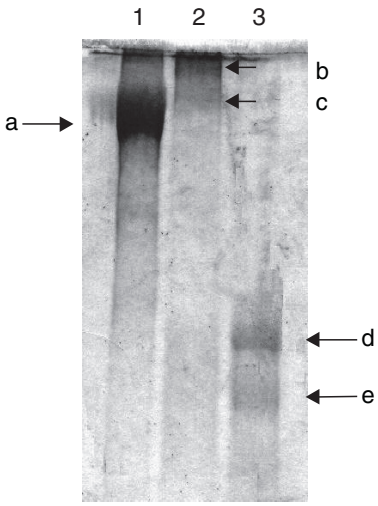

Fig. 4. The conjugation of Antibody to KLH. Lanes 1, 2, and 3 contain 15 ug mcKLH, 20 ug of antibody-KLH conjugates and 5 ug of unconjugated antibody respectively.

3.2.2. Antibody–Enzyme Conjugates

It is possible to conjugate antibodies to enzymes exactly as is given for KLH in **Subheading 3.2.1**. However, the carbodiimide-derivatized antibody can lose much of its activity. The complexes can contain several crosslinked molecules of each component! The only thing you can control is the ratio of each component to another compound. Most antibody–enzyme conjugates are therefore produced in more precise conditions using well-defined crosslinkers. The most popular consist of an NHS-ester linked to a maleimide group via a spacer arm ***(9)***. The spacer can be a benzene ring [*m*-maleimidobenzoyl-NHS ester (MBS)], cyclohexane [succinimidyl 4-(*n*-maleimido-methyl)-cyclohexane-1-carboxylate (SMCC)], or various lengths of nonaromatic carbon chain (EMCS). The selection of an appropriate spacer is very important. Rigid cyclic and aromatic spacers are themselves highly immunogeneic ***(9)***. Nonrigid carbon spacers have very little immunogenicity ***(9)***, and their flexibility can greatly enhance the sensitivity of competitive enzyme-linked immunosorbent assay (ELISAs) ***(10)*** when they are used to link SM to AP or horseradish peroxidase. NHS-esters link to primary amines at pH 7–9, whereas the maleimide groups react with sulfhydryl groups at pH 6.5–7.5. An antibody–AP conjugation procedure is given below as an example.

1. Dissolve 1–2 mg of the IgG in 1 mL 50 m*M* phosphate buffer, pH 7.0, containing 10 m*M* EDTA (*see* **Note 5**).
2. Reduce specifically at the hinge region by the addition of 2-mercaptoethylamine (6 mg in 100 µL buffer) for 90 min at 37°C.
3. Separate the reduced antibody from the reducing agent on a P10 desalting column using the same phosphate buffer containing EDTA. If 1-mL fractions are eluted,

the reduced antibody normally elutes in the fourth and fifth tubes and is stable for several hours in the presence of EDTA.

4. Dissolve one vial of AP (10,000 units, approx 4 mg) in 1 mL distilled water and prepare for coupling by dialyzing against 50 m*M* phosphate, pH 7.5, to remove amine-containing buffers and preservatives (*see* **Note 6**).
5. Dissolve 1 mg of the crosslinker (EMCS) in 100 µL DMSO and add immediately to the dialyzed AP (*see* **Note 7**).
6. Leave 30 min (no longer!) for the amine groups of the AP to couple to the NHS-ester end of the linker.
7. Remove excess unreacted linker on a P10 column.
8. Add the AP-EMCS fraction immediately to the reduced antibody and leave the final mixture for 2–16 h for the reduced antibody to react with the maleimide end of the EMCS–AP complex.
9. Dialyze to remove the EDTA from the antibody–EMCS–AP conjugate.

The antibody–EMCS–AP conjugate is checked by SDS electrophoresis in an 8% polyacrylamide gel (**Fig. 5**). Very little unreacted antibody and AP can be seen in lane 4.

3.2.3. Antibody–Antibody Conjugates

Antibody–antibody conjugates are prepared in exactly the same way as for anti-body–AP conjugates, which have just been described. Equal amounts of each antibody are used. The only problem to be considered is that one of the antibodies has to be linked via its amine groups. This can inactivate an antibody when the antibody has a susceptible amine residue in its binding region. However, a highly susceptible antibody is always reduced and linked via its hinge sulfhydryl residue to the maleimide group. It is unlikely that both antibodies would be susceptible to a loss in activity when they are linked through their amine residues. Some workers prefer to use the thiolating groups SATA ***(11)***, SPDP ***(12)***, and Trauts' reagent [iminothilane ***(13)***] to introduce sulfhydryl groups into antibodies and enzymes rather than use a reducing agent. All these agents react spontaneously with protein amine residues in aqueous solutions. Two reagents, SATA and SPDP, produce protected sulfhydryl residues, which can be released when required for crosslinking; the third directly incorporates a free SH group, but this can be unstable under certain conditions ***(14)***.

4. Notes

1. This is by far the most commonly used coupling procedure. Always use SM and carbodiimides in dry organic solvents at 1:1 molar ratios to activate the carboxyls. If the SM is only soluble in water, a large excess of EDC (around 50X) is required, and the stabilizing NHS has to be added before you add the carbodiimide.

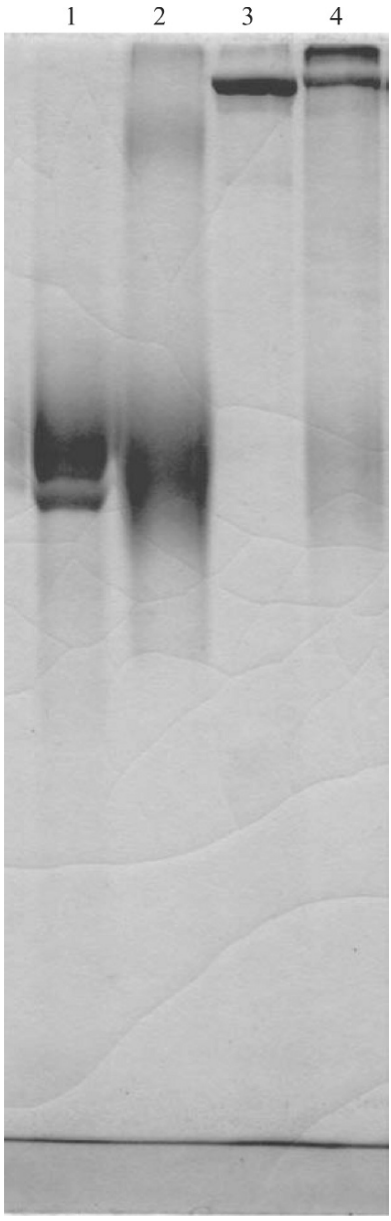

Fig. 5. The conjugation of a monoclonal antibody to AP using EMCS. Lane 1 contains AP, lane 2 contains AP treated with EMCS, lane 3 contains ed antibody and lane 4 contains the antibody-AP conjugates cross-linked by the EMCS.

2. The NHS-activated SM is always added in a large molar excess (20–50-fold) to the protein, and the extent of coupling required is discovered by trial and error. A pH > 7.0 is required to enable the activated ester to couple to the protein amine groups, as they have to be de-protonated to be able to

react. At 0.1 *M*, sodium bicarbonate has a pH of 8.3 and is a convenient and simple coupling solution.

3. It is very easy to couple an SM to a protein residue via a spacer arm using this technique. The NHS-activated SM in dry organic solvent is added to an equimolar solution of 6-aminocaproic acid (also in dry solvent) and left overnight. A peptide bond is formed with the amine residue on the caproic acid just as it would be with proteins, but here it is still in dry organic solvent. The SM acid group is now coupled via a five-carbon chain to another carboxylic acid. SM-COOH + 2HN-(CH2)5-COOH in the presence of DCC and NHS results in SM-CONH-(CH2)5-COOH. Another cycle of NHS and carbodiimide is added, and the SM–(CH2)5-CO–NHS-activated ester group is then coupled to the protein via the spacer. Alternatively, as this linker is formed in dry organic solutions, several cycles can be performed, and thus any length linker can be made, prior to the SM being coupled to the protein ***(10)***.
4. Although this is a quick and reliable method of derivatizing hydroxyl residues, diphosgene dissociates into phosgene gas, which is very dangerous. Handle very carefully in a fume hood!
5. It is very important that EDTA be present in the solutions used to reduce the antibody and in the P10 elution of the reduced antibody or it will reoxidize.
6. **It is also essential that the NHS-ester amine coupling to the enzyme be carried out at pH 7.5**. If a higher pH is used (e.g., the more normal 0.1 *M* bicarbonate buffer, pH 8.3 for 1–2 h), the maleimide group at the other end of the linker rapidly hydrolyzes. It is then impossible to bind the maleimide end of the linker to the reduced antibody in the second stage. The crosslinker maleimide group only has a half-life of 30 min at pH > 7.5. A large excess of linker at pH 7.5 and a short reaction time (20–30 min) followed by a quick separation (of unreacted linker) in a P10 column is used to reduce this problem. Lower temperatures can also be used to reduce the rate of maleimide hydrolysis. Maleimide hydrolysis while the first protein/enzyme is coupling via its amine groups is the major problem associated with maleimide-spacer-NHS-ester crosslinkers. A five-carbon straight chain linker was used in this example (EMCS), but three other linkers [MBS, SMCC, and N-(γ-maleimidobutyryloxy) succinimide ester (GMBS)] have successfully been used in an identical procedure.
7. More expensive sulfo-NHS derivatives of the above crosslinkers can be used if necessary. Their use is promoted because they are soluble in water. There are usually no problems using the normal linkers predissolved in a small amount of DMSO. However, some proteins and enzymes are extremely sensitive to the presence of organic solvents, and

the sulpho-crosslinker derivatives could then be directly substituted into the conjugation procedure.

The Chloramine T Method for Radiolabeling Protein

Graham S. Bailey

1. Introduction

Many different substances can be labeled by radioiodination. Such labeled molecules are of major importance in a variety of investigations, e.g., studies of intermediary metabolism, determinations of agonist and antagonist binding to receptors, quantitative measurements of physiologically active molecules in tissues and biological fluids, and so forth. In most of those studies, it is necessary to measure very low concentrations of the particular substance, and that in turn, implies that it is essential to produce a radioactively labeled tracer molecule of high specific radioactivity. Such tracers, particularly in the case of proteins, can often be conveniently produced by radioiodination.

Two γ-emitting radioisotopes of iodine are widely available, ^{125}I and ^{131}I. As γ-emitters, they can be counted directly in a well-type crystal scintillation counter (commonly referred to as a γ counter) without the need for sample preparation in direct contrast to β-emitting radionuclides, such as ^{3}H and ^{14}C. Furthermore, the count rate produced by 1 g atom of ^{125}I is approx 75 and 35,000 times greater than that produced by 1 g atom of ^{3}H and ^{14}C, respectively. In theory, the use of ^{131}I would result in a further sevenfold increase in specific radioactivity. However, the isotopic abundance of commercially available ^{131}I rarely exceeds 20% owing to contaminants of ^{127}I, and its half-life is only 8 d. In contrast, the isotopic abundance of ^{125}I on receipt in the laboratory is normally at least 90% and its half-life is 60 d. Also, the counting efficiency of a typical well-type crystal scintillation counter for ^{125}I is approximately twice that for ^{131}I. Thus, in most circumstances, ^{125}I is the radionuclide of choice for radioiodination.

Several different methods of radioiodination of proteins have been developed ***(1,2)***. They differ, among other respects, in the nature of the oxidizing agent for converting $^{125}I^-$ into the reactive species $^{125}I_2$ or $^{125}I^+$. In the main, those reactive species substitute into tyrosine residues of the protein, but substitution into

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

other residues, such as histidine, cysteine, and tryptophan, can occur in certain circumstances. It is important that the reaction conditions employed should lead on average to the incorporation of one radioactive iodine atom/molecule of protein. Greater incorporation can adversely affect the biological activity and antigenicity of the labeled protein.

The chloramine T method, developed by Hunter and Greenwood ***(3)***, is probably the most widely used of all techniques of protein radioiodination, and is used extensively for the labeling of antibodies. It is a very simple method in which the radioactive iodide is oxidized by chloramine T in aqueous solution. The oxidation is stopped after a brief period of time by addition of excess reductant. Unfortunately, some proteins are denatured under the relatively strong oxidizing conditions, so other methods of radioiodination that employ more gentle conditions have been devised, e.g., the lactoperoxidase method (*see* Chapter 175).

2. Materials

1. Na ^{125}I: 37 MBq (1 mCi) concentration 3.7 GBq/mL (100 mCi/mL).
2. Buffer A: 0.5 *M* sodium phosphate buffer, pH 7.4 (*see* **Note 1**).
3. Buffer B: 0.05 *M* sodium phosphate buffer, pH 7.4.
4. Buffer C: 0.01 *M* sodium phosphate buffer containing 1 *M* sodium chloride, 0.1% bovine serum albumin, and 1% potassium iodide, final pH 7.4.
5. Chloramine T solution: A 2 mg/mL solution in buffer B is made just prior to use (*see* **Note 2**).
6. Reductant: A 1 mg/mL solution of sodium metabisulfite in buffer C is made just prior to use.
7. Protein to be iodinated: A 0.5–2.5 mg/mL solution is made in buffer B.

3. Method

1. Into a small plastic test tube (1 × 5.5 cm) are added successively the protein to be iodinated (10 µL), radioactive iodide (5 µL), buffer A (50 µL), and chloramine T solution (25 µL) (*see* **Notes 3** and **4**).
2. After mixing by gentle shaking, the solution is allowed to stand for 30 s to allow radioiodination to take place (*see* **Note 5**).
3. Sodium metabisulfite solution (500 µL) is added to stop the radioiodination, and the resultant solution is mixed. It is then ready for purification as described in Chapter 178 and **Note 6**.

4. Notes

1. The pH optimum for the iodination of tyrosine residues of a protein by this method is about pH 7.4. Lower yields of iodinated protein are obtained at pH values below about 6.5 and above about 8.5. Indeed, above pH 8.5 the iodination of histidine residues appears to be favored.
2. If the protein is seriously damaged by the use of 50 µg of chloramine T, it may be worthwhile repeating the radioiodination using much less oxidant

(10 µg or less). Obviously, the minimum amount of chloramine T that can be used will depend, among other factors, on the nature and amount of protein to be iodinated.

3. The total volume of the reaction should be as low as practically possible to achieve a rapid and efficient incorporation of the radioactive iodine into the protein.
4. It is normal to carry out the method at room temperature. However, if the protein is especially labile, it may be beneficial to run the procedure at a lower temperature and for a longer period of time.
5. Because of the small volumes of reactants that are employed, it is essential to ensure adequate mixing at the outset of the reaction. Inadequate mixing is one of the most common reasons for a poor yield of radioiodinated protein by this procedure.
6. It is possible to carry out this type of reaction using an insoluble derivative of the sodium salt of *N*-chloro-benzene sulfonamide as the oxidant. The insoluble oxidant is available commercially (Iodo-Beads, Pierce, Rockford, IL). It offers a number of advantages over the employment of soluble chloramine T. It produces a lower risk of oxidative damage to the protein, and the reaction is stopped simply by removing the beads from the reaction mixture, thus avoiding any damage caused by the reductant.

The Lactoperoxidase Method for Radiolabeling Protein

Graham S. Bailey

1. Introduction

This method, introduced by Marchalonis ***(1)***, employs lactoperoxidase in the presence of a trace of hydrogen peroxide to oxidize the radioactive iodide $^{125}I^-$ to produce the reactive species $^{125}I_2$ or $^{125}I^+$. These reactive species substitute mainly into tyrosine residues of the protein, although substitution into other amino acid residues can occur under certain conditions. The oxidation can be stopped by simple dilution. Although the technique should result in less chance of denaturation of susceptible proteins than the chloramine T method, it is more technically demanding and is subject to a more marked variation in optimum reaction conditions.

2. Materials

1. Na ^{125}I: 37 MBq (1 mCi) concentration 3.7 GBq/mL (100 mCi/mL).
2. Lactoperoxidase: available from various commercial sources. A stock solution of 10 mg/mL in 0.1 *M* sodium acetate buffer, pH 5.6, can be made and stored at −20°C in small aliquots. A working solution of 20 µg/mL is made by dilution in buffer just prior to use.
3. Buffer A: 0.1 *M* sodium acetate buffer, pH 5.6 (*see* **Note 1**).
4. Buffer B: 0.05 *M* sodium phosphate buffer containing 0.1% sodium azide, final pH 7.4.
5. Buffer C: 0.05 *M* sodium phosphate buffer containing 1 *M* sodium chloride 0.1% bovine serum albumin and 1% potassium iodide, final pH 7.4.
6. Hydrogen peroxide: A solution of 10 µg/mL is made by dilution just prior to use.
7. Protein to be iodinated: A 0.5–2.5 mg/mL solution is made in buffer A.

It is essential that none of the solutions except buffer B contain sodium azide as antibacterial agent, since it inhibits lactoperoxidase.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Method

1. Into a small plastic test tube (1 × 5.5 cm) are added, in turn the protein to be iodinated (5 µL), radioactive iodide (5 µL), lactoperoxidase solution (5 µL), and buffer A (45 µL).
2. The reaction is started by the addition of the hydrogen peroxide solution (10 µL) with mixing (*see* **Note 2**).
3. The reaction is stopped after 20 min (*see* **Note 3**) by the addition of buffer B (0.5 mL) with mixing.
4. After 5 min, buffer C (0.5 mL) is added with mixing. The solution is then ready for purification as described in Chapter 178 (*see* **Note 4**).

4. Notes

1. The exact nature of buffer A will depend on the properties of the protein to be radioiodinated. Proteins differ markedly in their pH optima for radioiodination by this method ***(2)***. Obviously the pH to be used will also depend on the stability of the protein, and the optimum pH can be established by trial and error.
2. Other reaction conditions, such as amount of lactoperoxidase, amount and frequency of addition of hydrogen peroxide, and so forth, also markedly affect the yield and quality of the radioiodinated protein. Optimum conditions can be found by trial and error.
3. The longer the time of the incubation, the greater the risk of potential damage to the protein by the radioactive iodide. Thus, it is best to keep the time of exposure of the protein to the radioactive iodide as short as possible, but commensurate with a good yield of radioactive product.
4. Some of the lactoperoxidase itself may become radioiodinated, which may result in difficulties in purification if the enzyme is of a similar size to the protein being labeled. Thus, it is best to keep the ratio of the amount of protein being labeled to the amount of lactoperoxidase used as high as possible.

The Bolton and Hunter Method for Radiolabeling Protein

Graham S. Bailey

1. Introduction

This is an indirect method in which an acylating reagent (*N*-succinimidyl-3 [4-hydroxyphenyl]propionate, the Bolton and Hunter reagent), commercially available in a radioiodinated form, is covalently coupled to the protein to be labeled ***(1)***. The [^{125}I] Bolton and Hunter reagent reacts mostly with the side-chain amino groups of lysine residues to produce the labeled protein. It is the method of choice for radiolabeling proteins that lack tyrosine and histidine residues, or where reaction at those residues affects biological activity. It is particularly suitable for proteins that are sensitive to the oxidative procedures employed in other methods.

2. Materials

1. [^{125}I] Bolton and Hunter reagent: 37 MBq (1 mCi), concentration 185 MBq/mL (5 mCi/mL) (*see* **Note 1**).
2. Buffer A: 0.1 *M* sodium borate buffer, pH 8.5.
3. Buffer B: 0.2 *M* glycine in 0.1 *M* sodium borate buffer, pH 8.5.
4. Buffer C: 0.05 *M* sodium phosphate buffer containing 0.25% gelatin.
5. Protein to be iodinated: A 0.5–2.5 mg/mL solution is made in buffer A.

It is essential that none of the solutions contain sodium azide or substances with free thiol or amino groups (apart from the protein to be labeled), since the Bolton and Hunter reagent will react with those compounds.

3. Method

1. The [^{125}I] Bolton and Hunter reagent (0.2 mL) is added to a small glass test tube (1 × 5.5 cm) and is evaporated to dryness under a stream of dry nitrogen.
2. All reactants are cooled in iced water (*see* **Note 2**).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. The protein to be iodinated (10 µL) is added, and the tube is gently shaken for 15 min (*see* **Note 2**).
4. Buffer B (0.5 mL) is added (*see* **Note 3**). The solution is mixed and allowed to stand for 5 min.
5. Buffer C (0.5 mL) is added with mixing (*see* **Note 4**). The resultant solution is then ready for purification.

4. Notes

1. [^{125}I] Bolton and Hunter reagent is available from Amersham International (Little Chalfort, UK) and Dupont NEN (Stevenage, UK). The Amersham product is supplied in anhydrous benzene containing 0.2% dimethylformamide. Aliquots can be easily withdrawn from the vial. However, the Dupont NEN is supplied in dry benzene alone, and dry dimethylformamide (about 0.5% of the sample volume) must be added to the vial with gentle shaking to facilitate the removal of aliquots.
2. [^{125}I] Bolton and Hunter reagent is readily hydrolyzed in aqueous solution. Under the described conditions, its half-life is about 10 min.
3. Buffer B stops the reaction by providing an excess of amino groups (0.2 *M* glycine) for conjugation with the [^{125}I] Bolton and Hunter reagent. Thus, the carrier protein (0.25% gelatin) in buffer C does not become labeled.
4. This method of radioiodination has been used extensively, and various modifications of the described procedure, including time and temperature of the reaction, have been reported ***(2)***. For example, it is possible first to acylate the protein with the Bolton and Hunter reagent, and then carry out radioactive labeling of the conjugate using the chloramine T method. However, in general, this procedure does not seem to offer any advantage over the method described here. Also, the time and temperature of the reaction can be altered to achieve optimal labeling.

Preparation of ^{125}I-Labeled Peptides and Proteins with High Specific Activity Using IODO-GEN

J. Michael Conlon

1. Introduction

The reagent IODO-GEN (1,3,4, 6-tetrachloro-3α, 6α-diphenylglycoluril) was first introduced by Fraker and Speck in 1978 ***(1)*** and rapidly found widespread use for the radioiodination of both peptides and proteins ***(2)***. Although the usual application of the reagent in the laboratory is for introduction of an atom of ^{125}I, IODO-GEN has been used successfully for the preparation of proteins, particularly monoclonal antibodies, labeled with ^{131}I^{124} and ^{123}I for use in immunoscintigraphy and positron emission tomography ***(3–5)***. This chapter addresses only the use of IODO-GEN to radiolabel pure peptides/proteins in aqueous solution, but iodination of proteins on the cell surface of a wide range of intact eukaryotic and prokaryotic cells ***(6,7)*** and on subcellular organelles ***(8)*** and plasma lipoproteins ***(9)*** has been accomplished using the reagent. The advantages of IODO-GEN over alternative reagents previously used for radiolabeling such as chloramine T, lactoperoxidase/hydrogen peroxide, and ^{125}I-labeled Bolton–Hunter reagent (*N*-succinimidyl-3 [4-hydroxyphenyl] propionate) are that the reaction is rapid, technically simple to perform, and gives reproducibly high levels of incorporation of radioactivity with minimal oxidative damage to the protein.

The structure of IODO-GEN is shown in **Fig. 1**. The reagent is virtually insoluble in water and so a solution in dichloromethane or chloroform is used to prepare a thin film of material on the walls of the reaction vessel. Addition of an aqueous solution of Na^+ ^{125}I generates the reactive intermediate (I^+/I_3^+) that participates in electrophilic attack primarily at tyrosine but also at histidine residues in the peptide/protein. Reaction is terminated simply by transferring the contents of the reaction vessel to a clean tube, thereby obviating the need to add a reducing agent. In comparison to other radio-iodination methods, particularly the use of chloramine T and lactoperoxidase, oxidative damage to sensitive

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

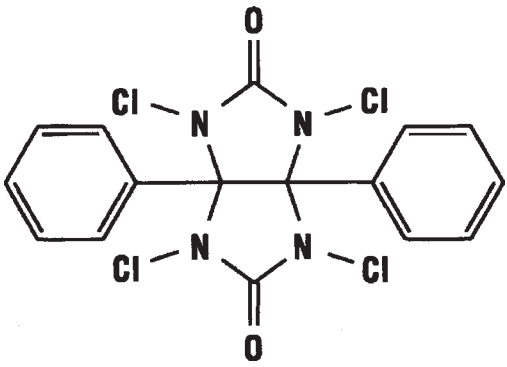

Fig. 1. The structure of IODO-GEN (1,3,4,6-tetrachloro-3α, 6α-diphenylglycoluril).

residues in the peptide/protein (particularly methionine and tryptophan) is much less using IODO-GEN ***(10)***. To minimize oxidative damage even further and to limit production of diiodotyrosyl derivatives, the strategy of trace labeling is recommended. This involves radioiodination of only approx 10% of the molecules and necessitates the separation, as completely as possible, of the radiolabeled peptide from the unreacted starting material in order to obtain a tracer of sufficiently high specific activity to be of use in radioimmunoassay, radioreceptor assay, or autoradiography. Reversed-phase high-performance liquid chromatography (RP-HPLC) combines rapidity and ease of operation with optimum separation of labeled and unlabeled peptide (reviewed in ***(11)***). The availability of wide-pore C_3 and C_4 columns generally permits good recoveries of labeled proteins with molecular mass (M_r) > 10,000. Techniques such as selective adsorption to diatomaceous materials (e.g., talc or microfine silica) and gel permeation chromatography give tracers of low specific activity, and ion-exchange chromatography is time consuming and results in a sample dilution that may be unacceptable.

Recent applications of IODO-GEN in the field of protein and peptide radioiodination involve the use of the reagent in the preparation of N-succinimidyl 4-guanidinomethyl-3-[^{131}I]iodobenzoate ***(12)***, N-succinimidyl 3-[^{131}I]iodo-4-phosphonomethylbenzoate ***(13)***, and N-succinimidyl-5-[^{131}I]iodopyridine-3-carboxylate ***(14)*** as superior conjugation alternatives to the Bolton–Hunter reagent, particularly for labelling monoclonal antibodies.

2. Materials

2.1. Apparatus

No specialized equipment is required to carry out the iodination, but the reaction should be carried out in an efficient fume hood. Reaction takes place in a 1.5-mL natural-colored polypropylene microcentrifuge (Eppendorf tube) (*see* **Note 1**), immersed in an ice bath. A nitrogen or argon cylinder is required

for removal of solvent. Liquids are dispensed with 10- and 100-µL pipets (e.g., Gilson Pipetman) that, because of inevitable contamination by radioactivity, should be dedicated to the reaction and stored in a designated area.

For HPLC, a system capable of generating reproducible linear two solvent gradients is required. Again, because of contamination by radioactivity, an injector, for example, Rheodyne Model 7125 with 1-mL sample loop; a 1-mL leak-free injection syringe, for example, Hamilton Gastight (cat. no. 1001); a 25 × 0.46 cm analytical reversed-phase column (*see* **Note 2** on column selection); and a fraction collector capable of collecting a minimum of 70 samples, for example, Frac 100 (Pharmacia, Uppsala, Sweden) should be dedicated to the radioiodination procedure. A UV detection system and chart recorder/integrator are not necessary unless it is important to demonstrate that the radiolabeled component has been completely separated from the starting material.

2.2. Chemicals

2.2.1. Iodination Reagents

1. IODO-GEN (Pierce, Rockford, IL): The reagent should be stored in a desiccator in the freezer and the bottle protected from light.
2. Dichloromethane (stabilized, HPLC grade): Redistillation is not required.
3. Carrier-free Na^+ $^{125}I^-$ in 0.1 *M* NaOH (3.7 GBq/mL; 100 mCi/mL, Amersham Pharmacia Biotech, Piscataway, NJ).
4. 0.2 *M* Disodium hydrogen phosphate–sodium dihydrogen phosphate buffer, pH 7.5 (*see* **Note 3**).

2.2.2. Chromatography

1. Solvent A: Add 1 mL of trifluoroacetic acid (Pierce HPLC/Spectro grade) to 1000 mL of water (*see* **Note 4**).
2. Solvent B: Mix 700 mL of acetonitrile (Fisher optima grade) with 300 mL of water and add 1 mL of trifluoroacetic acid. The solvents should be degassed, preferably by sparging with helium for 1 min, but passage through a filter is unnecessary.

3. Method

3.1. Radioiodination

1. Dissolve 1.5 mg of IODO-GEN in 2 mL of dichloromethane.
2. Pipet 20 µL of the solution into a polypropylene tube and remove the solvent in a gentle stream of nitrogen or argon at room temperature. The aim is to produce a film of IODO-GEN on the wall of the tube. If the reagent has formed a visible clump, the tube should be discarded and a new tube prepared. According to the manufacturer's instructions (Pierce), the tubes can be stored in a vacuum desiccator for up to 2 mo, but it is recommended that a tube is prepared freshly for each reaction. The tube is set in an ice bath for 10 min prior to the iodination (*see* **Note 5**).

3. Dissolve 10 nmol of the peptide (*see* **Note 6**) in 0.2 *M* sodium phosphate buffer, pH 7.5 (100 µL) and pipet the solution into the chilled IODO-GEN-coated tube.
4. Add the Na^+ $^{125}I^-$ solution (5 µL; 0.5 mCi or 10 µL; 1 mCi depending on the quantity of tracer required).
5. Allow the reaction to proceed for between 1 and 20 min (*see* **Note 7**). The contents of the tube should be gently agitated by periodically tapping the side of the tube with a gloved finger.
6. Reaction is stopped by aspirating the contents of the tube into a solution of 0.1% (v/v) trifluoroacetic acid–water (500 µL) contained in a second polypropylene tube. The reaction vessel may be washed with a further 200 µL of trifluoroacetic acid–water (500 µL) contained in a second polypropylene tube. The reaction vessel may be washed with a further 200 µL of trifluoroacetic acid–water and the washings combined with the reaction mixture.

3.2. Chromatography

1. Prior to carrying out the iodination, the column is equilibrated with 100% solvent A at a flow rate of 1.5 mL/min for at least 30 min. In the case of more hydrophobic peptides/proteins, the column is equilibrated with starting solvent containing up to 30% solvent B (21% acetonitrile).
2. The instrument is programmed to increase the proportion of solvent B from starting conditions to 70% (49 % acetonitrile) over 60 min using a linear gradient (*see* **Note 8**).
3. The reaction mixture is injected onto the column (*see* **Note 9**). The fraction collector, programmed to collect 1-min fractions, is started and the linear elution gradient is begun. A total of 60 fractions are collected.
4. At the end of the chromatography, the column is irrigated with 100% solvent B for 30 min. The column may be stored in this solvent.
5. The radioactivity in aliquots (2 mL) of each fraction is counted in a gamma scintillation counter (*see* **Note 10** for optimum storage conditions of tracer).

The results of a typical radioiodination are illustrated in **Fig. 2**. The reaction mixture comprised 10 nmol of rat galanin and 0.5 mCi of Na^+ $^{125}I^-$ and the reaction time was 2 min. Unreacted free iodide was eluted at the void volume of the column (fractions 5 and 6). The fraction denoted by the bar (tube 51) was of high specific activity (approx 74 TBq/mmol; 2000 Ci/mmol). The earlier eluting minor peak of radioactivity (tube 49) probably represented the diiodotyrosyl derivative. Before use in radioimmunoassay or radioreceptor studies, the quality of the tracer is assessed by incubating an aliquot (approx 20,000 cpm) with an excess of an antiserum raised against galanin (1 : 1000 dilution) in 0.1 *M* sodium phosphate buffer, pH 7.4 (final volume 300 µL) for 16 h at 4°C. Free and bound radioactivity are separated by addition of 100 µL of a 10 mg/mL solution of bovine γ-globulin (Sigma, St. Louis, MO) and 1 mL of 20% (w/v) solution of polyethylene glycol 6000 (Sigma, approx M_r 8000) in water followed by centrifugation (1600*g* for 30 min at 4°C). Under these conditions, >90% of the radioactivity is bound to antibody.

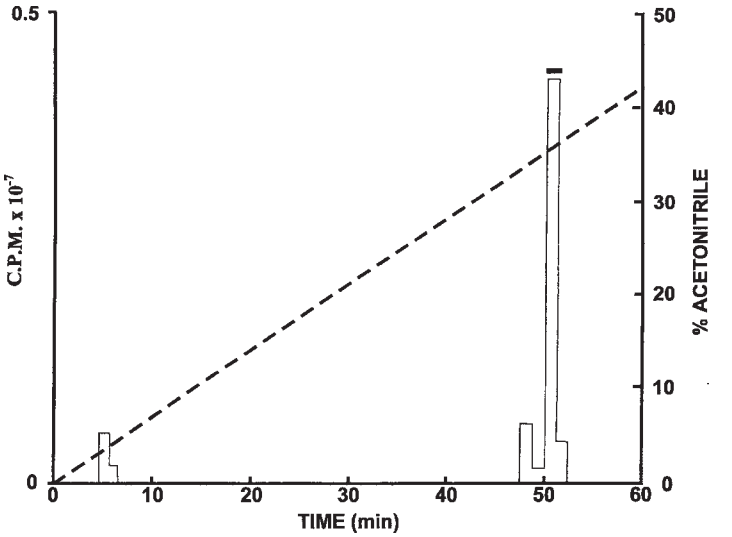

Fig. 2. RP-HPLC on a (0.46 × 25 cm) Vydac 218TP54 (C_{18}) column of the reaction mixture following incubation of 10 nmol of rat galanin with 0.5 mCi of Na ^{125}I in an IODOGEN-coated tube for 2 min at 0°C. Fractions (1 min) were collected and the fraction denoted by the *bar* contained tracer of high specific activity (74 TBq/mmol). The *dashed line* shows the concentration of acetonitrile in the eluting solvent.

4. Notes

1. A systematic comparison of the properties of different IODO-GEN-coated surfaces has concluded that soda-lime glass produced the most rapid rate of oxidation of Na ^{125}I ***(15)***. However, irreversible binding of most peptides to the walls of polypropylene tubes is much less than to glass and so clear polypropylene Eppendorf tubes are routinely used in the author's laboratory. The use of borosilicate glass tubes ***(15)*** and polysytrene tubes is not recommended. Glass test tubes (12 mm × 75 mm) precoated with IODO-GEN (50 µg) are available from Pierce.
2. The choice of column is dictated by the nature of the radiolabeled peptide to be purified. For relatively small (M_r < 3000) peptides, good resolution and recoveries are generally obtained with (0.46 × 25 cm) narrow pore (80 Å), 5-µm particle size octadecylsilane (C_{18}) columns such as Supelcosil LC-18-DB (Supelco, Bellefonte, PA), Ultrasphere ODS (Beckman, Duarte, CA), or Spheri-5 RP-18 (Brownlee/Perkin Elmer, Foster City, CA). For purification of radiolabeled tracers of higher molecular mass (M_r > 3000), the use of columns containing wide-pore (300 Å) 5-µm particle size C_{18} packing materials is recommended. Suitable columns include

Vydac 218TP54 (Separations Group, Hesperia, CA), Spherisorb wide-pore C_{18} (Waters Corporation, U. K.), Waters Delta-Pak C_{18} and Ultrapore C_{18} (Beckman). For purification of tracers of molecular mass > 10,000, such as the pituitary glycoprotein hormones, sharper peaks and better recoveries of radioactivity may be obtained using wide-pore silica with propyl and butyl carbon loading. Suitable columns include Beckman Ultrapore C_3 and Vydac 214TP54 C_4 columns.

3. The reaction is not markedly pH sensitive and high incorporations of ^{125}I may be achieved in the pH range 6–9 ***(16)***.
4. Suitable water can be obtained using a Milli-Q purification system (Millipore) supplied with water that has been partially purified by single distillation or by treatment with a deionization resin.
5. A low reaction temperature is important in minimizing damage to the radiolabeled peptide/protein. For example, the use of IODO-GEN at room temperature to prepare ^{125}I-labeled human growth hormone resulted in the production of tracer containing a significant amount of the hormone in an aggregated form whereas only the radio-labeled monomer was produced when the reaction was carried out at 0°C ***(17)***.
6. As many peptides are relatively insoluble in buffers of neutral pH, it is recommended that the peptide first be dissolved in a minimum volume (approx 5 µL) of 0.1% (v/v) trifluoroacetic acid/water and the volume made up to 100 µL with 0.2 *M* sodium phosphate buffer, pH 7.5.
7. The optimum reaction time must be determined for each peptide and protein, but some general guidelines can be given. For small peptides (<15 amino acid residues) containing a tyrosine residue in a sterically unhindered region of the molecule, for example, the N- or C-terminal residue, the reaction proceeds rapidly and reaction times of between 0.5 and 2 min are generally sufficient. For larger peptides and proteins, it is often necessary to prolong the reaction time to between 10 and 15 min. Peptides that do not contain a tyrosine residue but possess a sterically unhindered histidine (e.g., neurokinin B ***(18)*** and secretin) may be iodinated using IODO-GEN, but longer reaction times (up to 20 min) may be required.
8. The relatively steep gradient (0 → 70% solvent B, equivalent to 0 → 49% acetonitrile) over 60 min is recommended as the initial elution conditions when preparing a radiolabel for the first time. Better separation of the tracer and the unlabeled peptide will be obtained using a shallower gradient. For example, relatively hydrophilic peptides such as [Tyr^0]bradykinin and [Tyr^8]substance P ***(19)*** may be purified using a gradient of 0 → 35% acetonitrile over 60 min, whereas hydrophobic peptides such as corticotropin-releasing hormone, urotensin-1, and neurokinin B may be purified using a gradient of 21 → 49% acetonitrile over 60 min. In a case where

separation of radiolabeled peptide and starting material is incomplete, a label of higher specific activity may be obtained by prolonging the time of chromatography and collecting smaller fractions.

9. In some published protocols, the radiolabeled peptide or protein and unreacted ^{125}I- are separated prior to RP-HPLC, for example, by adsorption on Sep-Pak C_{18} cartridges (Waters Associates, Milford, MA) or by gel-permeation chromatography on a Sephadex G-10 desalting column (Pharmacia). This procedure is not necessary and it is recommended that the reaction mixture is injected directly onto the HPLC column.
10. The stability of radiolabeled peptides and proteins varies dramatically, with useful lives ranging from a few days to more than 2 mo. Repeated freezing and thawing of the tracer is not recommended and so the HPLC fraction(s) containing the radiolabel should be aliquoted immediately, diluted with one volume ethanol or methanol, and stored at as low a temperature as possible (−70°C is preferred). The volume of the aliquot should be related to the size of a typical assay.
11. Although IODO-GEN is almost insoluble in water, its solubility in buffers containing detergent increases appreciably. Under these circumstances, oxidative damage to the peptide/protein may occur and the use of an alternative reagent IODO-BEADS (Pierce) should be considered. IODO-BEADS comprise the sodium salt of *N*-chloro-benzenesulfonamide immobilized on nonporous polystyrene beads ***(20)***. The reaction conditions and purification protocol using IODO-BEADS are the same as using IODO-GEN except that one or more of the beads are substituted for the film of IODO-GEN. High incorporations of radio-activity are observed even in the presence of detergents or chaotropic reagents, for example, urea.

Purification and Assessment of Quality of Radioiodinated Protein

Graham S. Bailey

1. Introduction

At the end of a radioiodination procedure, the reaction mixture will contain the labeled protein, unlabeled protein, radioiodide, mineral salts, enzyme (in the case of the lactoperoxidase method), and possibly some protein that has been damaged during the oxidation. For most uses of radioiodinated proteins, it is essential to have the labeled species as pure as possible. In theory, any of the many methods of purifying proteins can be employed ***(1)***. However, the purification of the radioiodinated protein should be achieved as rapidly as possible. For that purpose, the most widely used of all separation techniques is gel filtration.

One of the most important parameters used to assess the quality of a purified labeled protein is its specific radioactivity, which is the amount of radioactivity incorporated/unit mass of protein. It can be calculated in terms of the total radioactivity employed, the amount of the iodination mixture transferred to the gel-filtration column, and the amount of radioactivity present in the labeled protein, in the damaged components, and in the residual radioiodine. However, in practice, the calculation does not usually take into account damaged and undamaged protein. The specific activity is thus calculated from the yield of the radioiodination procedure, the amount of radioiodide, and the amount of protein used, assuming that there are no significant losses of those two reactants. The yield of the reaction is simply the percentage incorporation of the radionuclide into the protein.

It is obviously important that the radioiodinated protein should as far as possible have the same properties as the unlabeled species. Thus, the behavior of both molecules can be checked on electrophoresis or ion-exchange chromatography.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

The ability of the two species to bind to specific antibodies can be assessed by radioimmunoassay.

This chapter will describe a protocol for the purification of a radiolabeled protein and an example of a calculation of specific radioactivity.

2. Materials

1. Sephadex G75 resin.
2. Buffer A: 0.05 *M* sodium phosphate containing 0.1% bovine serum albumin and 0.15 *M* sodium chloride, final pH 7.4.
3. Specific antiseum to the protein.
4. Buffer B: 0.1 *M* sodium phosphate buffer containing 0.15 *M* sodium chloride and 0.01% sodium azide, final pH 7.4.
5. γ-globulin solution: 1.4% bovine γ-globulins (Sigma, St. Louis, MO) in buffer B.
6. Polyethylene glycol/potassium iodide solution: 20% polyethylene glycol 6000 and 6.25% potassium iodide in buffer B.

3. Method

1. An aliquot (10 µL) of the mixture is retained for counting and the rest is applied to a column (1 × 20 cm) of Sephadex G75 resin (*see* **Notes 1** and **2**).
2. Elution is carried out at a flow rate of 20 mL/h, and fractions (0.6 mL) are automatically collected.
3. Aliquots (10 µL) are counted for radioactivity.
4. An elution profile of radioactivity against fraction number (for a typical profile, *see* **Fig. 1**) is plotted.
5. Immunoreactive protein is identified by reaction with specific antiserum to that protein in the following manner (**steps 6–13**) (*see* **Note 3**).
6. Aliquots (10 µL) of fractions making up the different peaks are diluted so that each gives 10,000 counts/min/100 µL.
7. Each diluted aliquot (100 µL) is incubated with the specific antiserum (100 µL) at 4°C for 4 h.
8. Protein bound to antibody and excess antibody are precipitated by the addition to each sample at 4°C of γ-globulin solution (200 µL) and polyethylene glycol/potassium iodide solution (1 mL) (*see* **Note 4**).
9. Each tube is vortexed and is allowed to stand at 4°C for 15 min.
10. Each tube is centrifuged at 4°C at 5000*g* for 30 min.
11. The supernatants are carefully removed by aspiration at a water pump, and the precipitates at the bottom of the tubes are counted for radioactivity.
12. Estimates of the yield of the radioiodination and specific radioactivity of the iodinated protein may then be made (*see* **Note 5**).
13. When the fractions containing radioiodinated protein have been identified, they are split into small aliquots that can be rapidly frozen or freeze-dried for storage (*see* **Note 6**).

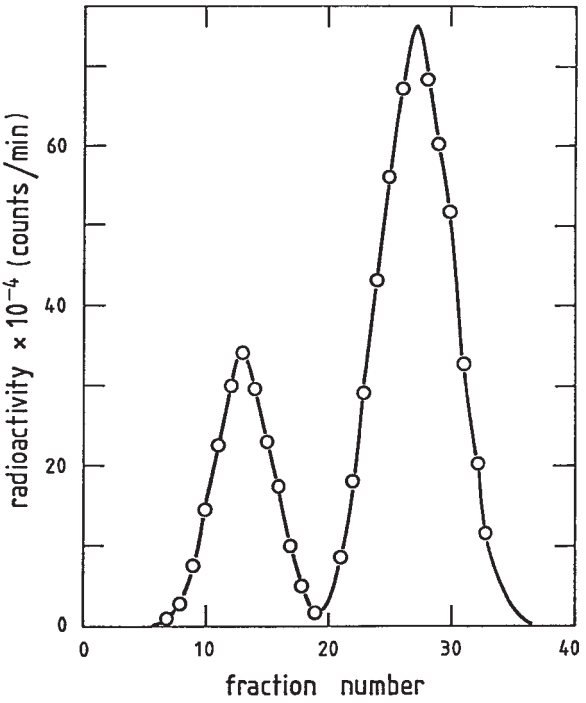

Fig. 1. Gel filtration of radioiodinated kallikrein of rat submandibular gland. The pure enzyme (10 µg) was iodinated with ^{125}I (18.5 MBq) by the chloramine T method. It was then purified on a column (1 × 20 cm) of Sephadex G-75 resin at a flow rate of 20 mL/h and collecting fractions of 0.6 mL. Aliquots (10 µL) of each fraction were measured for radioactivity. By radioimmunoassay, immunoreactive protein was found only in the first peak, and more than 90% of that radioactivity was bound by the antiserum to kallikrein from rat submandibular gland.

4. Notes

1. Gel filtration by high-performance liquid chromatography (HPLC) provides a more rapid and efficient purification of iodinated protein than the conventional liquid chromatography described here, but it does entail the use of expensive columns and apparatus with the attendant danger of their contamination with radioactivity ***(2)***.
2. A wide range of gel-filtration resins are available. In choosing a resin, the relative molecular masses (M_r) of the protein and other reactants and products must be borne in mind. Sephadex G-25 resin will separate the labeled protein from the low-mol-wt reagents, such as oxidants and reductants. However, if the labeled protein is contaminated with damaged protein

(e.g., aggregated species), then a gel-filtration resin of higher porosity, such as Sephadex G-100, may produce a more efficient separation of the undamaged, monoiodinated protein.

3. The occurence of immunoreactive protein in more than one peak indicates the presence of polymeric or degradated forms of the iodinated protein. Ideally, iodinated protein should be present in a single, sharp, symmetrical peak. If this is not the case, then it is probably best to repeat the radioiodination under milder conditions or use a different method of iodination.
4. Polyethylene glycol produces precipitation of antibody and antibody-bound protein with little precipitation of unbound protein. Potassium iodide decreases the precipitation by polyethylene glycol of unbound protein ***(3)***.
5. A typical example of the calculation of yield of iodination and specific radioactivity is as follows:

Counts of 10 µL incubation mixture prior to gel filtration = 1,567,925 counts/10 s (1)

Some of the radioiodinated protein is likely to bind to the reaction vessel and other surfaces, so it is best to calculate the radioactivity associated with the labeled protein in terms of the difference between total radioactivity applied to the column and the radioactivity associated with the unreacted iodide.

Counts in 10-µL aliquots of iodide peak = 388,845 counts/10 s (2)

Counts in 10-µL aliquots of protein peak = 1,567,925–388,845 counts/10 s = 1,179,080 counts/10 s (3)

Yield of radioiodination reaction = % incorporation of ^{125}I into protein

(1,179,080 × 100)/1,567,925 = 75.2% (4)

Amount of radioactivity incorporated into protein = % incorporation × original radioactivity= 75.2% × 18.5 MBq = 13.9 MBq (5)

Specific radioactivity = (amount of radioactivity in protein/amount of protein used)

= (13.9 MBq/10 µg) = (1.4 MBq/µg) (6)

6. Each aliquot should be thawed and used only once. Radioiodinated proteins differ markedly in their stability. Some can be stored for several wk (though it must be borne in mind that the half-life of ^{125}I is about 60 d), whereas others can only be kept for several days. If necessary, the labeled protein can be repurified by gel-filtration or ion-exchange chromatography prior to use.

Purification of IgG by Precipitation with Sodium Sulfate or Ammonium Sulfate

Mark Page and Robin Thorpe

1. Introduction

Addition of appropriate amounts of salts, such as ammonium or sodium sulfate, causes precipitation of IgG ***(1)*** from all mammals, and can be used for serum, plasma, ascites fluid, and hybridoma culture supernatant. Although such IgG is usually contaminated with other proteins, the ease of these precipitation procedures coupled with the high yield of IgG has led to their wide use in producing enriched IgG preparations. They are suitable for many immunochemical procedures, e.g., production of immunoaffinity columns, and as a starting point for further purification. It is not suitable however for conjugating with radiolabels, enzymes, or biotin since the contaminating proteins will also be conjugated, thereby reducing the efficiency of the labeling and the quality of the reagent. The precipitated IgG is usually very stable, and such preparations are ideally suited for long-term storage or distribution and exchange between laboratories.

Ammonium sulfate precipitation is the most widely used and adaptable procedure, yielding a 40% pure preparation; sodium sulfate can give a purer preparation for some species, e.g., human and monkey.

2. Materials

2.1. Ammonium Sulfate Precipitation

1. Saturated ammonium sulfate solution: Add excess $(NH_4)_2SO_4$ to distilled water (about 950 g to 1 L), and stir overnight at room temperature. Chill at 4°C, and store at this temperature. This solution (in contact with solid salt) is stored at 4°C.
2. PBS: 0.14 *M* NaCl, 2.7 m*M* KCl, 1.5 m*M* KH_2PO_4, 8.1 m*M* Na_2HPO_4. Store at 4°C.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2.2. Sodium Sulfate Precipitation

This requires solid sodium sulfate.

3. Methods

3.1. Ammonium Sulfate Precipitation

1. Prepare saturated ammonium sulfate at least 24 h before the solution is required for fractionation. Store at 4°C.
2. Centrifuge serum or plasma for 20–30 min at 10,000g_{av} at 4°C. Discard the pellet (*see* **Note 1**).
3. Cool the serum or plasma to 4°C, and stir slowly. Add saturated ammonium sulfate solution dropwise to produce 35–45% final saturation (*see* **Note 2**). Alternatively, add solid ammonium sulfate to give the desired saturation (2.7 g of ammonium sulfate/10 mL of fluid = 45% saturation). Stir at 4°C for 1–4 h or overnight.
4. Centrifuge at 2000–4000g_{av} for 15–20 min at 4°C (alternatively for small volumes of 1–5 mL, microfuge for 1–2 min). Discard the supernatant, and drain the pellet (carefully invert the tube over a paper tissue).
5. Dissolve the precipitate in 10–20% of the original volume in PBS or other buffer by careful mixing with a spatula or drawing repeatedly into a wide-gage Pasteur pipet. When fully dispersed, add more buffer to give 25–50% of the original volume and dialyze against the required buffer (e.g., PBS) at 4°C overnight with two to three buffer changes. Alternatively, the precipitate can be stored at 4 or −20°C if not required immediately.

3.2. Sodium Sulfate Precipitation (*see* Note 3)

1. Centrifuge the serum or plasma at 10,000g_{av} for 20–30 min. Discard the pellet, warm the serum to 25°C, and stir.
2. Add solid Na_2SO_4 to produce an 18% w/v solution (i.e., add 1.8 g/10 mL), and stir at 25°C for 30 min to 1 h.
3. Centrifuge at 2000–4000g_{av} for 30 min at 25°C.
4. Discard the supernatant, and drain the pellet. Redissolve in the appropriate buffer as described for ammonium sulfate precipitation (**Subheading 3.1., step 5**).

4. Notes

1. If lipid contamination is excessive in ascites fluids, thereby compromising the salt precipitation, add silicone dioxide powder (15 mg/mL) and centrifuge for 20 min at 2000g_{av} ***(2)*** before adding the ammonium or sodium salt.
2. The use of 35% ammonium sulfate will produce a pure IgG preparation, but will not precipitate all the IgG present in serum or plasma. Increasing saturation to 45% causes precipitation of nearly all IgG, but this will be contaminated with other proteins, including some albumin. Purification using $(NH_4)_2SO_4$ can be improved by repeating the precipitation, but this

may cause some denaturation. Precipitation with 45% $(NH_4)_2SO_4$ is an ideal starting point for further purification steps, e.g., ion-exchange or affinity chromatography and FPLC purification (*see* Chapters 139 and 140).

3. Sodium sulfate may be used for precipitation of IgG instead of ammonium sulfate. The advantage of the sodium salt is that a purer preparation of IgG can be obtained, but this must be determined experimentally. The disadvantages are that yield may be reduced depending on the IgG characteristics of the starting material, IgG concentration, and composition. Fractionation must be carried out at a precise temperature (usually 25°C), since the solubility of Na_2SO_4 is very temperature dependent. Sodium sulfate is usually employed only for the purification of rabbit or human IgG.

Purification of IgG Using Caprylic Acid

Mark Page and Robin Thorpe

1. Introduction

Caprylic (octanoic) acid can be used to purify mammalian IgG from serum, plasma, ascites fluid, and hybridoma culture supernatant by precipitation of non-IgG protein ***(1)*** (*see* **Note 1**). Other methods have been described where caprylic acid has been used to precipitate immunoglobulin depending on the concentration used. The concentration of caprylic acid required to purify IgG varies according to species (*see* **Subheading 3., step 2**). For MAb, it is usually necessary to determine experimentally the quantity required to produce the desired purity/yield. Generally, the product is of low to intermediate purity but this will depend on the starting material. Caprylic acid purified IgG preparations can be used for most immunochemical procedures, such as coating plates for antigen capture assays and preparation of immunoaffinity columns, but would not be suitable for conjugation with radioisotopes, enzymes, and biotin where contaminating proteins will reduce the specific activity.

2. Materials

1. 0.6 *M* sodium acetate buffer, pH 4.6. Adjust pH with 0.6 *M* acetic acid.
2. Caprylic acid (free acid).

3. Methods

1. Centrifuge the serum at 10,000 g_{av} for 20–30 min. Discard the pellet and add twice the volume of 0.06 *M* sodium acetate buffer, pH 4.6.
2. Add caprylic acid dropwise while stirring at room temperature. For each 25 mL of serum, use the following amounts of caprylic acid: human and horse, 1.52 mL; goat, 2.0 mL; rabbit, 2.05 mL; cow, 1.7 mL. Stir for 30 min at room temperature.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Centrifuge at 4000 g_{av} for 20–30 min. Retain the supernatant and discard the pellet. Dialyze against the required buffer (e.g., PBS) at 4°C overnight with two or three buffer changes.

4. Note

1. The method can be used before ammonium sulfate precipitation (*see* Chapter 179) to yield a product of higher purity.

181

Purification of IgG Using DEAE-Sepharose Chromatography

Mark Page and Robin Thorpe

1. Introduction

IgG may be purified from serum by a simple one-step ion-exchange chromatography procedure. The method is widely used and works on the principle that IgG has a higher or more basic isoelectric point than most serum proteins. Therefore, if the pH is kept below the isoelectric point of most antibodies, the immunoglobulins do not bind to an anion exchanger and are separated from the majority of serum proteins bound to the column matrix. The high capacity of anion-exchange columns allows for large-scale purification of IgG from serum. The anion-exchange reactive group, diethylaminoethyl (DEAE) covalently linked to Sepharose (e.g., DEAE Sepharose CL-6B, Pharmacia, Uppsala, Sweden) is useful for this purpose. It is provided preswollen and ready for packing into a column, and is robust and has high binding capacity. Furthermore, it is relatively stable to changes in ionic strength and pH. Other matrices (e.g., DEAE cellulose) are provided as solids, and will therefore require preparation and equilibration ***(1)***.

This procedure does not work well for murine IgG or preparations containing mouse or rat MAb, since these do not generally have the high pI values that IgGs of other species have. Other possible problems are that some immunoglobulins are unstable at low-ionic strength, e.g., mouse IgG_3, and precipitation may occur during the ion-exchange procedure. The product is of high purity (>90%) and can be used for most immunochemical procedures including conjugation with radioisotopes, enzymes, and so on, where pure IgG is required.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2. Materials

1. DEAE Sepharose CL-6B.
2. 0.07 *M* sodium phosphate buffer, pH 6.3.
3. 1 *M* NaCl.
4. Sodium azide.
5. Chromatography column (*see* **Note 1**).

3. Methods

1. Dialyze the serum (preferably ammonium sulfate fractionated; *see* Chapter 179) against 0.07 *M* sodium phosphate buffer, pH 6.3, exhaustively (at least two changes over a 24-h period) at a ratio of at least 1 vol of sample to 100 vol of buffer.
2. Apply the sample to the column, and wash the ion exchanger with 2 column volumes of sodium phosphate buffer. Collect the wash, which will contain IgG, and monitor the absorbance of the eluate at 280 nm (A_{280}). Stop collecting fractions when the A_{280} falls to baseline.
3. Regenerate the column by passing through 2–3 column volumes of phosphate buffer containing 1 *M* NaCl.
4. Wash thoroughly in phosphate buffer (2–3 column volumes), and store in buffer containing 0.1% NaN_3.
5. Pool the fractions from **step 2** and measure the A_{280} (*see* **Note 2**).

4. Notes

1. The column size will vary according to the user's requirements or the amount of antibody required. Matrix binding capacities are given by manufacturers and should be used as a guide.
2. The extinction coefficient ($E^{1\%}_{280}$) of human IgG is 13.6 (i.e., a 1 mg/mL solution has an A_{280} of 1.36). This can be used as an approximate value for IgGs from other sources.

182

Purification of IgG Using Ion-Exchange HPLC

Carl Dolman, Mark Page, and Robin Thorpe

1. Introduction

Conventional ion-exchange chromatography separates molecules by adsorbing proteins onto the ion-exchange resins that are then selectively eluted by slowly increasing the ionic strength (this disrupts ionic interactions between the protein and column matrix competitively) or by altering the pH (the reactive groups on the proteins lose their charge). Anion-exchange groups (such as diethylaminoethyl; [DEAE]) covalently linked to a support matrix (such as Sepharose) can be used to purify IgG in which the pH of the mobile-phase buffer is raised above the p*I* or IgG, thus allowing most of the antibodies to bind to the DEAE matrix. Compare this method with that described in Chapter 181 in which the IgG passes through the column. The procedure can be carried out using a laboratory-prepared column that is washed and eluted under gravity ***(1)***; however, high-performance liquid chromatography (HPLC) provides improved reproducibility (because the sophisticated pumps and accurate timers), speed (because of the small high-capacity columns), and increased resolution (because of the fine resins and control systems).

2. Materials

1. Anion-exchanger (e.g., Mono-Q HR 5/5 or HR 10/10, Pharmacia, Uppsala, Sweden.
2. Buffer A: 0.02 *M* triethanolamine, pH 7.7.
3. Buffer B: Buffer A containing 1 *M* NaCl.
4. 2 *M* NaOH.
5. Sodium azide.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Methods

1. Prepare serum by ammonium sulfate precipitation (45% saturation; *see* Chapter 179). Redissolve the precipitate in 0.02 *M* triethanolamine buffer, pH 7.7, and dialyze overnight against this buffer at 4°C. Filter the sample (*see* **Note 1**) before use (0.2 µm).
2. Assemble the HPLC system according to the manufacturer's instructions for use with the Mono-Q ion-exchange column.
3. Equilibrate the column with 0.2 *M* triethanolamine buffer, pH 7.7 (buffer A). Run a blank gradient from 0 to 100% buffer B (buffer A + 1 *M* NaCl). Use a flow rate of 4–6 mL/min for this and subsequent steps.
4. Load the sample depending on column size. Refer to the manufacturer's instruction for loading capacities of the columns.
5. Equilibrate the column with buffer A for at least 10 min.
6. Set the sensitivity in the UV monitor control unit, and zero the baseline.
7. Apply a salt gradient from 0 to 28% buffer B for about 30 min (*see* **Note 2**). Follow with 100% 1 *M* NaCl for 15 min to purge the column of remaining proteins.
8. Wash the Mono-Q ion-exchange with at least 3 column volumes each of 2 *M* NaOH followed by 2 *M* NaCl.
9. Store the Mono-Q ion-exchange column in distilled water containing 0.02% NaN_3.

4. Notes

1. It is essential that the sample and all buffers be filtered using 0.2-µm filters. All buffers must be degassed by vacuum pressure.
2. Using Mono-Q, IgG elutes between 10% and 25% buffer B, usually approx 15%. When IgG elutes at 25% (dependent on p*I*), then it will tend to coelute with albumin, which elutes at approx 27%. When this occurs, alternative purification methods should be employed.
3. Other anion-exchange media can be substituted for Mono-Q, for example, Anagel TSK DEAE (Anachem, Luton, UK).

183

Purification of IgG by Precipitation with Polyethylene Glycol (PEG)

Mark Page and Robin Thorpe

1. Introduction

PEG precipitation works well for IgM, but is less efficient for IgG; salt precipitation methods are usually recommended for IgG. PEG precipitation may be preferred in multistep purifications that use ion-exchange columns, because the ionic strength of the Ig is not altered. Furthermore, it is a very mild procedure that usually results in little denaturation of antibody. This procedure is applicable to both polyclonal antisera and most MAb containing fluids.

2. Materials

1. PEG solution: 20% (w/v) PEG 6000 in PBS.
2. PBS: 0.14 *M* NaCl, 2.7 m*M* KCl, 1.5 m*M* KH_2PO_4, 8.1 m*M* Na_2HPO_4.

3. Methods

1. Cool a 20% w/v PEG 6000 solution to 4°C.
2. Prepare serum/ascitic fluid, and so forth, for fractionation by centrifugation at 10,000g_{av} for 20–30 min at 4°C. Discard the pellet. Cool to 4°C.
3. Slowly stir the antibody containing fluid, and add an equal volume of 20% PEG dropwise (*see* **Note 1**). Continue stirring for 20–30 min.
4. Centrifuge at 2000–4000g_{av} for 30 min at 4°C. Discard the supernatant (*see* **Note 2**), and drain the pellet. Resuspend in PBS or other buffer as described for ammonium sulfate precipitation (*see* Chapter 179).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

4. Notes

1. Although the procedure works fairly well for most antibodies, it may produce a fairly heavy contamination with non-IgG proteins. If this is the case, reduce the concentration of PEG in 2% steps until the desired purification is achieved. Therefore, carry out a pilot-scale experiment before fractionating all of the sample.
2. PEG precipitation does not work for some antibodies. If the procedure is to be used for a valuable antibody for the first time, keep the supernatant in case precipitation has been inefficient.

184

Purification of IgG Using Protein A or Protein G

Mark Page and Robin Thorpe

1. Introduction

Some strains of *Staphylococcus aureus* synthesize protein A, a group-specific ligand that binds to the Fc region of IgG from many species ***(1,2)***. Protein A does not bind all subclasses of IgG, e.g., human IgG_3, mouse IgG_3, sheep IgG_1, and some subclasses bind only weakly, e.g., mouse IgG_1. For some species, IgG does not bind to protein A at all, e.g., rat, chicken, goat, and some MAbs show abnormal affinity for the protein. These properties make the use of protein A for IgG purification limited in certain cases, although it can be used to an advantage in separating IgG subclasses from mouse serum ***(3)***. Protein G (derived from groups C and G *Streptococci*) also binds to IgG Fc with some differences in species specificity from protein A. Protein G binds to IgG of most species, including rat and goat, and recognizes most subclasses (including human IgG_3 and mouse IgG_1), but has a lower binding capacity. Protein G also has a high affinity for albumin, although recombinant DNA forms now exist in which the albumin-binding site has been spliced out, and are therefore very useful for affinity chromatography. Other streptococcal immunoglobulin binding proteins are protein H (binds IgG Fc), protein B, which binds IgA and protein Arp, which binds IgG & IgA. These are not generally available for immunochemical use.

Another bacterial IgG-binding protein (protein L) has been identified ***(4)***. Derived from *Peptostreptococcus magnus,* it binds to some κ (but not λ) chains. Furthermore, protein L binds to only some light-chain subtypes, although immunoglobulins from many species are recognized ***(5,6)***.

Finally, hybrid molecules produced by recombinant DNA procedures, comprising the appropriate regions of IgG-binding proteins (e.g., protein L/G, protein L/A) also have considerable scope in immunochemical techniques. These proteins are therefore very useful in the purification of IgG by affinity chromatography. Columns are commercially available (MabTrap G II, Pharmacia,

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

Uppsala, Sweden) or can be prepared in the laboratory. The product of this method is of high purity and is useful for most immunochemical procedures including affinity chromatography and conjugation with radioisotopes, enzymes, biotin, and so forth.

2. Materials

1. PBS: 0.14 *M* NaCl, 2.7 m*M* KCl, 1.5 m*M* KH_2PO_4, 8.1 m*M* Na_2HPO_4.
2. Sodium azide.
3. Dissociating buffer: 0.1 *M* glycine-HCl, pH 3.5. Adjust the pH with 2 *M* HCl.
4. 1 *M* Tris.
5. Binding buffer: Optimal binding performance occurs using a buffer system between pH 7.5 and 8.0. Suggested buffers include 0.1 *M* Tris-HCl, 0.15 *M* NaCl, pH 7.5; 0.05 *M* sodium borate, 0.15 *M* NaCl, pH 8.0; and 0.1 *M* sodium phosphate, 0.15 *M* NaCl, pH 7.5.
6. IgG preparation: serum ascitic fluid, or hybridoma culture supernatant.
7. Protein A, G column.

3. Methods

Refer to Chapter 186 for CNBr activation of Sepharose and coupling of protein A, G.

1. Wash the column with an appropriate binding buffer.
2. Pre-elute the column with dissociating buffer, 0.1 *M* glycine-HCl, pH 3.5.
3. Equilibrate the column with binding buffer.
4. Prepare IgG sample: If the preparation is serum, plasma, or ascitic fluid, dilute it at least 1:1 in binding buffer and filter through 0.45-µm filter. Salt-fractionated preparations (*see* Chapter 179) do not require dilution, but the protein concentration should be adjusted to approx 1–5 mg/mL. Hybridoma culture supernatants do not require dilution.
5. Apply sample to column at no more than 10 mg IgG/2-mL column.
6. Wash the column with binding buffer until the absorbance at 280 nm is <0.02.
7. Dissociate the IgG-ligand interaction by eluting with dissociating buffer. Monitor the absorbance at 280 nm, and collect the protein peak. Neutralize immediately with alkali (e.g., 1 *M* Tris, unbuffered).
8. Wash the column with binding buffer until the pH returns to that of the binding buffer. Store the column in buffer containing at least 0.15 *M* NaCl and 0.1% sodium azide.
9. Dialyze the IgG preparation against a suitable buffer (e.g., PBS) to remove glycine/Tris.

Analysis and Purification of IgG Using Size-Exclusion High Performance Liquid Chromatography (SE-HPLC)

Carl Dolman and Robin Thorpe

1. Introduction

The use of size-exclusion chromatography (SEC; also known as gel filtration chromatography) for purification of IgG has been widely used. SEC with dextran, agarose, and polyacrylamide soft gels was one of the first techniques developed for the purification of proteins. Soft gels, however, cannot tolerate high pressure and require long separation times. They also have limited stability to extremes of pH and to salt. These and other limitations of "conventional" size-exclusion chromatography are responsible for the problems with resolution often observed when analyzing/purifying IgG using such methods. However, many of these problems can be solved by using high performance liquid chromatography (HPLC) systems with appropriate size-exclusion columns.

Silica-based particles such as those used for many HPLC SEC columns are ideal for analysis and purification of IgG, as they are inert, have well-defined pore size, and because of their rigidity can be run at relatively high pressure, allowing reasonable flow rates and relatively quick separation times. Different pore sizes of the silica beads allow fractionation of different ranges of protein molecular weights. The column chosen should therefore have a pore size that allows the fractionation of proteins of molecular weights in the range 10,000–500,000, as this will separate aggregated, dimeric, monomeric, and fragmented immunoglobulins as discrete peaks (e.g., TSK G3000SW; *see* **Fig. 1**). Resolution of peaks is also dependent on column length, and in the past it has been necessary to join two columns to achieve optimal results. This of course doubles the time taken to run a sample. The alternative is to use a column with

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

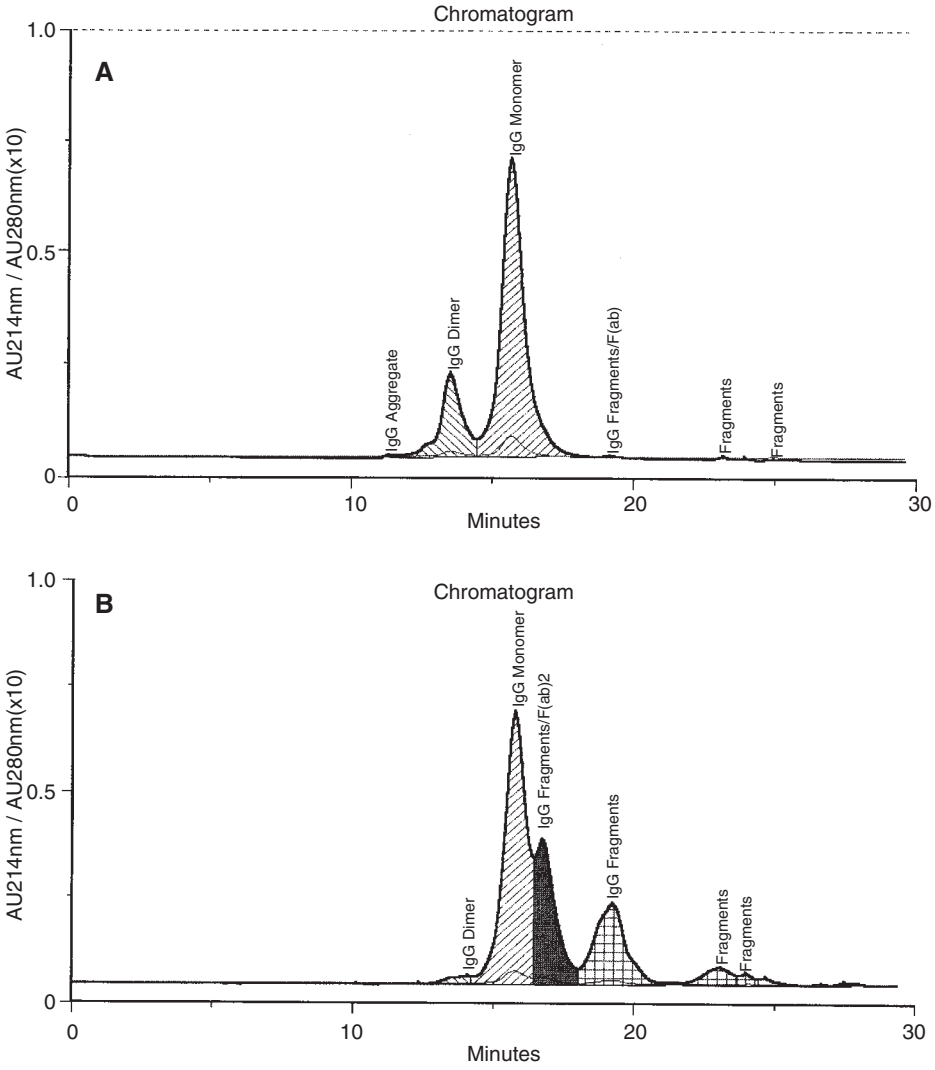

Fig. 1. Typical profiles for intact **(A)** and fragmented **(B)** human therapeutic immunoglobulin products.

smaller bead dimensions, for example, the TSK G3000SW$_{XL}$, which has 5-µm beads compared to the 10-µm beads used for G3000SW columns.

As well as being much quicker than conventional size-exclusion chromatography, SE-HPLC is capable of much increased resolution, and the fully automated systems provide much greater reproducibility than "conventional" chromatography setups.

2. Materials

1. The principal equipment used is a modular HPLC system (e.g., Gilson, Waters) comprising an autosampler, pump, UV-detector, and fraction collector.
2. The equipment is controlled using a Unipoint system controller or equivalent software.
3. TSK G3000SW$_{XL}$ 7.8 mm × 300 mm (or equivalent) column (supplied locally by Anachem, Luton, UK).
4. Mobile phase: 0.2 *M* sodium phosphate, pH 6.0 + 0.1 *M* sodium sulfate, pH 6.0.
5. 18 Mohm deionized water.
6. 50% Methanol in deionized water.

3. Methods (*see* **Note 1**)

1. Assemble the HPLC components except the column according to the manufacturer's instructions. Equilibrate the system in the mobile phase (*see* **Note 2**).
2. Install the column (and guard column; *see* **Note 3**).
3. Equilibrate the column with mobile phase (*see* **Note 2**), making sure any bacteriostatic storage agent (*see* **Note 4**) is completely removed.
4. Monitor the baseline at 214 nm and/or 280 nm until stable (allow the UV-detector lamp up to 1 h to warm up).
5. Inject sample (*see* **Note 5**).
6. Monitor eluant at 214 nm and/or 280 nm and record data via computer software or integrator.
7. If purifying IgG, set the fraction collector to collect peaks using peak detection or collect 0.1–0.2 mL fractions.

4. Notes

1. All solutions should be 0.22-µm filtered and degassed under vacuum prior to use.
2. The flow rate should be 0.5 mL/min for 7.8 mm internal diameter (i.d.) columns (equal to a linear flow rate of 62.8 cm/h).
3. A guard column can be installed between the autosampler and the main SEC column to prolong the life of the main column, particularly when the sample purity is low.
4. Columns should be stored in the mobile phase with a bacteriostatic agent such as 0.02% azide. Ensure the column is saturated by passing several column volumes of this storage solution through it prior to removing the column from the system.
5. The sample volume is dependent on column size. Volumes above 100 µL will adversely affect sample resolution for 7.8 mm i.d. columns. For analytical purposes use 20 µL of a 1 mg/mL sample. For purification do not exceed a volume of 100 µL or a total load of 1 mg for 7.8 mm × 30 cm columns.

186

Purification of IgG Using Affinity Chromatography on Antigen-Ligand Columns

Mark Page and Robin Thorpe

1. Introduction

Affinity chromatography is a particularly powerful procedure, which can be used to purify IgG, subpopulations of IgG, or the antigen binding fraction of IgG present in serum/ascitic fluid/hybridoma culture supernatant. This technique requires the production of a solid matrix to which a ligand having either affinity for the relevant IgG or vice versa has been bound ***(1)***. Examples of ligands useful in this context are:

1. The antigen recognized by the IgG (for isolation of the antigen-specific fraction of the serum/ascitic fluid, and so forth).
2. IgG prepared from an anti-immunoglobulin serum, e.g., rabbit antihuman IgG serum or murine antihuman IgG MAb for the purification of human IgG (*see* **Note 1**).
3. IgG-binding proteins derived from bacteria, e.g., protein A (from *Staphylococcus aureus* Cowan 1 strain) or proteins G or C (from *Streptococcus* and *see* Chapter 184).

The methods for production of such immobilized ligands and for carrying out affinity-purification of IgG are essentially similar, regardless of which ligand is used. Sepharose 4B is probably the most widely used matrix for affinity chromatography, but other materials are available. Activation of Sepharose 4B is usually carried out by reaction with cyanogen bromide (CNBr); this can be carried out in the laboratory before coupling, or ready-activated lyophilized Sepharose can be purchased. The commercial product is obviously more convenient than "homemade" activated Sepharose, but it is more expensive and may be less active.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

2. Materials

1. Sepharose 4B.
2. Sodium carbonate buffer: 0.5 *M* Na_2CO_3, pH 10.5. Adjust pH with 0.1 *M* NaOH.
3. Cyanogen bromide. **(Warning: CNBr is toxic and should be handled in a fume hood.)**
4. Sodium hydroxide: 1 *M*; 4 *M*.
5. Sodium citrate buffer: 0.1 *M* trisodium citrate, pH 6.5. Adjust pH with 0.1 *M* and citric acid.
6. Ligand solution: 2–10 mg/mL in 0.1 *M* sodium citrate buffer, pH 6.5.
7. Ethanolamine buffer: 2 *M* ethanolamine.
8. PBS: 0.14 *M* NaCl, 2.7 m*M* KCl, 1.5 m*M* KH_2PO_4, 8.1 m*M* Na_2HPO_4.
9. IgG preparation: serum, ascitic fluid, hybridoma culture supernatant.
10. PBS containing 0.1% sodium azide.
11. Disassociating buffer: 0.1 *M* glycine, pH 2.5. Adjust pH with 1 *M* HCl.
12. 1 *M* Tris-HCl, pH 8.8. Adjust pH with 1 *M* HCl.

3. Method

3.1. Activation of Sepharose with CNBr and Preparation of Immobilized Ligand

Activation of Sepharose with CNBr requires the availability of a fume hood and careful control of the pH of the reaction—failure to do this may lead to the production of dangerous quantities of HCN as well as compromising the quality of the activated Sepharose. CNBr is toxic and volatile. All equipment that has been in contact with CNBr and residual reagents should be soaked in 1 *M* NaOH overnight in a fume hood and washed before discarding/returning to the equipment pool. Manufacturers of ready activated Sepharose provide instructions for coupling (*see* **Note 2**).

1. Wash 10 mL (settled volume) of Sepharose 4B with 1 L of water by vacuum filtration. Resuspend in 18 mL of water (do not allow the Sepharose to dry out).
2. Add 2 mL of 0.5 *M* sodium carbonate buffer, pH 10.5, and stir slowly. Place in a fume hood and immerse the glass pH electrode in the solution.
3. **Carefully** weigh 1.5 g of CNBr into an air-tight container (Note: weigh in a fume hood; wear gloves)—remember to decontaminate equipment that has contacted CNBr in 1 *M* NaOH overnight.
4. Add the CNBr to the stirred Sepharose. Maintain the pH between 10.5 and 11.0 by dropwise addition of 4 *M* NaOH until the pH stabilizes and all the CNBr has dissolved. If the pH rises above 11.5, activation will be inefficient, and the Sepharose should be discarded.
5. Filter the slurry using a sintered glass or Buchner funnel, and wash the Sepharose with 2 L of cold 0.1 *M* sodium citrate buffer, pH 6.5—do not allow the Sepharose to dry out. Carefully discard the filtrate (use care: this contains CNBr).

6. Quickly add the filtered washed Sepharose to the ligand solution (2–10 mg/mL in 0.1 *M* sodium citrate, pH 6.5), and gently mix on a rotator ("windmill") at 4°C overnight (*see* **Note 3**).
7. Add 1 mL of 2 *M* ethanolamine solution, and mix at 4°C for a further 1 h—this blocks unreacted active groups.
8. Pack the Sepharose into a suitable chromatography column (e.g., a syringe barrel fitted with a sintered disk) and wash with 50 mL of PBS. Store at 4°C in PBS containing 0.1% sodium azide.

3.2. Sample Application and Elution

1. Wash the affinity column with PBS. "Pre-elute" with dissociating buffer, e.g., 0.1 *M* glycine-HCl, pH 2.5. Wash with PBS; check that the pH of the eluate is the same as the pH of the PBS (*see* **Note 4**).
2. Apply the sample (filtered through a 0.45-µm membrane) to the column. As a general rule, add an equivalent amount (mole:mole) of IgG in the sample to that of the ligand coupled to the column. Close the column exit, and incubate at room temperature for 15–30 min (*see* **Note 5**).
3. Wash non-IgG material from the column with PBS; monitor the A_{280} as an indicator of protein content.
4. When the A_{280} reaches a low value (approx 0.02), disrupt the ligand–IgG interaction by eluting with dissociating buffer. Monitor the A_{280}, and collect the protein peak into tubes containing 1 *M* Tris-HCl, pH 8.8 (120 µL/1 mL fraction) to neutralize the acidic dissociating buffer.
5. Wash the column with PBS until the eluate is at pH 7.4. Store the column in PBS containing 0.1% azide. Dialyze the IgG preparation against a suitable buffer (e.g., PBS) to remove glycine/Tris.

4. Notes

1. The use of subclass-specific antibodies or MAb allows the immunoaffinity isolation of individual subclasses of IgG.
2. Coupling at pH 6.5 is less efficient than at higher pH, but is less likely to compromise the binding ability of immobilized ligands (especially antibodies).
3. Check the efficiency of coupling by measuring the A_{280} of the ligand before and after coupling. Usually at least 95% of the ligand is bound to the matrix.
4. Elution of bound substances is usually achieved by using a reagent that disrupts noncovalent bonds. These vary from "mild" procedures, such as the use of high salt or high or low pH, to more drastic agents, such as 8 *M* urea, 1% SDS or 5 *M* guanidine hydrochloride. Chaotropic agents, such as 3 *M* thiocyanate or pyrophosphate, may also be used. Usually an eluting agent

is selected that is efficient, but does not appreciably denature the purified molecule; this is often a compromise between the two ideals. In view of this, highly avid polyclonal antisera obtained from hyperimmune animals are often not the best reagents for immunoaffinity purification, as it may be impossible to elute the IgG in a useful form. The 0.1 *M* glycine-HCl buffer, pH 2.5, will elute most IgG, but may denature some MAb. "Pre-elution" of the column with dissociating reagent just before affinity chromatography ensures that the isolated immunoglobulin is minimally contaminated with ligand.

5. The column will only bind to its capacity and therefore some IgG may not be bound; however, this can be saved and passed through the column again. The main problem is with back pressure or even blockage, but this can be reduced by diluting the sample by at least 50% with a suitable buffer (e.g., PBS). Incubation of the IgG containing sample with the ligand matrix is not always necessary, but this will allow maximal binding to occur. Alternatively, slowly recirculate the sample through the column, typically at <0.5 mL/min.

Purification of IgG Using Thiophilic Chromatography

Mark Page and Robin Thorpe

1. Introduction

Immunoglobulins recognize sulphone groups in close proximity to a thioether group ***(1)***, and, therefore, thiophilic adsorbents provide an additional chromatographic method for the purification of immunoglobulins that can be carried out under mild conditions preserving biological activity. A thiophilic gel is prepared by reducing divinylsulfone (coupled to Sepharose 4B) with β-mercaptoethanol. The product is of intermediate purity and would be useful for further processing, e.g., purification by ion-exchange, size exclusion, and/or affinity chromatography.

2. Materials

1. Sepharose 4B.
2. 0.5 *M* sodium carbonate.
3. Divinylsulfone.
4. Coupling buffer: 0.1 *M* sodium carbonate buffer, pH 9.0.
5. β-mercaptoethanol.
6. Binding buffer: 0.1 *M* Tris-HCl, pH 7.6, containing 0.5 *M* K_2SO_4.
7. IgG preparation: serum, ascitic fluid, or hybridoma culture supernatant.
8. 0.1 *M* ammonium bicarbonate.

3. Methods

Caution: Divinylsulfone is highly toxic and the column preparation procedures should be carried out in a well-ventilated fume cabinet.

1. Wash 100 mL of Sepharose 4B (settled volume) with 1 L of water by vacuum filteration.
2. Resuspend in 100 mL of 0.5 *M* sodium carbonate, and stir slowly.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Add 10 mL of divinylsulfone dropwise over a period of 15 min with constant stirring. After addition is complete, slowly stir the gel suspension for 1 h at room temperature.
4. Wash the activated gel thoroughly with water until the filtrate is no longer acidic (*see* **Note 1**).
5. Wash activated gel with 200 mL of coupling buffer using vacuum filtration and resuspend in 75 mL of coupling buffer.
6. In a well-ventilated fume cabinet, add 10 mL of β-mercaptoethanol to the gel suspension with constant stirring, and continue for 24 h at room temperature (*see* **Note 2**).
7. Filter and wash the gel thoroughly. The gel may be stored at 4°C in 0.02% sodium azide.
8. Pack 4 mL of the gel in a polypropylene column (10 × 1 cm) and equilibrate with 25 mL of binding buffer.
9. Perform chromatography at 4°C. Mix 1 mL of IgG containing sample with 2 mL of binding buffer, and load onto the column.
10. After the sample has entered the gel, wash non-IgG from the column with 20 mL of binding buffer; monitor the A_{280} as an indicator of protein content in the wash until the absorbance returns to background levels.
11. Elute the bound IgG with 0.1 *M* ammonium bicarbonate, and collect into 2-mL fractions. Monitor the protein content by absorbance at 280 nm, and pool the IgG containing fractions (i.e., those with protein absorbance peaks). Dialyze against an appropriate buffer (e.g., PBS) with several changes, and analyze by gel electrophoresis under reducing conditions (*see* Chapter 188).

4. Notes

1. The activated gel can be stored by washing thoroughly in acetone and kept as a suspension in acetone at 4°C.
2. Immobilized ligands prepared by the divinylsulfone method are unstable above pH 8.0.

Analysis of IgG Fractions by Electrophoresis

Mark Page and Robin Thorpe

1. Introduction (*see* Note 1)

After using a purification procedure it is necessary to obtain some index of purity obtained. One of the simplest methods for assessing purity of an IgG fraction is by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Although "full-size" slab gels can be used with discontinuous buffer systems and stacking gels, the use of a "minigel" procedure, using a Tris-bicine buffer system ***(1)***, rather than the classical Tris-glycine system, is quicker and easier, and gives improved resolution of immunoglobulin light-chains (these are usually smeared with the Tris-glycine system). Gel heights can be restricted to <10 cm and are perfectly adequate for assessing purity and monitoring column fractions.

2. Materials

1. Gel solution: 2.0 mL of 1 *M* Tris, 1 *M* bicine, 4.0 mL 50% w/v acrylamide containing 2.5% w/v *bis*-acrylamide, 0.4 mL 1.5% w/v ammonium persulfate, 0.2 mL 10% w/v SDS.
   Make up to 20 mL with distilled water.
2. Gel running buffer: 2.8 mL 1 *M* Tris, 1 *M* bicine, 1.4 mL 10% w/v SDS.
   Make up to 140 mL with distilled water.
3. Sample buffer: 1.0 g sucrose, 0.2 mL 1 *M* Tris, 1 *M* bicine, 1.0 mL 10% SDS, 0.25 mL 2-mercaptoethanol.
   Make up to 3 mL with distilled water, and add 0.001% w/v Bromophenol blue. Store at −20°C.
4. Coomassie blue R stain: Add coomassie brilliant blue R (0.025 g) to methanol (50 mL), and stir for 10 min. Add distilled water (45 mL) and glacial acetic acid (5 mL). Use within 1 mo.
5. Destain solution: glacial acetic acid (7.5 mL) and methanol (5 mL). Make up to 100 mL with distilled water.

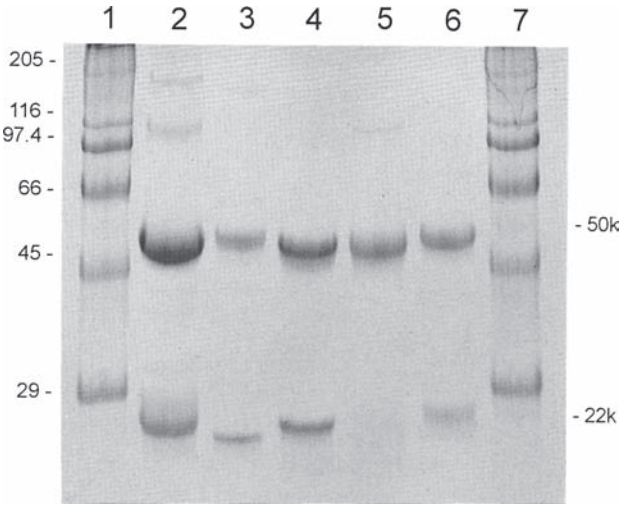

Fig. 1. SDS-PAGE minigel depicting purified IgG preparations derived from human serum (*lane 2*), mouse ascitic flude (*lanes 3* and *4*), rabbit serum (*lane 5*), and sheep serum (*lane 6*). Samples are elctrophoresed under reducing conditions and stained with Coomassie blue. All IgGs consist predominantly of two bands comprising heavy (50,000 M_r) and light (22,000 M_r) chains with no major contaminating proteins. Molecular-weight markers are shown in *lanes 1* and *7* and their molecular weights (in thousands) given on the left.

6. *N,N,N′,N′*-Tetramethylethylenediamine (TEMED).
7. Molecular-weight markers (mol-wt range 200,000–14,000).
8. Purified IgG or column fraction samples.

3. Methods

1. Prepare sample buffer.
2. Adjust antibody preparation to 1 mg/mL in 0.1 *M* Tris, 0.1 *M* bicine (*see* **Note 2**).
3. Mix the sample in the ratio 2:1 with sample buffer.
4. Heat at 100°C for 2–4 min.
5. Prepare gel solution and running buffer as described in **Subheading 2**.
6. Assemble gel mold according to manufacturer's instructions.
7. Add 30 µL TEMED to 10 mL of gel solution, pour this solution between the plates to fill the gap completely, and insert the comb in the top of the mold (there is no stacking gel with this system). Leave for 10 min for gel to polymerize.
8. Remove comb and clamp gel plates into the electrophoresis apparatus. Fill the anode and cathode reservoirs with running buffer.
9. Load the sample(s) (30–50 µL/track), and run an IgG reference standard and/or mol-wt markers in parallel.
10. Electrophorese at 150V for 1.5 h.

11. Remove gel from plates carefully, and stain with Coomassie blue R stain for 2 h (gently rocking) or overnight (stationary) (*see* **Note 3**).
12. Pour off the stain, and rinse briefly in tap water.
13. Add excess destain to the gel. A piece of sponge added during destaining absorbs excess stain. Leave until destaining is complete (usually overnight with gentle agitation).

4. Notes

1. The "minigel" is easily and quickly prepared consisting of a resolving (separating) gel only and takes approx 1.5 h to run once set up. The IgG sample is prepared for electrophoresis under reduced conditions, and is run in parallel with either a reference IgG preparation or with standard mol-wt markers. The heavy chains have a characteristic relative molecular weight of approx 50,000 and the light-chains a molecular weight of 22,000 (**Fig. 1**).
2. The extinction coefficient ($E^{1\%}_{280}$) of human IgG is 13.6 (i.e., a 1 mg/mL solution will have an A_{280} of 1.36).
3. Mark the gel uniquely prior to staining so that its orientation is known. By convention, a small triangle of the bottom left- or right-hand corner of the gel is sliced off.

Purification of Immunoglobulin Y (IgY) from Chicken Eggs

Christopher R. Bird and Robin Thorpe

1. Introduction

Chickens produce an immunoglobulin G (IgG) homologue, sometimes referred to as IgY (to reflect the differences in the heavy chain domain compared with mammalian IgG), which can be conveniently isolated from the yolk of eggs ***(1)***. The concentration of immunoglobulin in the egg yolk is roughly the same as in serum (10–15 mg/mL), and an average egg can yield approx 80–100 mg of immunoglobulin. Eggs can therefore provide an abundant source of polyclonal antibody that may be aquired noninvasively from eggs laid by immunized chickens ***(2)***. The production of polyclonal antibodies in chickens provides other advantages over using conventional mammalian species. The mechanism of antibody production and organization of the avian immune system is quite different from that of mammals, and as chickens are phylogenetically distant from mammals because of their evolutionary divergence millions of years ago, it is possible to generate antibody responses to highly conserved proteins that do not easily elicit an immune response in mammalian species. Chicken immunoglobulins possess other characteristics that differ from mammalian antibodies that may offer advantages in certain immunological techniques. Most of the interactions via the Fc region in mammalian antibodies do not occur with chicken immunoglobulin. Chicken IgG does not activate mammalian complement systems, and does not react with mammalian rheumatoid factors, and neither protein A or protein G bind to chicken IgG. Although chicken antibodies can be substituted for mammalian antibodies in many techniques (and may even be advantageous) it may be necessary to optimize conditions in certain systems particularly with precipitation techniques where chicken IgG appears to be less efficient then conventional mammalian polyclonal antibodies.

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

To isolate chicken immunoglobulins from egg yolk the lipid first has to be removed. This can be achieved by dextran sulfate precipitation after which the chicken immunoglobulins can be purified by sodium sulfate precipitation.

2. Materials

1. Tris-buffered saline (TBS): 0.14 *M* NaCl in 10 m*M* Tris-HCl, pH 7.4.
2. 1 *M* Calcium chloride.
3. Dextran sulphate solution: 10% (w/v) in TBS.
4. Centrifuge.
5. Anhydrous sodium sulfate.
6. Saturated sodium sulfate solution: 36% (w/v) in water.

3. Methods

Break the eggshell and carefully separate the egg yolk from the white to minimize contamination of the yolk with egg white proteins. Place the yolk on a piece of filter paper in which a small hole has been cut. Position the yolk above the hole and pierce the yolk membrane with a needle and collect the yolk in a suitable container (e.g., 50-mL centrifuge tube). The yolk membrane and any remaining egg white will stick to the filter paper. Approximately 10 mL of yolk is obtained from an average sized egg.

1. Dilute the egg yolk with 4 vol of TBS.
2. Centrifuge at 2000–3000*g* for 20 min at room temperature with the brake off.
3. Remove the supernatant, and discard the membrane pellet and add 120 µL of dextran sulfate solution/mL of supernatant, mix well, and incubate at room temperature for 30 min.
4. Add 50 µL of 1 *M* $CaCl_2$/mL and mix well. Incubate for a further 30 min at room temperature.
5. Centrifuge at 2000–3000*g* for 30 min and collect the supernatant, which should be clear; if not, repeat **steps 3** and **4** using half the amounts of dextran sulfate and calcium chloride. The pellet can be washed once at this stage with 50 mL of TBS, and the supernatant combined with the first dextran sulfate supernatant obtained.
6. Adjust the volume of the pooled supernatants to 100 mL with TBS. Stir the supernatant and slowly add 20 g of sodium sulfate until completely dissolved and leave to stand for 30 min at room temperature.
7. Centrifuge for 20 min at 2000–3000*g* and discard the supernatant.
8. Redissolve the precipitate in 10 mL TBS and centrifuge for 20 min at 2000–3000*g*. Collect the supernatant and discard the pellet.
9. Stir the supernatant and slowly add 8 mL of 36% (w/v) sodium sulfate solution and leave to stand for 30 min at room temperature.
10. Centrifuge at 2000–3000*g* for 20 min, discard the supernatant, and redissolve the pellet in 5 mL of TBS. Dialyze and filter the purified immunoglobulin.

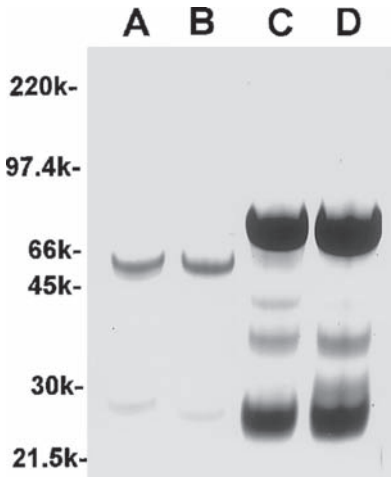

Fig. 1. Coomassie Blue stained SDS-polyacrylamide gel (10% total acrylamide) showing the different mobility of chicken IgG heavy chain compared to mammalian IgG. *Lanes: A*, protein G purified sheep IgG; *B*, therapeutic human IgG; *C* and *D*, two different preparations of purified chicken IgG. All samples were run reduced.

4. Notes

1. Eggs may be stored at 4°C until several have accumulated and then processed together. Alternatively separated egg yolk can be diluted with buffer containing preservative and stored at 4°C prior to purification.
2. 36% (w/v) Sodium sulfate is a supersaturated solution and requires heating to fully dissolve, after which the solution should be stored at 30–40°C before use. The entire procedure for IgG precipitation with sodium sulfate should be carried out at 20–25°C; otherwise the sodium sulfate may precipitate.
3. Purified chicken IgG can sometimes aggregate after freezing and thawing; therefore storing sterile solutions of purified chicken IgG at 4°C may be advisable; alternatively they can be lyophilized for longer term storage.
4. The chicken IgG heavy chain has a different mobility from mammalian IgG, which can be demonstrated by reducing sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) (**Fig. 1**).

Affinity Purification of Immunoglobulins Using Protein A Mimetic (PAM)

Giorgio Fassina, Giovanna Palombo, Antonio Verdoliva, and Menotti Ruvo

1. Introduction

While antibodies of the G class can be conveniently purified by affinity chromatography using immobilized protein A or G even at large scale, scaling up purification of IgM, IgA, and IgE and IgY still presents several problems, as specific and cost-effective ligands for these classes of immunoglobulins are not available. Protein A ***(1)***, which is widely used for the affinity purification of antibodies from sera or cell culture supernatants, does not recognize immunoglobulins of the M, A, E, and Y classes well and is not used to capture and purify these immunoglobulins from crude sources. Moreover, these two proteins are obtained from microorganisms or genetically modified bacteria, which carries the risk of affecting the safety of the purified antibodies through the presence of contaminants such as viruses, pirogens, or DNA fragments. As a result, the availability of alternative ligands for the affinity purification of antibodies is highly important from an industrial aspect. After immobilization on solid supports, the mannan binding protein (MBP), an affinity ligand for IgM, provides affinity media useful for IgM isolation based on a temperature-dependent interaction of the ligand with the immunoglobulins ***(2)***. The use of immobilized MBP for the purification of IgM is based on the adsorption in the presence of calcium at a temperature of 4°C, and the elution at room temperature of adsorbed immunoglobulins in the presence of ethylene-diamineotetraacetic acid (EDTA). This ligand shows low binding affinity for IgG, but binds to bovine and human IgM with lower affinity than murine IgM. However, in addition to the complexity of MBP isolation, functional binding capacities of MBP columns are limited to 1 or 2 mg of IgM per milliliter of support. IgA, which is involved

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

in the first specific defense against natural infection ***(3)*** and represents the second most abundant immunoglobulin in serum ***(4)***, can be purified through the combination of different fractionation techniques such as ammonium sulfate precipitation, ion-exchange chromatography, and gel filtration ***(5, 6)***. All these procedures are time consuming, labor intensive, and are not compatible with industrial scaling up. Lectin jacalin, isolated from jackfruit seeds ***(7)***, binds to IgA and can be conveniently used for the affinity purification of IgA from colostrum or serum ***(8)***. However, several aspects limit the use of this lectin for large-scale purification of monoclonal IgA from cell culture supernatants. First, jacalin is a biologically active lectin, being a potent T cell mitogen and a strong B cell polyclonal activator ***(9)***, thus requiring a careful control for ligand leakage into the purified preparation. Second, jacalin binds to the carbohydrate moiety of IgA, and D-galactose is required to elute IgA from affinity columns, which is costly and impractical for large-scale operations.

Antibodies of the E class, which represent an extremely important class of immunoglobulins from a biological and clinical point of view, require complex and time-consuming isolation protocols that make their characterization very difficult. The main purification procedure is represented by immunoaffinity chromatography using anti-IgE antibodies immobilized on solid supports ***(10, 11)***. Even if selective enough for research application, scaling up immunoaffinity chromatography for preparative applications is very expensive and not easily accomplished. Other approaches for IgE purification include classical chromatographic protocols based on the combination of different sequential procedures such as salting out, affinity chromatography on lysine–Sepharose, ion-exchange, gel filtration, and immuno-affinity chromatography to remove interfering proteins ***(12)***. Studies carried out with immobilized protein A show that this protein, known to recognize the immunoglubulin Fc region, does not bind to monoclonal IgE, but binds 12–14% of serum polyclonal IgE. Protein G binds to neither polyclonal nor monoclonal IgE ***(13)***.

IgY is an important class of immunoglobulins obtained from chicken egg yolk that represents an economical source of polyclonal antibodies ***(14)***. Despite the advantages in production of immunoglobulins from egg yolk in terms of efficiency ***(15)***, immunogenicity against mammal proteins ***(15)***, and applications in therapeutics and diagnostics ***(16, 17)***, only fewer than 2% of the total number of polyclonal antibodies produced worldwide and commercially available are raised in chickens. This low diffusion is related to difficulties in purifying IgY from egg yolk, particularly from the lipidic fraction, which represents the main contaminant. The complex isolation methods described in the literature ***(18–20)*** and the lack of ligands usable for the affinity purification of IgY make the isolation of this class of immunoglobulins a laborious process that cannot be scaled up easily for industrial applications.

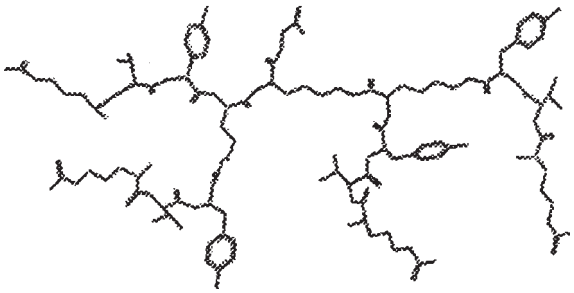

Fig. 1. Structure of PAM (TG19318) ($GKK_2[YTR]_4$).

A synthetic peptide ligand (PAM, Protein A Mimetic, TG19318) (*see* **Fig. 1**), derived from the synthesis and the screening of a combinatorial peptide library ***(21)***, has been identified in our laboratory for its ability to recognize, as a protein A mimetic, the constant portion of immunoglobulins. Its applicability in affinity chromatography for the downstream processing of antibodies has been fully established in studies examining the specificity and selectivity for polyclonal and monoclonal antibodies derived from different sources. Ligand specificity is broader than for any existing ligand, as IgGs derived from human, cow, horse, pig, mouse, rat, rabbit, goat, and sheep sera ***(21, 22)***, as well as IgYs derived from egg yolk ***(23)*** have been efficiently purified on PAM affinity columns. The ligand proved useful not only for IgG purification, but also for IgM ***(24)***, IgA ***(25)***, and IgE ***(26)*** isolation from sera or cell culture supernatants (*see* **Table 1**). PAM ligand, a tetrameric tripeptide, can be produced at low cost by means of chemical solution phase or solid phase synthesis in large amounts, does not contain biological contaminants such as viruses, pyrogens, or DNA fragments, as recombinant or extractive ligands such as protein A or G. In addition, the low toxicity of TG19318 and the low molecular weight of the resulting fragments considerably reduce the problems of contamination by leaked ligand, as is the case for protein A. Preliminary experiments suggest that the ligand is more stable to proteolytic digestion when coupled to solid supports, and the enzymatic activity normally found in crude feedstock derived from cell culture supernatants does not lead to noticeable loss of capacity. The ligand can be easily immobilized on preactivated solid supports, as the presence of four peptide chains departing from a central core, of which only a limited number are involved in the coupling with the solid phase, leaves the others fully available for the interaction. All the different supports tested so far maintain the ligand recognition properties for immunoglobulins, even if with different functional capacities. The affinity columns with immobilized PAM are not affected by the presence of denaturants, detergents, or other sanitation reagents commonly used for pirogen removal, and TG19318 columns

Table 1
Immunoglobulins Specificity of PAM (TG 19318)

Ig class	Species	Source
IgG	Human	Serum
	Rabbit	Serum
	Cow	Milk
	Cow	Serum
	Sheep	Serum
	Rat	Serum
(IgG2b)	Rat	Cell supernatant
	Mouse	Serum
(IgG2a)	Mouse	Cell supernatant
(IgG1K)	Mouse	Cell supernatant
	Pig	Serum
	Horse	Serum
	Goat	Serum
IgM	Human	Serum
	Mouse	Serum
	Mouse	Ascites
	Mouse	Cell supernatant
IgA	Human	Serum
	Mouse	Serum
	Mouse	Cell supernatant
IgE	Rat	Ascites
IgY	Chicken	Egg yolk

can withstand a large array of harsh sanitizing agents with no capacity losses. Immunoglobulin adsorption on TG19318 affinity columns occurs with neutral buffers at low ionic strength and at room temperature. Elution of adsorbed immunoglobulins may be achieved under mild conditions not causing immunoglobulin denaturation, simply by changing the buffer pH to acid or alkaline conditions, with acetic acid (pH 3) or sodium bicarbonate (pH 9.0). Increasing the ionic strength of the dissociation buffer favors a more efficient elution of adsorbed antibodies.

Affinity interaction is strong enough to allow purification of antibodies directly from diluted supernatants in which the immunoglobulin concentration is very low, from 10 to 50 μg/mL. The main contaminant, albumin, is always efficiently removed in the purification step with any type of support tested for TG19318 immobilization. Column capacity depends on the type of support used for ligand immobilization, and may range from 10 to 25 mg of immunoglobulin/mL of support.

Purification of antibodies with clinical and therapeutic applications represents a key step in the validation process of these molecules, but the complex and the

labor-intensive isolation procedures may alter the quality and the safety of the purified product. In this scenario, the availability of a synthetic ligand able to recognize antibodies independently from their class is of great importance from an industrial point of view, as it may simplify the isolation procedures, leading to lower production costs and reducing considerably the presence of biological contaminants in the purified antibody preparation.

2. Materials

2.1. Synthesis of PAM

1. Automated peptide synthesizer (Perkin-Elmer 431 A).
2. Resin Gly-hydroxymethylphenoxy (Gly-HMP).
3. 9-Fluorenyl-methoxycarbonyl-Lys(9-fluorenyl-methoxycarbonyl) (Fmoc-Lys[Fmoc]).
4. Fmoc-Arg(pentamethylchromane) (Fmoc-Arg[Pmc]).
5. Fmoc-Thr(*O-tert*-butyl) (Fmoc-Thr[OtBu]).
6. Fmoc-Tyr(OtBu).
7. *N*-Methyl-2-pyrrolidone.
8. Piperidine (20% in *N*-methyl-2-pyrrolidone).
9. 1 *M* Dicyclohexylcarbodiimide in *N*-methyl-2-pyrrolidone.
10. 1 *M* Hydroxybenzotriazole (HOBt) dissolved in *N*-methyl-2-pyrrolidone.
11. Methanol.
12. Dichloromethane.
13. Cleavage mixture: Trifluoroacetic acid (TFA)–phenol–water–ethanedithiol–thioanisol.
14. Ether.
15. High-performance liquid chromatography (HPLC) system.
16. Lichrospher RP-8 column (25 × 1 cm internal diameter [i.d.]).
17. Water–acetonitrile–TFA.

2.2. PAM Immobilization on Affinity Media

1. 0.5 *M* NaCl, 0.1 *M* Sodium bicarbonate, pH 8.5.
2. 0.1 *M* Tris-HCl, pH 8.5.
3. 0.1 *M* Acetic acid, 0.5 *M* NaCl, pH 4.0.
4. 0.1 *M* Tris-HCl, 0.5 *M* NaCl, pH 8.0.
5. NHS–Sepharose 4 Fast Flow (Pharmacia Biotech).
6. 3M Emphaze Biosupport Medium AB1 (Pierce).
7. HPLC system.
8. Lichrospher RP-8 column (25 × 1 cm i.d.).
9. Water–acetonitrile–TFA (95:5:0.1).

2.3. Affinity Purification on PAM Columns

1. HPLC/FPLC system.
2. 50–100 m*M* sodium phosphate, pH 7.0.
3. 25–50 m*M* bis-Tris buffer, pH 6.5.

4. 0.1 *M* Acetic acid.
5. 0.1 *M* Sodium bicarbonate, pH 8.5.
6. Protein A–Sepharose 4B (Pharmacia).

3. Methods

3.1. Synthesis of PAM

PAM can be produced in adequate amounts by solid-phase peptide synthesis on automatic peptide synthesizers, such as the Perkin-Elmer model 431A, software version 1.1, according to the synthesis procedure suggested by the manufacturer based on a consolidated methodology well known and widely reported in the literature.

1. Deprotect the Gly-HMP resin (0.1 mmol) by treatment with 3.0 mL of piperidine (20% in *N*-methyl-2-pyrrolidone) for 14 min, at room temperature with stirring.
2. Wash the resin 5× with 2.5 mL of *N*-methyl-2-pyrrolidone for 9 min under agitation at room temperature.
3. In the meantime, preactivate the amino acid residue in position 2 (Fmoc-Lys[Fmoc], 1 mmol) from the C-terminus (1 mmol) by incubation with 1 mL of 1 *M* HOBt dissolved in *N*-methyl-2-pyrrolidone and 1 mL of 1 *M* dicyclohexylcarbodiimide in *N*-methyl-2-pyrrolidone.
4. Incubate the activated amino acid with the resin for 51 min under constant agitation.
5. Wash the resin with *N*-methyl-2-pyrrolidone (four washes for 0.5 min with 2 mL).
6. Subject the resin to a further deprotection cycle with piperidine and a further coupling cycle with the next amino acid.
7. Repeat this sequential step procedure until all the amino acid residues are assembled. In detail, the following amino acid derivatives need to be used: Fmoc-Lys (Fmoc), Fmoc-Arg (Pmc), Fmoc-Thr (OtBu), and Fmoc-Tyr (OtBu).
8. Wash the resin with methanol, dichloromethane, and again with methanol and accurately dry the resin under vacuum for 12 h, after completion of synthesis cycles and removal of the N-terminal Fmoc group by piperidine treatment.
9. Detach protected peptide from resin by incubation of 100 mg of resin with 5 mL of a mixture of trifluoroacetic acid–phenol–water–ethandithiol–thioanisol 84:4:3:3:3 by vol for 2 h at room temperature under agitation.
10. Filter the resin using a sintered glass filter and reduce the filtrate in volume to few milliliters by vacuum evaporation and treat the residual liquid with 50 mL of cold ethyl ether.
11. Separate the precipitated peptidic material by centrifugation and resuspend the centrifuged material in 25 mL of water–acetonitrile–TFA 50:50:0.1, freeze, and lyophilize.
12. Purify the lyophilized material from contaminants by high-performance liquid chromatography (HPLC) using a Lichrospher RP-8 column (25 × 1 cm i.d.), equilibrated at a flow rate of 3 mL/min with water–acetonitrile–TFA 95/5/0.1, and

eluting with a linear gradient of acetonitrile ranging from 5 to 80% in 55 min. Collect material corresponding to the main peak, freeze, and lyophilize.

13. Confirm chemical identity of PAM by determination of:
    a. Amino acid composition;
    b. N-terminal residue;
    c. Molecular weight by mass spectrometry.

3.2. PAM Immobilization on Affinity Media

3.2.1. PAM Immobilization on NHS-Sepharose 4 Fast Flow

1. Dissolve the peptide ligand in 0.1 *M* Na bicarbonate, 0.5 *M* NaCl, pH 8.5.
2. Collect the required amount of NHS-Sepharose 4 Fast Flow, remove the storage solution, and wash with 1 m*M* HCl.
3. Mix the PAM solution with gel suspension in a ratio 2:1 and leave the mixture to incubate for several hours at room temperature under gentle agitation, monitoring the extent of peptide incorporation by reverse phase (RP)-HPLC analysis of reaction mixture at different times (*see* **Note 1**).
4. Wash away excess ligand and incubate with 0.1 *M* Tris, pH 8.5, for 1 h at room temperature to deactivate residual active groups.
5. Wash peptide derivatized resin with at least three cycles of 0.1 *M* acetic acid, 0.5 *M* NaCl, pH 4.0, and 0.1 *M* Tris-HCl, 0.5 *M* NaCl, pH 8.0.
6. Store the product in 20% ethanol at 4°C.

3.2.2. PAM Immobilization on 3M Emphaze Biosupport Medium AB1

1. Dissolve the peptide ligand in 0.2 *M* Na bicarbonate, 0.6 *M* Na citrate, pH 8.0, at a concentration of 5–10 mg/mL.
2. Weigh out the required amount of 3M Emphaze and add the PAM solution directly to the dry beads.
3. Leave the mixture to incubate for several hours at room temperature under gentle agitation, monitoring the extent of peptide incorporation by RP-HPLC analysis of the reaction mixture at different times (*see* **Note 1**).
4. Wash away excess ligand with coupling buffer and incubate with 0.1 *M* Tris, pH 8.5, for 1 h at room temperature to deactivate residual active groups.
5. Wash peptide derivatized resin with at least three cycles of 0.1 *M* acetic acid, 0.5 *M* NaCl, pH 4.0, and 0.1 *M* Tris-HCl, 0.5 *M* NaCl, pH 8.
6. Store the product in 20% ethanol at 4°C.

3.3. Purification of Immunoglobulins on PAM Columns

3.3.1. Affinity Purification of IgG on the PAM-Emphaze Column

1. Dilute sera, ascitic fluids, or cell culture supernatants containing IgG 1:1 (v/v) with the column equilibration buffer, preferably 25–50 m*M* *bis*-Tris, pH 6.5, filtered through a 0.22-µm filter (Nalgene).
2. Load the sample on to the column equilibrated at a linear flow rate of 60 cm/h with 25–50 m*M* *bis*-Tris buffer, pH 6.5 (*see* **Notes 2** and **3**), monitoring the effluent

by UV detection at 280 nm. Wash the column with the equilibration buffer until the UV absorbance returns to baseline.
3. Elute bound antibodies with 0.2 *M* acetic acid, pH 3.5 (*see* **Note 4**), wash the column with five volumes of 0.1 *M* acetic acid, and neutralize desorbed material immediately with 1.5 *M* Tris, pH 9.0.
4. Determine by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and enzyme-linked immunosorbent assay (ELISA) purity and activity. The purity of adsorbed antibodies should be usually very high, ranging from 80% to 95%.
5. Store the column in 20% ethanol or 0.05% sodium azide (w/v) (*see* **Notes 5–7**).

3.3.2. Affinity Purification of IgM on the PAM-Sepharose 4 Fast Flow Column

3.3.2.1. Purification from Cell Culture Supernatants

Immobilized PAM is useful also for the capture of monoclonal IgM directly from crude cell supernatants (*see* **Note 8**) according to the following steps:

1. Load samples of crude cell culture supernatant obtained from stable hybridoma cell lines secreting murine IgM against specific antigens, even if containing a low concentration of IgM (10–100 mg/mL) on a PAM-affinity column equilibrated at a flow rate of 60 cm/h with 50–100 m*M* sodium phosphate, pH 7.0. Samples containing up to 5 mg of IgM may be loaded onto 1-mL bed volume columns. As before, it is recommended to dilute 1:1 (v/v) the samples with the elution buffer prior to application.
2. Wash the column with the equilibration buffer until complete removal of the unretained material is achieved, and then elute with 0.1 *M* acetic acid. Material desorbed by the acid treatment is collected and immediately neutralized.
3. Determine the protein content by the biuret method and IgM content by IgM specific ELISA assay (*see* **Note 9**).

3.3.2.2. Purification from Sera

IgM from sera can be purified by affinity chromatography on a PAM column after a preliminary IgG adsorption step on protein A–Sepharose 4B according to the protocol:

1. Load the serum sample on a protein A–Sepharose 4B affinity column equilibrated with 50 m*M* sodium phosphate, pH 7.0, at a flow rate of 60 cm/h.
2. Collect the column unretained material and dilute 1:1 (v/v) with 100 m*M* sodium phosphate, pH 7.0.
3. Load the protein A unretained fraction on the PAM column equilibrated at a flow rate of 60 cm/h with 50 m*M* sodium phosphate, pH 7.0. Wash the column and elute bound IgM as described previously in **Subheading 3.3.1**.
4. Collect fractions corresponding to the unbound and bound materials for SDS-PAGE analysis and ELISA determination of antibody recovery using an anti-IgM antibody conjugated to peroxidase for detection (*see* **Note 10**).

3.3.3. Affinity Purification of IgA on the PAM-Sepharose Fast Flow Column

3.3.3.1. Purification from Cell Culture Supernatants

Immunoglobulins of the A class secreted in cell culture supernatants derived from the cultivation of hybridoma can be conveniently purified on PAM columns equilibrated with 100 m*M* phosphate buffer, pH 7.0, at a flow rate of 60 cm/h.

1. Dilute sample containing up to 5 mg of IgA 1;1 (v/v) with 100 m*M* sodium phosphate, pH 7.0 and filter through a 0.22-mm filter and then load the sample onto the column.
2. Wash the column with loading buffer until the unbound material is completely removed.
3. Elute the adsorbed immunoglobulins with 0.1 *M* acetic acid and immediately neutralize with 1.5 *M* Tris, pH 9.0. Each fraction is checked for purity by SDS-PAGE and gel filtration analysis (*see* **Note 11**) and for IgA immunoreactivity using an ELISA assay (*see* **Note 12**).

3.3.3.2. Purification from Sera

Isolation of IgA from serum requires the prior removal of the IgG fraction. As in the case of IgM purification from sera, IgA-containing serum needs to be first fractionated on a protein A–Sepharose column, following conventional purification protocols.

1. Dilute 1:1 (v/v) the flow through material from protein A chromatography, lacking IgG and containing mainly IgA, IgM, and albumin, with 100 m*M* sodium phosphate, pH 7.0, and use directly for a subsequent fractionation on PAM columns.
2. Elute the bound fraction, after adsorption and column washing with 100 m*M* sodium phosphate, by a buffer change to 0.1 *M* acetic acid and immediately neutralize.

3.3.4. Affinity Purification of IgE on the PAM-Sepharose 4 Fast Flow Column

Monoclonal IgE obtained from the cultivation of stable hybridoma cell lines or contained in ascitic fluid can also be conveniently purified on PAM affinity columns.

1. Dilute samples containing up to 5 mg of IgE 1:1 with 100 m*M* sodium phosphate, pH 7.0, filter through a 0.22-mm filter, and then directly load onto a PAM column (1 mL bed volume) equilibrated at a flow rate of 1.0 mL/min with 100 m*M* sodium phosphate, pH 7.0, at room temperature.
2. Wash the column after sample loading with loading buffer to remove any unbound material.
3. Elute adsorbed immunoglobulins by a buffer change to 0.1 *M* acetic acid and immediately neutralize with 1.5 *M* Tris, pH 9.0. Each fraction should be checked

for antibody reactivity by ELISA and for purity by SDS-PAGE electrophoresis. As in other cases, no traces of albumin are contaminating the purified IgE preparation. Immunoreactivity of IgE purified on PAM-columns can be determined by ELISA assay on polystyrene microtiter plates (*see* **Note 13**).

3.3.5. Affinity Purification of IgY on the PAM Emphaze Column

Y immunoglobulins from water-soluble yolk extract (*see* **Note 14**) can be isolated in a single-step protocol by affinity chromatography on a PAM column according to the following procedure:

1. Dialyze or dilute the sample 1:1 (v/v) with the starting buffer (25 m*M* *bis*-Tris, pH 6.5), filtered through a 0.45-mm filter (Nalgene).
2. Load the sample onto the column (1 mL bed volume) equilibrated at a flow rate of 1.0 mL/min with 25 m*M* *bis*-Tris, pH 6.5, monitoring the effluent by UV detection at 280 nm.
3. After elution of unbound material, change the eluent to 0.1 *M* acetic acid, pH 3.0, to elute bound material, and neutralize eluted IgY immediately with a few drops of 1 *M* Tris, pH 9.5.
4. Characterize collect fractions by SDS-PAGE, gel permeation, and radial immunodiffusion analysis to determine IgY recovery and purity, and by ELISA, to evaluate the immunoreactivity recovered after purification (*see* **Note 15**).

3.3.6. Sterilization of the PAM Matrix by Autoclaving

PAM resin can be sterilized by autoclaving according to the following procedure:

1. Centrifuge the resin to replace the storage buffer with 0.05 *M* Na phosphate, pH 7.0.
2. Autoclave the sample for up to 30 min at 120°C.
3. Repeat **step 1** to remove autoclaving buffer (*see* **Note 16**).
4. Store the matrix in 20% ethanol at 4°C.

4. Notes

1. PAM immobilization on preactivated solid supports occurs easily, with coupling yields generally between 80 and 95%. Recommended ligand density is between 6 and 10 mg/mL of support.
2. Optimal interaction of immunoglobulins to immobilized PAM occurs in the pH range 6.5–7.5. Compatible buffers are Tris, *bis*-Tris, and sodium phosphate. Phosphate-buffered saline (PBS) is not recommended because the high content of chloride ions interferes with binding. High salt concentrations reduce binding capacity.
3. The use of sodium phosphate as binding buffer, at concentrations from 100 to 200 m*M*, is suggested for samples containing high amounts of phospholipids.

4. Elution of adsorbed immunoglobulins can be performed using acetic acid or 0.1 *M* sodium bicarbonate, pH 8.5. Addition of sodium chloride to the elution buffer leads to recovery of antibodies in a more concentrated form.
5. PAM column sanitation is easily accomplished, as the ligand is stable to the vast majority of sanitizing agents and is not susceptible of denaturation.
6. Chemical stability of PAM is very high, and in the immobilized form is also sufficiently stable to enzymatic degradation. Columns can be reused for more than 40 purification cycles without appreciable loss of capacity.
7. Removal of adsorbed or precipitated proteins on the columns can be performed by repetitive washings with 0.1 *M* sodium hydroxide and 1 m*M* hydrochloridric acid. Check first supports compatibility with these eluents.
8. Binding affinity of PAM is higher for IgM than for IgG. Samples containing both immunoglobulins classes will be enriched in the IgM fractions.
9. Usually very high recovery (80%) is obtained. SDS-PAGE analysis of eluted fractions shows an excellent degree of purification, as no albumin traces are detected in the column-bound fraction, and all the material migrates at the expected molecular weight for IgM. Densitometric scanning of the purified fraction gel lane shows generally purity close to 95%. Column flowthrough material contains, on the other hand, the vast majority of albumin and the other contaminants. Extent of purification can be monitored also by gel filtration chromatography on calibrated columns. Gel filtration profiles of the affinity purified IgM validate SDS-PAGE data, indicating that a single affinity step on PAM columns is sufficient to remove albumin and capture and concentrate the IgM fraction. The effect of purification conditions on the maintenance of antibody antigen binding ability can be evaluated by ELISA assays on microtiter plates coated with the IgM corresponding antigen. For all cases tested, results indicate that the affinity fractionation step is mild and does not lead to loss of immunoreactivity, indicating that the purified antibody is fully active.
10. The vast majority of immunoreactivity (close to 80%) is generally found in the bound fraction, while only little activity is detected in the flow-through fraction. SDS-PAGE analysis indicates that the column bound fraction contains mainly IgM (85% purity), with only trace amounts of IgG or other contaminating proteins. Only IgA are detected as minor contaminants, as this class of immunoglobulins, which is found in sera at very low concentrations, is also recognized by immobilized PAM. Immunoreactivity recovery of IgM from affinity purification can be checked using aliquots of crude material, unbound and bound fractions, directly coated on microtiter plates at the same concentration (10 µg/mL) in 0.1 *M* sodium carbonate buffer, pH

8.5, overnight at 4°C. After the plates are washed 5× with PBS, wells are then blocked with 100 µL of PBS containing 3% bovine serum albumin (BSA) for 2 h at room temperature, to prevent nonspecific adsorption of proteins. Plates are washed several times with PBS. IgM detection is performed by filling each well with 100 µL of an anti-IgM-peroxidase conjugate solution diluted 1 : 1000 with PBS containing 0.5% BSA, and incubating for 1 h at 37°C. Plates are then washed with PBS 5×, and developed with a chromogenic substrate solution consisting of 0.2 mg/mL ABTS in 0.1 *M* sodium citrate buffer, pH 5.0, containing 5 m*M* hydrogen peroxide. The absorbance at 405 nm of each sample is measured with a Model 2250 EIA Reader (Bio-Rad). If the antigen is available, recovery of immunoreactivity can be evaluated by immobilizing the antigen on microtiter plates, dissolved in 0.1 *M* sodium carbonate buffer, pH 8.5, overnight at 4°C. The plates are washed and saturated as described previously, and filled with crude, unbound and bound materials at the same concentration (10 µg/mL) diluted with PBS–0.5% BSA. The antibody detection and the development of the chromogenic reaction are then carried out as described in **Note 10**.

11. Determination by ELISA of IgA recovery indicates that the column retains 80% of the IgA immunoreactivity initially found in the sample. Gel electrophoretic analysis of the purified fraction indicates the absence of contaminating albumin; however, all the IgM originally present in the sample will be retained by the column. Detection of IgA immunoreactivity in the fractions derived from the affinity step can be accomplished by ELISA by immobilizing IgA containing samples on microtiter plates and detecting IgA with an anti-IgA antibody. SDS-PAGE analysis indicates that the majority of IgA in the sample is retained by the column, and only minute amounts of albumin are detected in the purified preparation. These results are confirmed by the gel filtration analysis, where the column bound fraction shows mainly the presence of IgA. ELISA determination of the IgA content of the column bound and unbound fractions after the purification step indicates that the majority (80–90%) of the initial immunoreactivity is retained by the column.
12. Aliquots of crude material, unbound and bound fractions (100 µL) are incubated on microtiter plates (Falcon 3912) in 0.1 *M* sodium carbonate buffer, pH 8.5, overnight at 4°C. After washing the plates 5× with PBS (50 m*M* phosphate, 150 m*M* sodium chloride), pH 7.5, plate wells are saturated with 100 µL of PBS containing 3% of BSA, for 2 h at room temperature, to prevent nonspecific protein adsorption. Plates are then washed with PBS several times. Detection of IgA antibody is performed by adding to each well 100 µL of an anti-IgA peroxidase conjugate solution (Sigma) diluted 1 : 1000 with PBS–0.5% BSA (PBS-B). The plates are incubated for 1 h

at 37°C, washed with PBS-B containing 0.05% of Tween, then developed with a chromogenic substrate solution consisting of 0.2 mg/mL of ABTS in 0.1 *M* sodium citrate buffer, pH 5.0, containing 5 m*M* hydrogen peroxidase. The absorbance of each sample is measured with a Model 2250 EIA Reader (Bio-Rad).

13. Microtiter plates (Falcon 3912) are incubated with a 10 µg/mL solutions of crude sample, unbound and bound fractions (100 µL/well) in 0.1 *M* sodium carbonate buffer, pH 8.5, overnight at 4°C. After the plates are washed 5× with PBS (50 m*M* phosphate, 150 m*M* sodium chloride), pH 7.5, wells are saturated with 100 µL of a PBS solution containing 3% BSA, for 2 h at room temperature to block the uncoated plastic surface. The wells are then washed with PBS and incubated with the biotinylated antigen (10 µg/mL) in PBS containing 0.5% BSA (PBS-B). After 1 h of incubation the plates are washed 5× with PBS containing 0.05% of Tween (PBS-T), then filled with 100 µL of a streptavidin peroxidase conjugate solution (Sigma) diluted 1 : 1000 with PBS–0.5% BSA. The plates are incubated for 1 h at 37°C, washed with PBS-T 5×, and then developed with a chromogenic substrate solution consisting of 0.2 mg/mL of ABTS in 0.1 *M* sodium citrate buffer, pH 5.0, containing 5 m*M* hydrogen peroxidase. The absorbance at 405 nm of each sample is measured with a Model 2250 EIA Reader (Bio-Rad). For antigen biotinylation, 2 mg of antigen, dissolved in 1 mL of 50 m*M* sodium phosphate buffer, pH 7.5, is treated with 200 µg of biotinamidocaproate *N*-hydroxysuccinimide ester dissolved in 20 µL of dimethyl sulfoxide (DMSO), under agitation at room temperature. After 2 h of incubation, 240 µL of a 1 *M* lysine solution is added to deactivate residual active groups, under stirring for 2 h. At the end the biotinylated antigen is extensively dialyzed against 50 m*M* sodium phosphate, pH 7.5, and used without any further treatment.
14. Water-soluble proteins are separated from the lipidic fraction of egg yolk by the water dilution method. Egg yolk is separated from the white, washed with distilled water to remove as much albumen as possible, diluted 1:9 with acidified distilled water, and incubated at least 6 h at 4°C. After incubation, sample is centrifuged at 10,000*g* for 20 min, the supernatant separated from pellet, filtered on 0.45-µm Nalgene filters, and loaded onto a PAM affinity column. Usually 10.4 mg of antibodies/mL of egg yolk are obtained with a purity close to 30%.
15. Radial immunodiffusion and SDS-PAGE analysis of eluted material show an excellent degree of purification in terms of recovery and purity, both very high and close to 98%. The gel filtration profile of purified IgY validates SDS-PAGE data, indicating that a single affinity step is sufficient to remove all contaminants and capture and concentrate the IgY fraction. The effect of

purification conditions on the maintenance of antibody–antigen recognition can be evaluated by ELISA assays on microtiter plates coated with the IgY corresponding antigen. Results indicate that after the affinity fractionation step, antibodies were recovered fully active, with the majority of the immunoreactivity, about 99%, retrieved in the bound fraction.

16. Chemical and chromatographic stability of PAM resin after sterilization procedure can be tested by monitoring the release of the ligand from the resin by RP-HPLC analysis of the sterilizing buffer and measuring the Ig binding capacity of the matrix in column experiments. The investigations indicate that this treatment leads to significant loss of ligand (up to 5%), so that under process conditions the capacity of PAM columns to bind the immunoglobulins was quite reduced (up to 30%).

Detection of Serological Cross-Reactions by Western Cross-Blotting

Peter Hammerl, Arnulf Hartl, Johannes Freund, and Josef Thalhamer

1. Introduction

Antisera are frequently used tools for the characterization of proteins and peptides because they provide unique information about the structural features of antigens. Proteins that share structural similarities can be identified by serological cross-reactions. The Western blotting technique combines two steps that are characteristic for immunoaffinity chromatography ***(1)***. One is the preparation of monospecific antibodies against a particular antigen and the second is the testing of their reactivity with the same or different antigens from any source of antigenic material.

As a rule, such experiments turn out to be elaborate and time-consuming procedures, consisting of many different steps; particularly because either a purified antigen or a monospecific antibody are basic requirements. In many cases, monospecific antibodies need to be purified from polyspecific antisera by immunoaffinity chromatography. However, only small amounts of monospecific antibody are required for analytical purposes. In such a case it may be sufficient to elute antibodies from selected bands off a Western blot. One protocol, for example, has been published by Beall and Mitchell ***(2)***.

In contrast to experimental setups for the immunochemical analysis of one particular antigen, the method described in this chapter is especially designed for single-step analysis of cross-reactivities of multiple antigens, within the same or between different protein mixtures. The principle is to test antibodies that have bound to particular antigen bands of a Western blot against all antigen bands on a second blot. This is done by electrotransfer of antibodies from one Western blot to a second one, taking advantage of the dissociative effect of chaotropic ions on antigen–antibody complexes.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

The strategy can be dissected into the following steps:

1. Two antigen mixtures are separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), each mixture on a separate gel. The samples are loaded onto the entire width of the gels. After electrophoresis, the proteins are blotted onto nitrocellulose (NC) paper.
2. One of the two blots (referred to as the "donor" blot in this text) is incubated with a polyspecific antiserum and then placed onto the second blot ("receptor" blot), upside down, with the protein bands crossing the bands on the second blot. This assembly is wrapped in a dialysis membrane.
3. Antibodies are electrophoretically transferred from the donor blot to the receptor blot in the presence of NaSCN, which dissociates antigen–antibody complexes.
4. The donor blot is then discarded. The receptor blot, still wrapped in the dialysis membrane, is equilibrated with phosphate-buffered saline (PBS) to allow binding of the transferred antibodies to the protein bands.
5. Bound antibodies are detected by use of an enzyme-linked second antibody.

This method may be useful in a wide variety of serological studies. For example, it may help to identify structurally related molecules of different molecular weight within protein mixtures, for example, cellular extracts. It may provide information about the serological relationship of different antigen mixtures, and thereby help to investigate evolutionary distances. It may also find application in analyses of subunit composition of proteins and, in combination with peptide mapping, it can be a useful tool for epitope characterization.

2. Materials

2.1. SDS-PAGE

All solutions for SDS-PAGE should be prepared with chemicals of the highest purity available using double-distilled water.

1. Solution A (acrylamide): 29% (w/v) acrylamide, 1% (w/v) *bis*-acrylamide; store at 4°C, light sensitive, stable for approx 4 wk.
2. Solution B (separating gel buffer): 1.5 *M* Tris-HCl, pH 8.8; store at 4°C.
3. Solution C (stacking gel buffer): 0.5 *M* Tris-HCl, pH 6.8; store at 4°C.
4. SDS: 10% (w/v); store at room temperature.
5. Sample buffer: 62.5 m*M* Tris-HCl, pH 6.8, 20% (v/v) glycerol, 4% SDS, 1% (v/v) of a saturated aqueous solution of Bromophenol blue. Stored aliquots of 1 mL at −20°C may be thawed and frozen repeatedly.
6. Electrophoresis buffer: 25 m*M* Tris, 192 m*M* glycine, 0.1% (w/v) SDS. Do not adjust pH.
7. Dithiothreitol (DTT): 1 *M* Dithiotreitol. Stored aliquots of 1 mL at −20°C may be thawed and frozen repeatedly.
8. Iodoacetamide (IAA): 1 *M* IAA. Stored aliquots of 1 mL at −20°C may be thawed and frozen repeatedly.

9. *N*,*N*,*N*′,*N*′-Tetramethylethylendiamine (TEMED): store at 4°C.
10. Ammonium persulfate (APS): 10% (w/v) APS. Store aliquots of 0.1 mL at −20°C.
11. *n*-Butanol (water saturated): Mix equal volumes of *n*-butanol and water and shake well. After separation of the two phases, the upper one is water-saturated butanol. Store at room temperature.

2.2. Electrotransfer

All buffers for this protocol contain methanol. Caution: methanol is toxic and volatile, and should be handled in a fume hood. Wear gloves and protective clothing and do not leave bottles open at the workbench.

1. Buffer A: 0.3 *M* Tris, 20% (v/v) methanol. Do not adjust pH. Store at 4°C.
2. Buffer B: 25 m*M* Tris, 20 % (v/v) methanol. Do not adjust pH. Store at 4°C.
3. Buffer C: 40 m*M* Aminocaproic acid, 25 m*M* Tris, 20% (v/v) methanol. Do not adjust pH. Store at 4°C.

2.3. Cross-Blot

1. Borate-Tween (BT): 50 m*M* $Na_2B_4O_7$, pH 9.3, 0.1 % (v/v) Tween 20. Store at 4°C.
2. SCN-borate-Tween (SBT): 1 *M* NaSCN, 50 m*M* $Na_2B_4O_7$, pH 9.3, 0.1 % (v/v) Tween 20. Store at 4°C.

2.4. Immunostaining

1. PBS: 8.1 m*M* Na_2HPO_4, 1.5 m*M* KH_2PO_4, 2.7 m*M* KCl, 140 m*M* NaCl. Store at 4°C.
2. PBS-Tween: 0.1% (v/v) Tween 20 in PBS. Store at 4°C.
3. PTS: 8.1 m*M* Na_2HPO_4, 1.5 m*M* KH_2PO_4, 2.7 m*M* KCl, 0.5 *M* NaCl, 0.1% (v/v) Tween 20. Store at 4°C.
4. 10 mg/mL Bovine serum albumin (BSA): Store aliquots of 10 mL at −20°C.
5. NC paper.
6. Horseradish peroxidase conjugated antibody with specificity for the immunoglobulin isotype of the test antiserum.
7. Chloronaphthol, solid. Store at −20°C. Caution: irritant to skin, eyes, and respiratory organs. Wear gloves, protective glasses, and clothing, especially when handling the solid substance (buffy crystals). May be purchased as tablets, which can be handled with lower risk.
8. 30% Hydrogen peroxide: Store at 4°C. Caution: strong oxidant. Corrosive. Avoid contact with eyes and skin.

2.5. Miscellaneous

1. Electrophoresis apparatus for SDS-PAGE: Mini-Protean (Bio-Rad, Richmond, CA) or equivalent.
2. Gradient mixer for 2 × 5 mL.
3. Semidry blotting apparatus.

3. Methods

Most conveniently, this protocol may be carried out according to the following time schedule:

Day 1: Casting two SDS gels.
Day 2: Casting the stacking gels.
Running SDS-PAGE.
Blotting of the gels onto NC.
Incubating one blot and of reference strips from both blots with antiserum.
Cross-blotting.
Reequilibration overnight.
Day 3: Incubation with second antibody.
Detection of spots by enzyme reaction.

This schedule proved convenient in our laboratory. Other schedules are possible, as time values for antibody incubations and washing steps given are minimum requirements from our experience and may be different with other materials.

3.1. SDS-PAGE

3.1.1. Casting Gradient Gels

Volumes are given for the Mini-Protean gel system (Bio-Rad) for gels of 83 × 55 × 1.5 mm.

1. Clean glass plates with detergent, rinse thoroughly with tap water followed by double-distilled (dd-) water, and let dry.
2. Assemble glass plates and prepare two gel solutions as follows:
   5% Acrylamide: 1.65 mL of solution A;
   2.50 mL of solution B;
   5.73 mL of dd-water;
   20% Acrylamide: 6.65 mL of solution A;
   2.50 mL of solution B;
   0.73 mL of dd-water.
   Degas under vacuum (e.g., in a sidearm flask) and add 100 µL of SDS.
3. Close the outlet valve and the valve connecting the two chambers of the gradient mixer. Pipet 3.6 mL of the 20% mix into the chamber of the gradient mixer that is connected to the outlet tubing, and then 3.6 mL of the 5% mix into the second chamber. To each chamber, add 1.8 µL of TEMED and 9 µL of APS and mix well.
4. Open the valves and cast the gel at a flow rate of not more than 2.5 mL/min. Control the flow rate either by hydrostatic pressure or by use of a peristaltic pump.
5. Immediately thereafter, rinse the gradient mixer with water and prepare for casting the second gel. Carefully overlay the casted gels with 1 mL of water-saturated butanol and polymerize for at least 3 h or overnight at room temperature. Do not move the gels while still fluid.

3.1.2. Sample Preparation

For gels 1.5 mm thick, approx 10–50 µg of protein in a volume of 20–50 µL/cm of gel width may be loaded. However, the optimal protein concentration may vary with the complexity of the sample.

1. Mix equal volumes of protein solution and sample buffer.
2. Add 1/20 volume of 1 *M* DTT and boil in a water bath for 5 min.
3. Alkylate free sulfhydryl residues on the proteins by adding 1/5 volume of 1 *M* IAA and incubating at 37°C for 30–60 min (*see* **Note 1**).

3.1.3. Casting Stacking Gels

1. Aspirate butanol from the polymerized gel and rinse the gel surface 3× with water. Let gels dry in an inverted position for 5–10 min (*see* **Notes 2** and **3**).
2. Meanwhile, prepare the stacking gel mix as follows:
   Stacking gel solution: 0.65 mL of solution A;
   1.25 mL of solution C;
   5.0 mL of dd-water.
3. Degas as described in **Subheading 3.1.** and add 50 µL of SDS, 50 µL of APS, and 5 µL of TEMED. Mix carefully and apply 1.3 mL onto each gel. Make sure there is 5 mm remaining from the stacking gel surface to the top of the glass plates for sample application. Overlay with water saturated butanol and polymerize for 10 min (*see* **Note 4**).

3.1.4. Running Electrophoresis

1. Assemble electrophoresis apparatus and fill with electrophoresis buffer.
2. Load protein samples onto gels and run at constant current, starting with 75 V for the Bio-Rad Mini-Protean system. Stop electrophoresis when bromophenol blue tracer dye has reached the bottom of the gel (*see* **Note 5**).

3.2. Electrotransfer onto NC

1. For each gel, cut one sheet of NC paper and 15 pieces of Whatman 3MM paper to fit the dimensions of the separating gel (*see* **Note 6**).
2. For each gel, prewet six sheets of the Whatman paper in buffer A, another six sheets in buffer C, and three sheets in buffer B. Prewet the single sheet of NC paper in buffer B.
3. Disassemble the electrophoresis unit, discard the stacking gel, and mount the blot in the following order, making sure that no air bubbles are trapped between individuals tacks:
   a. Place the Whatman stack from buffer A onto the anode plate of the semidry blotting apparatus.
   b. Place the Whatman stack from buffer B on top and cover it with the NC sheet.
   c. Place the gel onto the NC paper, then cover it with the Whatman stack from buffer C.
4. Close the apparatus by mounting the cathode plate on top of the assembly and perform electrophoresis at a constant current of 1.4 mA/cm^2 for 2 h.

3.3. Blocking and Incubation of the Blots with Antiserum

All incubations are done on a laboratory shaker, either at room temperature for the time indicated or at 4°C overnight.

1. Disassemble blotting apparatus and incubate the blot, which is intended as the antibody source (i.e., the "donor" blot) in PBS-Tween at room temperature for 30 min. Incubate the second blot ("receptor" blot) in 1% BSA in PBS for 2 h.
2. Incubate the donor blot with antiserum in PBS-Tween with 1 mg/mL of BSA (*see* **Note 7**).
3. From the central area of both blots, cut square-shaped pieces fitted to the dimension of the separating gel. Make asymmetrical marks on edges of the square-shaped NC pieces to help remember the orientation of the antigen bands. Set aside the remaining pieces of the donor blot in PBS-Tween. Incubate the remaining pieces of the receptor blot with antiserum in PBS-Tween with 1 mg/mL of BSA. These margin pieces will serve as reference strips to identify spots on the cross blot.
4. Place donor blot onto a glass filter and wash with 20 mL of PTS in aliquots of approx 3 mL under vacuum using a sidearm flask. Incubate donor blot in PTS for 10 min on a laboratory shaker.
5. Repeat **step 4** twice (*see* **Note 8**).

3.4. Cross Blot

3.4.1. Electrotransfer of Antibodies

1. Prewet one stack of Whatman paper, 1 cm thick and sufficiently sized to cover the donor blot, in BT and a second, equally sized, stack in SBT.
2. Prewet a piece of dialysis membrane (with a pore size of approx 10 kDa) in BT, which is sufficiently sized to wrap the donor blot (i.e., at least twice the area of the donor blot).
3. Assemble the cross-blot as follows (**Fig. 1**):
   a. Place the Whatman stack soaked in BT onto the anode of the semidry blotting apparatus.
   b. Place the dialysis membrane on top, in such a way that one half covers the Whatman stack while the second half rests beside it on the anode plate.
   c. Place the receptor blot, with the protein bands upside, onto the part of the dialysis membrane, which covers the anodal Whatman stack.
   d. Place the donor blot, with the protein bands downward, onto the receptor blot in such a way that the bands on the donor blot are perpendicular to the bands on the receptor blot (*see* **Note 9**).
   e. Cover the donor blot with the dialysis membrane.
   f. Place the Whatman stack soaked with SBT onto the assembly and cover it with the cathodal plate of the semidry apparatus.
4. Perform electrophoresis at a constant current of 3 mA/cm^2 for 90 min (*see* **Note 10**).

3.4.2. Reequilibration of the Receptor Blot

1. Presoak two Whatman stacks of the same size as in **Subheading 3.4.1., step 1** in PTS.
2. **Important note:** During the following step, take extreme care not to slip the receptor blot against dialysis membrane! (*See* **Note 11**.)

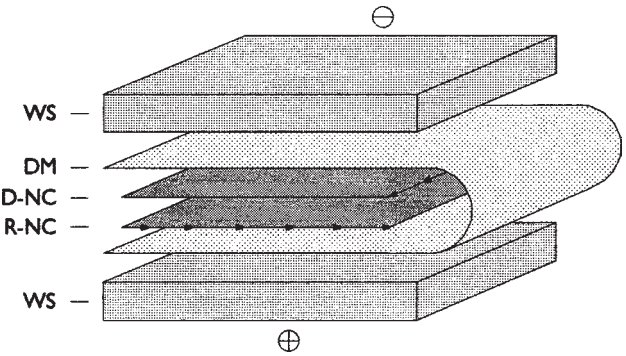

Fig. 1. Experimental setup for a cross-blot experiment: + and – indicate the position of the graphite electrodes of the semidry blotting apparatus. WS, stack of Whatman paper; DM, dialysis membrane; D-NC, donor blot NC sheet; R-NC, receptor blot NC sheet. The perpendicular orientation of the antigens bands on the blots to each other is indicated by arrows. The protein bands on the donor blot are faced downwards against the receptor blot, while the bands on the receptor blot are faced upwards against the donor blot.

a. Disassemble the semidry apparatus.
b. Remove the cathodal Whatman stack.
c. Open the upper part of the dialysis membrane using a pair of forceps.
d. Remove the donor blot and place into PBS-Tween.
e. Close the dialysis membrane so that the receptor blot is completely wrapped in it.
f. Place the receptor blot, wrapped in the dialysis membrane, between two Whatman stacks prewetted in PTS.
g. Place this assembly into an appropriately sized tray and cover it with a glass plate and a weight of approx 50 g to stabilize it.
h. Fill tray with additional PTS and incubate overnight without agitation.

3.4.3. Immunostaining

1. Remove the receptor blot from "reequilibration" assembly and wash all NC pieces (i.e., donor blot, receptor blot, and reference strips) in PBS-Tween 3 × 10 min on a laboratory shaker (*see* **Note 12**).
2. Incubate with enzyme-linked second antibody according to the manufacturer's instructions (*see* data sheet) in PBS-Tween with 1 mg/mL of BSA.
3. Wash blots as described in **step 1**.
4. Wash twice for 5 min in PBS.
5. Meanwhile, prepare the staining solution as follows:
   a. Solubilize approx 10 mg of chloronaphthol in 1–3 mL of ethanol and mix with 50 mL of PBS under vigorous agitation.
   b. Incubate the solution for 5 min, filter through Whatman 3MM (or equivalent), and add 25 µL of 30% hydrogen peroxide.
6. Incubate NC papers in separate trays in staining solution until bands and spots become visible.
7. Stop the staining reaction by washing the blots in water and dry.

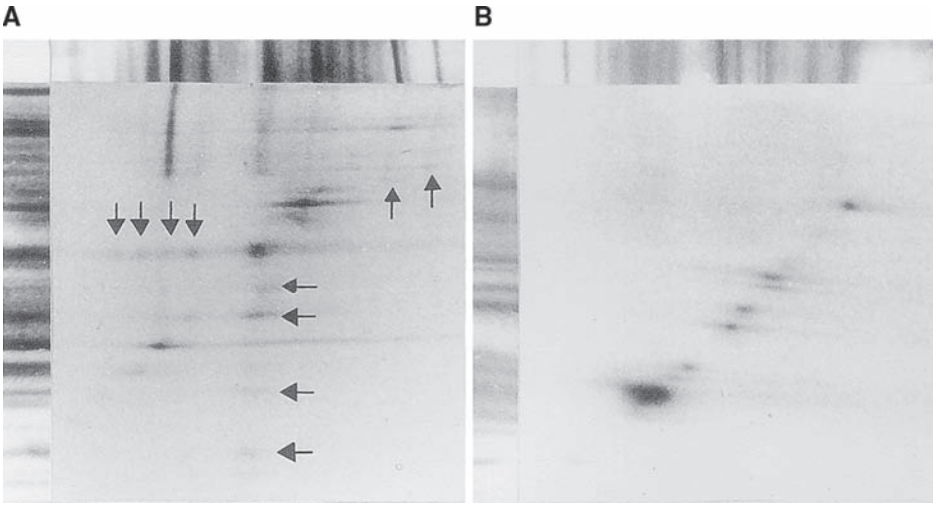

Fig. 2. Two examples of a cross-blot experiment carried out with cytoplasmic extracts of E. coli (taken from ref. 1). To the left of each cross-blot, a reference strip derived from the receptor blot and, on top of each cross-blot, a reference strip derived from the donor blot is included. (**A**) Homologous cross-blot of E. coli B wild-type strain antigens and a rabbit anti E. coli antiserum showing numerous cross-reactions between proteins of different molecular weight (*arrows*). (**B**) Homologous cross-blot of E. coli CSH 57B antigens. The diagonal line of spots indicates a high specificity of the cross-reactions between proteins of the same molecular weight. No cross-reactions between proteins of different molecular weight could be detected in this experiment.

8. For documentation and interpretation of results, place the receptor blot and the reference strips together as shown in **Fig. 2** and photograph (*see* **Note 13**).

4. Notes

1. Samples for SDS-PAGE may be prepared in different ways. Depending on your requirements and intentions, the reduction of inter- and intramolecular disulfide bonds by DTT and alkylation of the resulting sulfhydryl groups may be omitted. However, be aware that remaining APS in the polymerized gel causes an oxidizing environment. This may result in protein oligomerization due to the formation of disulfide bonds between free SH- residues on individual molecules. In many cases, this may be the reason for irreproducible results in SDS-PAGE. For nonreduced samples, it may be beneficial to omit boiling of the sample. In this case, incubate at 37°C for 30 min before applying the sample onto gel.
2. Many types of electrophoresis equipment contain parts made of acrylic glass or equivalent. Avoid butanol or any other organic solvent coming into contact with such parts. This can “corrode” the plastic surface. As a

consequence, the transparency of these parts may be lost with time, which can cause difficulties in handling, (e.g., sample application).

3. While washing the gel surface, do not leave water on the gel for too long a time, as this would dilute the buffer and SDS concentration in the upper part of the gel.
4. The protocol for SDS-PAGE described here uses the discontinuous buffer system of Laemmli and colleagues ***(3)***. For the band sharpening effect of this system a sharp increase in pH and buffer concentration between stacking and separating gel is essential. As soon as the stacking gel is casted, however, the two different buffer systems start to diffuse into each other, and consequently interfere with the beneficial effect of the system. Therefore, it is essential to minimize the time between casting the stacking gel and starting the electrophoresis. For this reason, we do not recommend casting the stacking gels before the samples are ready for application. The polymerization of the stacking gel is complete as soon as a second fluid phase is visible between the gel and the butanol phase.
5. For repeated runs, the electrophoresis buffer may be reused several times. After each run, mix the cathodal and the anodal buffers to restore the pH value. Reuse this buffer only as the anodal buffer in the following runs. For the cathode, use fresh buffer in every run. Reused buffer contains chloride ions from the separating gel of the previous run, which would eliminate the effect of the discontinuous buffer system.
6. Other blotting systems (e.g., in a tank blot module in 10 m*M* Na_2CO_3 or other buffer systems) are also suitable for this purpose. From our experience, the best results are obtained by semidry blotting, especially with respect to homogeneous transfer efficiency.
7. The working dilution of antiserum depends on parameters such as antibody titer and affinity, and therefore varies with the material used. For this reason, no suggestions on antiserum dilution and time of incubation are given in this protocol. It should be adjusted according to the experience of the investigator with the material at hand. However, conditions that ensure a maximum of specificity are a crucial requirement, especially for the cross-blotting method. Therefore, do not use too high a concentration of antiserum and add BSA at 1 mg/mL to minimize unspecific protein–protein interactions. If problems occur, increasing the ionic strength to 0.5 *M* NaCl may be helpful.
8. A rigorous washing procedure was included in the protocol to optimize the washing efficiency. Possibly, this is not necessary for all applications, depending on the materials used. Keep in mind that any antibody, which remains unspecifically attached to the donor blot, will increase background and unspecific signals on the receptor blot.

9. Make sure that the donor and receptor blot are cut of exactly equal size and placed onto each other accurately. This will facilitate the identification of individual spots in the final result. It may be helpful to mark the position of two NC sheets by penetrating them with a needle at three sites after they have been placed together.
10. The relatively long electrophoresis time used in the cross-blot step is intended to maximize the efficiency of antibody elution from the donor blot. However, some antibody species may not survive such a long exposure to 1 *M* NaSCN. This could be indicated by increased unspecific signals or low sensitivity in the final results. In such a case, try a shorter electrophoresis time or a lower concentration of NaSCN in the cathodal Whatman stack. Generally, it may be advantageous to minimize the electrophoresis time in this step so as not to exceed the buffer capacity in the Whatman stacks. This would cause a change in pH, which might affect the direction of antibody migration.
11. This is the most crucial step of the entire procedure. Right after the electrotransfer, the antibodies are not yet bound to the antigens on the receptor blot due to the presence of NaSCN. Instead, they are most likely trapped in the pores of the NC sheet and loosely attached on the surface of the dialysis membrane. Therefore, any movement of the receptor sheet against the anodal surface of the dialysis membrane will result in an extreme decrease of the spot sharpness. The donor blot is removed in this step so that it does not compete with the antigens on the receptor blot during the subsequent reequilibration step. Given a sufficient sensitivity according to our experience with previous experiments, the removal of the donor blot may be omitted.
12 Alternate staining procedures are also possible, for example, second antibody conjugated to alkaline phosphatase and staining with nitroblue tetrazolium (NBT) and bromochloroindolyl phosphate (BCIP).

    As the staining intensity on the receptor blot is significantly lower than that on the reference strips, one may wish to employ a more sensitive detection system such as luminogenic enzyme substrates. However, some of these systems require the use of special membranes. As of now we have no experience to indicate that these membranes are also compatible with the cross blot procedure.
13. Interpretation of results: Only positive signals should be taken as a result. The failure of a band on the donor blot to react with a band on the receptor blot does not necessarily prove the absence of cross-reactivity. Such negative results could also be due to inefficient elution of an antibody from the donor blot or to denaturation of the eluted antibody. Likewise, the concentration of the antigen and/or antibody on the donor blot may be too low

to give a signal on the receptor blot. As a rule, do not necessarily expect a signal on the cross-blot from donor blot bands which give only faint signals on the donor blot reference strips.

Generally, it is sometimes difficult to judge the specificity of an antigen–antibody reaction. This is more likely for antibodies, which have been exposed to low pH values or chaotropic agents. With cross-blot results, be doubtful about donor blot bands, which give a signal with each band on the receptor blot. Also, receptor blot bands that react with each donor blot band should generally not be taken too seriously, unless special circumstances let you expect such a behavior.

When working with different antigen mixtures on donor and receptor blots, respectively, include a homologous cross-blot as a control and reference. This is done by cross-blotting antibodies from a donor blot to a receptor blot containing the same antigens as the donor blot. Such homologous cross-blots have a "natural" internal reference because each antigen band on the donor blot is crossing "itself" on the receptor blot. In this way, the cross-blot yields a diagonal line of spots that are helpful in estimating both the sensitivity and the specificity you can expect with a particular band on the donor blot. Similarly, a homologous cross-blot may also be carried out with the receptor antigens. This will help to estimate the resistance of the receptor antigens against exposure to the cross-blot conditions.

Enzymatic Digestion of Monoclonal Antibodies

Sarah M. Andrew

1. Introduction

Originally, digestion of antibodies by proteolytic enzymes was used to study their structure. Many diverse structures can be obtained by fragmentation of the different classes of antibody with different enzymes, or by using the same enzyme and changing the conditions (**Fig. 1**). Not all the fragments obtained have significant binding activity; for example, in several studies by this author, Fv fragments obtained by digestion have been found to have lost their binding activity. Fragmentation of antibody is now usually carried out to introduce required properties (e.g., a decrease in molecular size), or to remove undesirable properties (e.g., nonspecific Fc receptor binding).

The most usual digestions carried out are:

1. Production of bivalent $F(ab')_2$ from mouse McAb IgG;
2. Production of univalent Fab from mouse McAb IgG;
3. Production of bivalent IgMs from mouse McAb IgM; and
4. Production of bivalent $F(ab')_{2\mu}$ from mouse McAb IgM.

$F(ab')_2$ and $F(ab')_{2\mu}$ are produced by digestion with pepsin and Fab is produced by digestion with papain. One useful fragmentation uses papain that has been preactivated with cysteine. This cleaves IgG_1 to produce $F(ab')_2$, and IgG_{2a} IgG_{2b} to produce Fab. It is a very stable fragmentation in which the times of incubation are not at all critical. The IgG-like subunit of IgM (IgMs) is the product of a mild reduction; this is most conveniently done using cysteine, which reduces the IgM and alkylates the subunit, thus preventing reassociation.

After digestion of the antibodies, it is necessary to purify the fragments for two reasons: to separate the fragment from any remaining intact antibody; and to separate the fragments of interest from other miscellaneous fragments produced by the process of digestion. Purification of IgG fragments by protein A affinity

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

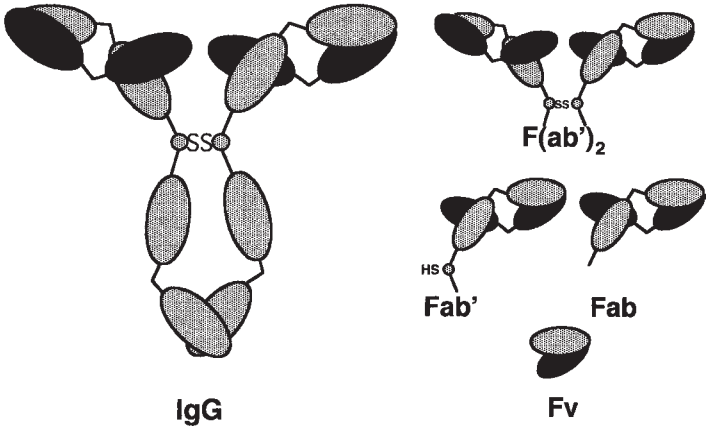

Fig. 1. Diagramatic representation of the major fragments of an IgG molecule that can be produced by enzymatic digestion, as described in the text.

chromatography is possible if an intact Fc region remains after fragmentation, as it does in the case of undigested antibody and, sometimes, in digestions with pepsin. In general this method of purification is rough and ready and size exclusion chromatography is recommended as an additional step.

2. Materials

2.1. Digestion with Pepsin

1. Purified solution of mouse McAb (IgG or IgM) at a concentration of ≥1 mg/mL.
2. 0.2 *M* Sodium acetate buffer brought to pH 4.0 with glacial acetic acid.
3. 0.2 *M* Sodium acetate buffer brought to pH 4.5 with glacial acetic acid.
4. 0.1 mg/mL pepsin (Sigma, St. Louis, MO) in acetate buffer at appropriate pH (*see* **Subheadings 3.1.** and **3.2.**).
5. 2 *M* Tris base.
6. Phosphate-buffered saline (PBS) brought to pH 8.0 using NaOH.
7. Protein A-Sepharose CL-4B (Sigma number P 3391) swollen in PBS, pH 8.0, and packed into a 10 × 100 mm column, or a 1-mL HiTrap Protein A column (Sigma).
8. PBS.
9. A size exclusion column equivalent to 26 × 900 mm Sephacryl S-200 (Pharmacia, Uppsala, Sweden).
10. Centriprep 100 concentrator (Amicon, Beverly MA; Stonehouse, Glocestershire, UK).

2.2. Digestion with Papain

1. Purified solution of mouse IgG McAb at a concentration of ≥1 mg/mL.
2. PBS made to 0.02 *M* with respect to ethylenediaminetetra-acetic acid (EDTA) and 0.2 *M* with respect to cysteine.

3. Iodoacetamide crystals.
4. PBS brought to pH 8.0 using NaOH.
5. Protein A-Sepharose CL-4B (Sigma number) swollen in PBS, pH 8.0, and packed into 10 × 100 mm column, or a 1 mL HiTrap Protein A column (Sigma).
6. PBS.
7. A size exclusion column equivalent to 26 × 900 mm Sephacryl S-200 (Pharmacia) (optional).

2.3. Reduction and Alkylation with Cysteine

1. Purified solution of mouse IgM McAb at a concentration of ≥1 mg/mL in PBS.
2. 0.1 *M* cysteine stock solution in PBS (L-cysteine free base, Sigma).
3. Borate-buffered saline: 0.015 *M* sodium borate, 0.15 *M* sodium chloride, made to pH 8.5 with Sodium hydroxide.
4. A size exclusion column equivalent to 26 × 900 mm Sephacryl S-200 (Pharmacia).

3. Methods

3.1. Preparation of $F(ab')_2$ from IgG

The various subclasses of mouse IgG vary in their susceptibility to pepsin fragmentation. IgG_1 is quite resistant to digestion and and it is impossible to fragment IgG_{2b} to $F(ab')_2$ because it breaks down to Fab (*see* **Notes 1–3**). The method below is one that should work in most cases.

1. Dialyze the IgG against acetate buffer, pH 4.0, overnight at 4°C. Use any known amount of antibody between 1 and 20 mg.
2. Determine the concentration at A_{280}.
3. Add 0.1 mg/mL pepsin in acetate buffer, pH 4.0, to give an enzyme-to-antibody ratio of 1:20 (w:w).
4. Incubate for 6 h in a water bath at 37°C.
5. Stop the reaction by adding sufficient Tris base to bring the pH to roughly 8.0 (start by adding 50 µL Tris, mix, and test the pH with pH paper).
6. Dialyze the mixture against PBS, pH 8.0, overnight.
7. Equilibrate the protein A column with PBS, pH 8.0, and load the dialyzed mixture onto it 1 mL at a time. Collect the unbound fraction that contains the $F(ab')_2$ fragments.
8. If further purity is desired, the mixture should be concentrated to a volume of ≤3 mL and added to a precalibrated size exclusion column (26 × 900 mm Sephacryl S-200 or equivalent). At this stage regular PBS can be used to equilibrate the column and elute the fractions.
9. Collect 2.5-mL fractions over the molecular weight range of $F(ab')_2$ (110 kDa). The purity of the product can be assessed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) in nonreducing conditions and in reducing conditions when a doublet at 25 kDa is seen.

3.2. Preparation of F(ab′)$_{2\mu}$ from IgM (*see* Note 3)

1. Dialyze the IgM against acetate buffer, pH 4.5, overnight at 4°C.
2. Determine the concentration at A_{280} (*see* Chapter 1).
3. Add 0.1 mg/mL pepsin in acetate buffer, pH 4.5, to give an enzyme-to-antibody ratio of 1:20 (w:w).
4. Incubate for between 6 and 12 h in a water bath at 37°C.
5. Stop the reaction by adding sufficient Tris base to bring the pH to roughly 8.0 (start by adding 50 µL Tris, mix, and test the pH with pH paper).
6. Dialyze the mixture against PBS overnight, or concentrate and change the buffer using a Centriprep 100 concentrator.
7. Concentrate the mixture to a volume of ≤3 mL and add to a precalibrated size exclusion column (26 × 900 mm Sephacryl S-200 or equivalent). Elute fractions of between 1 and 2.5 mL. The molecular weight of F(ab′)$_{2\mu}$ is 130 kDa. Assess purity on an 8% polyacrylamide gel under nonreducing conditions.

3.3. Preparation of Fab from IgG

Again, there is a variable susceptibility to the enzyme between the IgG subclasses. The method described is one that should give good results in most cases. If fragments are not obtained, variations in the concentration of enzyme or time of incubation can be tried. *See* **Notes 1**, **2**, and **4** for further information.

1. Use IgG in PBS at a concentration between 1 and 5 mg/mL.
2. Dissolve sufficient papain in an equal volume of digestion buffer to the volume of antibody solution to give a papain-to-antibody ratio of 1:20 (w:w).
3. Add the two equal solutions, one containing antibody and one containing papain together; mix thoroughly but gently.
4. Incubate for 4–6 h at 37°C.
5. Stop the reaction by adding crystalline iodoacetamide to make the mixture 0.03 *M* with respect to iodoacetamide, and dissolve by mixing gently.
6. Dialyze the mixture against PBS, pH 8.0, overnight at 4°C.
7. Equilibrate the protein A column in PBS, pH 8.0, then add the dialyzed mixture to it. Collect the unbound fraction. Wash the column with PBS, pH 8.0, to completely recover the Fab fragments.
8. Concentrate the Fab fragment mixture to a volume <5 mL.
9. Load the mixture containing the Fab fragments onto the size exclusion column equilibrated in PBS. Collect fractions corresponding to a molecular weight of 50 kDa.
10. Check the purity of the final product on a 10% SDS-polyacrylamide gel in nonreducingc onditions.

3.4. Preparation of IgG Fragments Using Preactivated Papain

Bivalent F(ab′)$_2$ fragments can be obtained from IgG_1 by this method. The protocol is also useful for producing monovalent Fab fragments from IgG_{2a} and IgG_{2b}. *See* **Note 4** for further information.

3.4.1. Preactivate the Papain

1. Make up a 2 mg/mL solution of papain in PBS with 0.05 *M* cysteine. Warm at 37°C for 30 min.
2. Equilibrate a PD10 column with acetate/EDTA buffer and apply the papain mixture.
3. Collect 10 × 1 mL fractions eluting with acetate/EDTA buffer. Assay the fractions at A_{280} and pool the two or three fractions containing protein.
4. Calculate the concentration of the preactivated papain using the following formula:

$$A_{280}/2.5 = \text{mg preactivated papain/mL} \quad (1)$$

3.4.2. Digest the IgG

1. Dialyse the IgG against acetate/EDTA buffer and determine the concentration after dialysis.
2. Mix the preactivated papain solution and the IgG solution in an enzyme-to-antibody ratio of 1:20.
3. Incubate for 6–18 h at 37°C.
4. Stop the reaction by adding crystalline iodoacetamide to a concentration of 0.03 *M*.
5. Dialyse the mixture against PBS, pH 8.0.
6. Purify the fragments as in **Subheading 3.3**.

3.5. Preparation of IgM Subunits from Pentameric IgM (*see* **Note 5**)

1. Add cysteine to IgM in PBS (up to 10 mg in 5 mL); make the solution 0.05 *M* with respect to cysteine.
2. Incubate the mixture for 2 h at 37°C.
3. Separate the fragments from intact antibody on a 26 × 900 mm size exclusion column or equivalent. The buffer in the column should be made 3 m*M* with respect to EDTA, if possible, because this prevents reassociation of the IgM fragments. Collect the fractions corresponding to a molecular weight of 180 kDa.

4. Notes

1. It is possible, but expensive, to buy kits for digestion of mouse antibody (Pierce, Warrington, UK). These kits work extremely well and can be a time-saving option. Each laboratory must consider whether the time saved in preparation is worth the extra expenditure on a kit. Fragmentation of antibodies from human and rabbit is described in ***ref. 6***; generally the methods and enzymes used are similar.
2. The most common problems likely to occur when following these methods are that the antibody does not digest or that the molecule overdigests

to produce small unrecognizable fragments. These can be overcome by varying the concentrations of enzyme, the times of digestion and, in the case of pepsin, the pH of the mixture ***(1)***. Generally, it is unwise to embark on fragmentation of IgG if the subclass of the antibody is not known. In digestion with both pepsin and papain the susceptibility to digestion varies with subclass. The order of susceptibility has been found to be IgG_{2b} > IgG_3 > IgG_{2a} > IgG_1 ***(2,3)***. Not all antibodies fall into this order (IgG_{2a} can be extremely sensitive to the action of papain in the presence of cysteine) and individual exceptions must be expected.

3. Digestion with pepsin has a great subclass variability. IgG_{2b} does not digest to $F(ab')_2$ fragments at all; the monovalent Fab/c (a single binding site and an intact Fc portion) is produced instead. This molecule has a very similar molecular weight to $F(ab')_2$; thus, is easy to imagine success with the fragmentation. The reason for the problem is thought to be an asymmetric glycosylation of the heavy chains in the molecule. All IgG subclasses can be further digested by pepsin to produce monovalent Fab fragments because there is a site of secondary cleavage on the NH_2-terminal side of the disulfide bonds. Further digestion with pepsin at a pH of 3.5 can produce Fv fragments after approx 3 h of incubation. There are reports of these having activity as antigen-binding fragments ***(4)***, but the personal experience of this author and colleagues suggests this is rare. It is also unfortunately true that it is difficult to produce active fragments from IgM. It has been suggested that IgM heavy chains can be truncated ***(5)***, but this has not been confirmed. The method given for IgM $F(ab')_{2\mu}$ will work, but one should not be too disappointed if the affinity is low.
4. On the whole, papain fragmentations work well and the timings of the incubations are not critical. Initially, care should be taken to mix the papain as it is in suspension; it will dissolve completely at the concentration given in the method. The methods using preactivated papain work extremely well and the incubation times are not at all critical.
5. The digestion to IgMs from IgM causes dissociation of the inter subunit disulfide bonds. It is possible to reduce the intrachain disulfide bonds on further reduction. This is why cysteine is the reducing agent chosen. Reduction by dithiothreitol or mercaptoethanol can be used, but more care is required with the incubations and a separate alkylation step is required.

How to Make Bispecific Antibodies

Ruth R. French

1. Introduction

This protocol describes the production of bispecific $F(ab')_2$ antibody derivatives (BsAbs) by the linking of two FabƎ fragments via their hinge region SH groups using the bifunctional crosslinker *o*-phenylenedimaleimide (*o*-PDM) as described by Glennie et al. ***(1, 2)***. The procedure is illustrated in **Fig. 1**. The first step is to obtain $F(ab')_2$ from the two parent IgG antibodies. Methods for digestion of IgG to $F(ab')_2$ are described in Chapter 151. Fab′ fragments are then prepared from the two $F(ab')_2$ species by reduction with thiol, thus exposing free SH groups at the hinge region (three SH-groups for mouse IgG1 and IgG2a antibodies) (*see* **Note 1**). One of the FabƎ species (Fab′-A) is selected for alkylation with *o*-PDM. Because *o*-PDM has a strong tendency to crosslink adjacent intramolecular SH-groups, two of the three hinge SH-groups will probably be linked together, leaving a single reactive maleimide group available for conjugation (**Fig. 1**; *see* **Note 2**). Excess *o*-PDM is then removed by column chromatography, and the Fab′-A(mal) is mixed with the second reduced Fab′ (Fab′-B) under conditions favoring the crosslinking of the maleimide and SH groups. When equal amounts of the two parent Fab′ species are used, the major product is bispecific $F(ab')_2$, resulting from the reaction of one Fab′-A(mal) with one of the SH groups at the hinge of Fab′-B. Increasing the proportion of Fab′-A(mal) in the reaction mixture results in a significant amount of $F(ab')_3$ product by the reaction of two molecules of Fab′-A(mal) with two free SH-groups at the hinge of a single Fab′-B molecule (*see* **Note 3**). The remaining free SH groups on Fab′-B are alkylated, and the $F(ab')_2$ bispecific antibody product (Fab′-A × Fab′-B) is separated by gel filtration chromatography. Each stage of the procedure is checked by HPLC.

Using this method, well-defined derivatives are produced with good yield, and the products are easily isolated; starting with 10 mg each of two parent

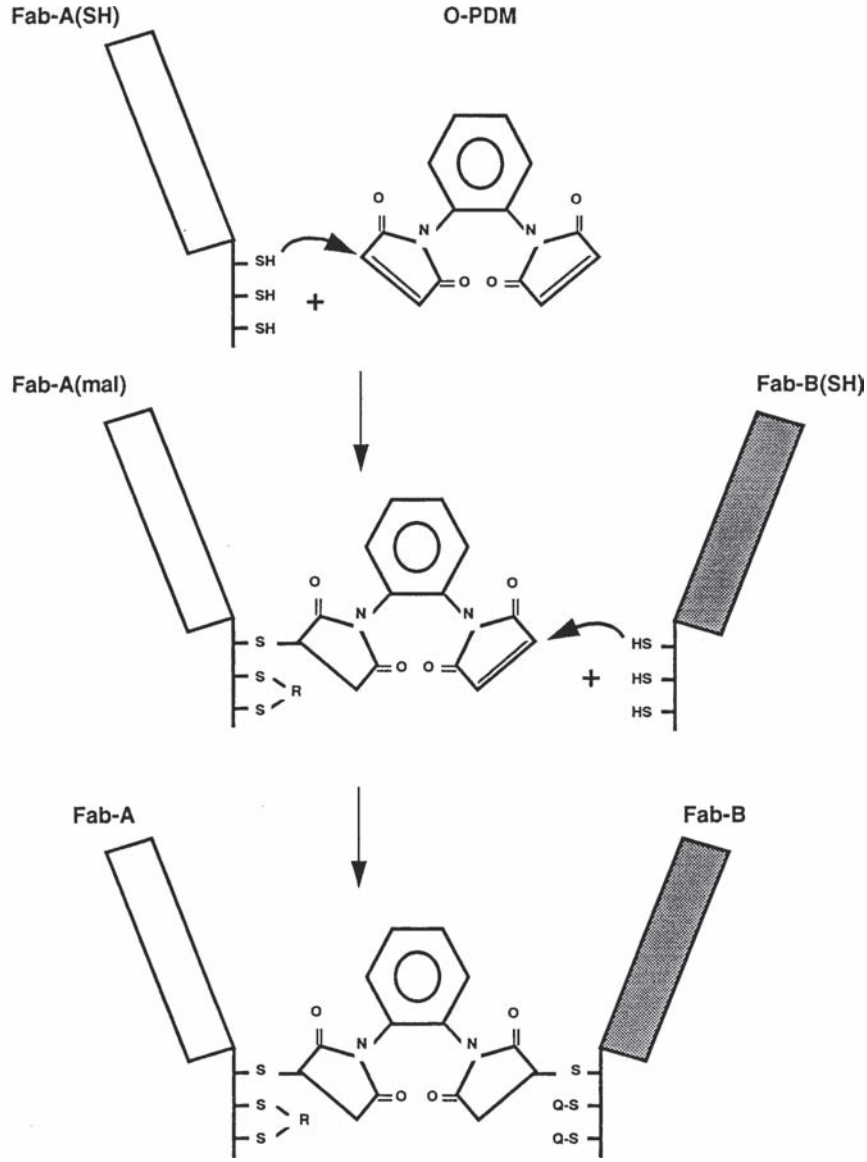

Fig. 1. Preparation of BsAb using *o*-PDM as crosslinker. The $F(ab')_2$ BsAb illustrated is produced from Fab′ fragments derived from mouse IgG1 or IgG2a antibody. Two adjacent hinge SH-groups of Fab′-A are cross-linked by *o*-PDM (R, *o*-phenylenedisuccinimidyl linkage), leaving one with a free maleimide group for cross-linking with an SH-group at the hinge of Fab′-B. Unconjugated SH-groups at the Fab′-B hinge are blocked by alkylation (Q, carboxyamidomethyl). Increasing the ratio of Fab′-A(mal) to Fab′-B(SH) will favor the production of bispecific $F(ab')_3$, in which two molecules of Fab′-A(mal) are linked to one molecule of Fab′-B.

$F(ab')_2$ species, expect to obtain 5–10 mg BsAb. The derivatives can be produced at relatively low cost, and quickly. It is possible to obtain the BsAb product from the parent IgG in five working days. The protocols can be scaled up to produce larger amounts (100–150 mg) of derivative if required. While the derivatives obtained are unlikely to be used for clinical applications because of the problem of immunogenicity, they can provide a very useful tool for proof-of-principle studies in in vitro and in vivo models.

Two potential problems should be taken into consideration when using this technique. First, that the derivatives produced are almost always contaminated with trace amounts of parent IgG antibody or Fc fragments, which are coharvested with the parent $F(ab')_2$ and the final product. If the presence of Fcthis is likely to be a problem for the application of the BsAb, preparations can be checked for Fc by SDS-PAGE, or assayed tested for Fc by enzyme-linked immunosorbent assay (ELISA), and, if necessary, Fc removed by immunoaffinity chromatography ***(2)***. Second, and probably more important, is the problem of the contamination of the BsAb product with endotoxins, which are lipopolysaccharides (LPS) derived from cell membrane of Gram-negative bacteria. In vivo exposure to LPS, even at low concentrations, can cause a systemic inflammatory reaction, leading to multiple adverse effects, including a pyrogenic reaction and endotoxin shock. LPS acts through activation of the immune system, with the release of a range of pro-inflammatory mediators, such as tumor necrosis factor, IL-6 and IL-1, and consequently LPS contamination can complicate the study of the biological effects of BsAb, both in vitro or in vivo. During the preparation of the parent $F(ab')_2$ and the BsAb, steps should be taken to avoid endotoxin contamination; products for the the measurement and removal of endotoxins are included in **Note 9**.

2. Materials

2.1. Reagents

To avoid endotoxin contamination of products, all reagents are prepared using commercially available endotoxin-free water, and glassware is cleaned using 0.2 M NaOH followed by thorough rinsing with endotoxin-free water.

1. 2 *M* TE8: 2 *M* Tris-HCl, pH 8.0, 100 m*M* ethylenediaminetetra-acetic acid (EDTA). Prepare 0.2 *M* TE8 from 2 *M* stock.
2. $F(ab')_2$ reducing solution: 220 m*M* 2-ME, 1 m*M* EDTA. Make up 10 mL. Use a fume cupboard.
3. Sephadex G25 (Pharmacia, Uppsala, Sweden) and Ultragel AcA44 (Biosepra S. A., Villeneuve la Garenne, France) gel filtration media.
4. G25 column buffer (50 m*M* AE); 3.35 g sodium acetate, 526 µL glacial acetic acid, 0.186 g EDTA, made up to 1 L. Degas before use under vacuum or using nitrogen.
5. High performance liquid chromatography (HPLC) buffer: 0.2 *M* phosphate, pH 7.0. Add 0.2 *M* Na_2HPO_4 to 0.2 *M* NaH_2PO_4 to obtain the required pH.

6. *o*-PDM/DMF for Fab′(SH) alkylation: 12 m*M* *o*-PDM in dimethylformamide. Make up just prior to use. Chill in a methylated spirit/ice bath. Caution: *o*-PDM is toxic and should be handled with care.
7. 1 *M*: NTE8 1 *M* NaCl, 0.2 *M* Tris-HCl, pH 8.0, 10 m*M* EDTA.
8. Iodoacetamide: 250 m*M* in 0.2 *M* TE8 and 50 m*M* in 1 *M* NTE8.

2.2. Chromatography Equipment

1. Two chromatography columns packed with Sephadex G25 (*see* **Subheading 2.1**) and equilibrated and run in 50 m*M* AE are required. The first (column 1) should be 1.6 cm in diameter, packed to a height of 25 cm with gel, and pumped at approx 60 mL/h. The second (column 2) should be 2.6 cm in diameter, packed to a height of 20 cm with gel, and pumped at approx 200 mL/h. The columns must be fitted with two end-flow adaptors and water jackets to allow chilling throughout the procedure. Pharmacia K Series columns are ideal. (Cleaning of columns to avoid endotoxin contamination, *see* **Note 9**).
2. Two larger columns packed with polyacrylamide agarose gel (Ultragel AcA44; *see* **Subheading 2.1**) and run in 0.2 *M* TE8 are used for the size exclusion chromatography of the BsAb products. These should be 2.6 cm in diameter, and packed to a height of 80 cm with gel. The two columns should be joined in series using Teflon capillary tubing and pumped at approx 30 mL/h. Chilling is not required at this stage of the preparation, and the columns can be run at room temperature. (Cleaning of columns to avoid endotoxin contamination, *see* **Note 9**).
3. Two peristaltic pumps capable of rates between 15 and 200 mL/h for column chromatography.
4. Chiller/circulator to cool columns. A polystyrene box containing water and crushed ice and a submersible garden pond pump (rate approx 10 L/min) can be used as an alternative to a commercial chiller.
5. UV monitor, chart recorder, and fraction collector.
6. Amicon stirred concentration cell (Series 8000, 50 or 200 mL) with a 10,000 M_r cutoff filter for concentration of products.
7. HPLC system fitted with Zorbex Bio series GF250 column (Du Pont Company, Wilmington, DE) or equivalent gel-permeation column capable of fractionation up to approx 250,000 M_r.

3. Methods

3.1. Preparation of Bispecific F(ab′)$_2$ Derivatives

The method described here is for the preparation of F(ab′)$_2$ BsAb starting with 5–20 mg of each parent F(ab′)$_2$ to obtain 1–8 mg of BsAb product.

1. Use equal amounts of F(ab′)$_2$ from the two parent antibodies. The F(ab′)$_2$ should be in 0.2 *M* TE8 at 5–12 mg/mL in a final volume of 1–3 mL. Keep a 50 µL sample of both F(ab′)$_2$ preparations for HPLC analysis (*see* **Subheading 3.3**).
2. Reduce both parent F(ab′)$_2$ preparations to Fab′(SH) using 1/10 vol F(ab′)$_2$ reducing solution (final concentration 20 m*M* 2-ME). Incubate at 30°C for 30 min and

then keep on ice. Maintain the tempterature at 0–5°C for the rest of the procedure unless stated otherwise.

3. Select the species to be maleimidated (Fab′-A[SH]) (*see* **Note 3**). Remove 2-ME by passing through the smaller Sephadex G25 column (column 1). Collect the protein peak, which elutes after approx 8–10 min, in a graduated glass tube in an ice bath (*see* **Note 4**). Take a 45 µL sample from the top of the peak for HPLC analysis (*see* **Subheading 3.3**). Keep the column running to completely elute 2-ME, which runs as a small secondary peak.
4. When the chart recorder has returned to baseline, load the second Fab′(SH) species [Fab′-B(SH)] onto the column, and separate as for Fab′-A(SH), again taking a sample for HPLC analysis (*see* **Subheading 3.3.**).
5. After the Fab′-B(SH) has been loaded onto the G25 column, the Fab′-A(SH) partner can be maleimidated. Rapidly add a 1/2 vol (normally 4–5 mL) of cold *o*-PDM/DMF to the Fab′-A(SH), seal the tube with Parafilm or similar, and mix by inverting two to three times (*see* **Note 5**). Stand in an ice bath for 30 min.
6. When the Fab′-B(SH) has been collected, connect the larger Sephadex G25 column (column 2) to the chart recorder. After the 30 min incubation, load the Fab′-A(SH)/*o*-PDM/DMF mixture onto this column. Collect the Fab′-A(mal) protein peak (elutes after 8–10 min) (*see* **Note 6**).
7. Pool the Fab′-A(mal) and the Fab′-B(SH). Immediately concentrate in a stirred Amicon concentration cell to around 5 mL, and then transfer to a tube for overnight incubation at 4°C (*see* **Note 7**).
8. During conjugation, in addition to the required BsAb, disulfide bonded homodimers may also form. To eliminate these, after overnight incubation add 1/10 volume 1 *M* NTE8 to the mixture to increase the pH, and then 1/10 vol $F(ab')_2$ reducing solution to reduce the homodimer disulfide bonds. Incubate at 30°C for 30 min.
9. Alkylate to block sulphydryl groups by the addition of 1/10 vol 250 m*M* iodoacetamide in 0.2 *M* TE8 (*see* **Note 8**). Check the composition of the mixture by HPLC (*see* **Subheading 3.3**).
10. Separate the products on two AcA44 columns run in series. Collect 10–15 min fractions. A typical elution profile is shown in **Fig. 2**.
11. Pool the fractions containing the BsAb product. To minimize contamination, only take the middle two-thirds of the peak. Concentrate and dialyze into appropriate buffer.
12. If required, check the final product by HPLC (*see* **Subheading 3.3**).

3.2. Preparation of Bispecific $F(ab')_3$ Derivatives

This is as for the preparation of bispecific $F(ab')_2$ except that the ratio of Fab′(mal) to Fab′(SH) is increased from 1:1 to 2:1 or greater. Therefore, start with at least twice as much of the $F(ab')_2$ which is to provide two arms of the $F(ab')_3$ product.

3.3. HPLC Monitoring

For rapid analysis of products during the preparation, an HPLC system is used as described in **Subheading 2.2**. This will resolve IgG, $F(ab')_2$, and Fab′

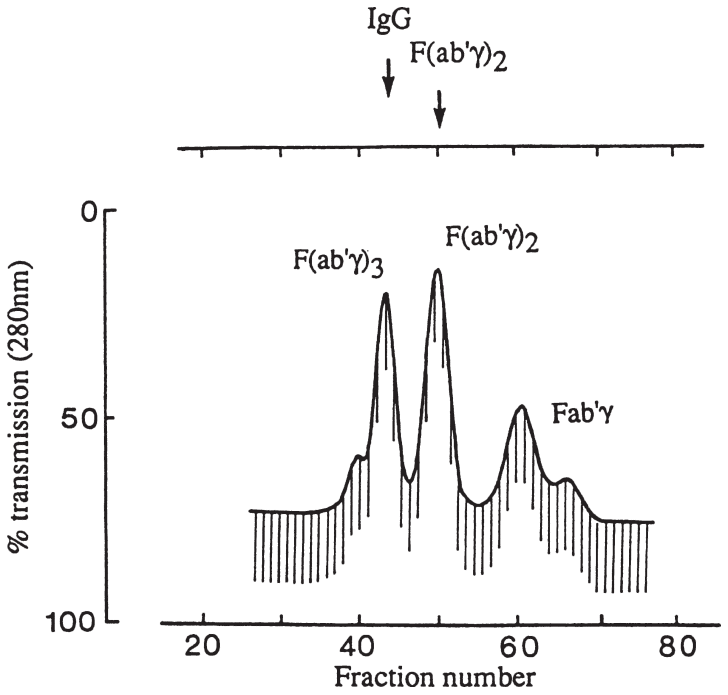

Fig. 2. Chromatography profile showing the separation of parent Fab′ and bispecific $F(ab')_2$ and $F(ab')_3$ products on AcA44 columns. In this case, Fab′-A(SH) and Fab′-B(mal) were mixed at a ratio of 2:1 to increase the formation of bispecific $F(ab')_3$. The unreacted Fab′ fragments and the $F(ab')_2$ and $F(ab')_3$ products are indicated. The *arrows* show the points at which protein standards eluted from the same columns.

sized molecules in approx 20 min, and can be performed while the preparation is in progress. The parent $F(ab')_2$ and the alkylated reaction mixture can be loaded directly onto the column and the eluted product monitored at 280 nm. However, we have found that F(ab′)SH rapidly reoxidizes back to $F(ab')_2$ while on the column. This can be overcome by alkylating the free SH-groups by the addition of 5 µL 50 m*M* iodoacetamine in 1 *M* NTE8 to the 45-µL sample from the G25 column.

Fab′ will elute from the column later than $F(ab')_2$ resulting in a shift in the position of the peak on reduction. In most cases >95% of the $F(ab')_2$ is reduced. Following alkylation and overnight incubation, the reaction mixture typically elutes from HPLC as a triplet, containing a mixture of alkylated FabƆ and Fab′(mal), which elute in a similar postion to Fab′(SH), bispecific $F(ab')_2$ product, which elutes similarly to the parent $F(ab')_2$, and a smaller amount of bispecific $F(ab')_3$, which elutes similarly to IgG.

4. Notes

1. Two SH groups may also be produced by the reduction of the heavy/light chain disulfide bond. However, under the conditions used, this bond is not fully reduced, and any SH groups that are produced are less likely to be available for conjugation ***(1,2)***. This procedure relies on one maleimidated hinge SH-group remaining free for conjugation after the intramolecular cross-linking of adjacent SH-groups with *o*-PDM. It follows that the Fab′ species chosen to be maleimidated must be derived from IgG with an odd number of hinge region disulfide bonds. Of the mouse IgG subclasses, IgG1 and IgG2a (three bonds), and IgG3 (one bond) qualify, whereas IgG2b (four bonds) does not. $F(ab')_2$ derived from rabbit Ig (one bond) and rat IgG1 (three bonds)can also be employed. However, rat IgG2a and IgG2c both have two, and rat IgG2b has four and so cannot be used as the maleimidated partner.
2. If $F(ab')_3$ derivatives are required, the number of SH-groups at the hinge of the unmaleimidated partner should be at least two and preferably three, because this determines the number of Fab′(mal) arms that can be conjugated.
3. We have found that a few antibodies give consistently low yields of BsAb when used as the maleimidated partner. If large quantities of a derivative are required, it is worthwhile performing small scale pilot preparations to determine which maleimidated partner gives the optimal yield.
4. It is very important to avoid contamination of the Fab′-A(SH) with 2-ME. In order to minimize the risk, stop collecting when the recorder has returned two-thirds of the way back to the baseline. In order to ensure that Fab′-B(SH) is not contaminated with 2-ME left over from the first run, make sure that it is not loaded until the chart recorder has returned to the baseline.
5. Sometimes the mixture becomes slightly cloudy.
6. To avoid contamination with *o*-PDM/DMF, which elutes as a second large peak, stop collecting when the chart recorder has returned halfway to baseline.
7. To avoid loss of product, slightly over concentrate, then wash the cell with a small volume of chilled buffer.
8. It is very important to add excess iodoacetamide at this stage; otherwise the BsAb derivative can precipitate.
9. To minimise contamination with endotoxin, buffers and reagents are made up using commercially available endotoxin-free water, and glass vessels washed with 0.2 M NaOH and thoroughly rinsed with endotoxin-free water before use. In addition, where possible chromatography columns are cleaned up regularly by running through with 0.2 M NaOH for 30 min

followed by extensive washing with running buffer. *However, please check the manufacturers' instructions to ensure that this is not detrimental to the gel matrix being used*. As both the preparation of the parent $F(ab')_2$ and the BsAb are multistage processes involving incubation with enzyme and several column chromatography and concentration steps, it is still possible that the product will be contaminated with LPS. To assay for endotoxin, we use Endosafe^R –PTS cartridges (Charles River Laboratories, Charleston, SC) and collect the 'clean product' in an endotoxin-free disposable plastic container. To remove any endotoxin we use EndoTrap^R Red endotoxin removal columns (Lonza, Walkersville, MD); these have a high binding capacity for endotoxin, and can be regenerated and re-used. To avoid re-contamination, minimise manipulations of the "clean" BsAband use endotoxin-free disposable plasticware.

Antigen Measurement Using ELISA

William Jordan

1. Introduction

The initial description of the enzyme-linked immunosorbent assay (ELISA) almost 30 yr ago ***(1)*** marked a technological advance that has had an immense impact in both clinical diagnostic and basic scientific applications. This assay represents a simple and sensitive technique for specific, quantitative detection of molecules to which an antibody is available. Although there are a huge number of variations based on the original ELISA principle, this chapter focuses on perhaps the two most useful and routinely performed: (1) the indirect sandwich ELISA—providing high sensitivity and specificity and (2) the basic direct ELISA—useful when only one antibody to the sample antigen is available.

1.1. The Direct ELISA

During the indirect sandwich ELISA (**Fig. 1A**), an antibody specific for the substance to be measured is first coated onto a high-capacity protein binding microtiter plate. Any vacant binding sites on the plate are then blocked with the use of an irrelevant protein such as fetal calf serum (FCS) or Bovine serum albumin (BSA). The samples, standards, and controls are then incubated on the plate, binding to the capture antibody. The bound sample can be detected using a secondary antibody recognizing a different epitope on the sample molecule, thus creating the "sandwich." The detection antibody is commonly directly conjugated to biotin, allowing an amplification procedure to be carried out with the use of streptavidin bound to the enzyme horseradish peroxidase (HRP). As streptavidin is a tetrameric protein, binding four biotin molecules, the threshold of detection is greatly enhanced. The addition of a suitable substrate such as 3,3′,5,5′-tetramethylbenzidine (TMB) allows a colormetric reaction to occur in the presence of the HRP that can be read on a specrophotometer with the

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

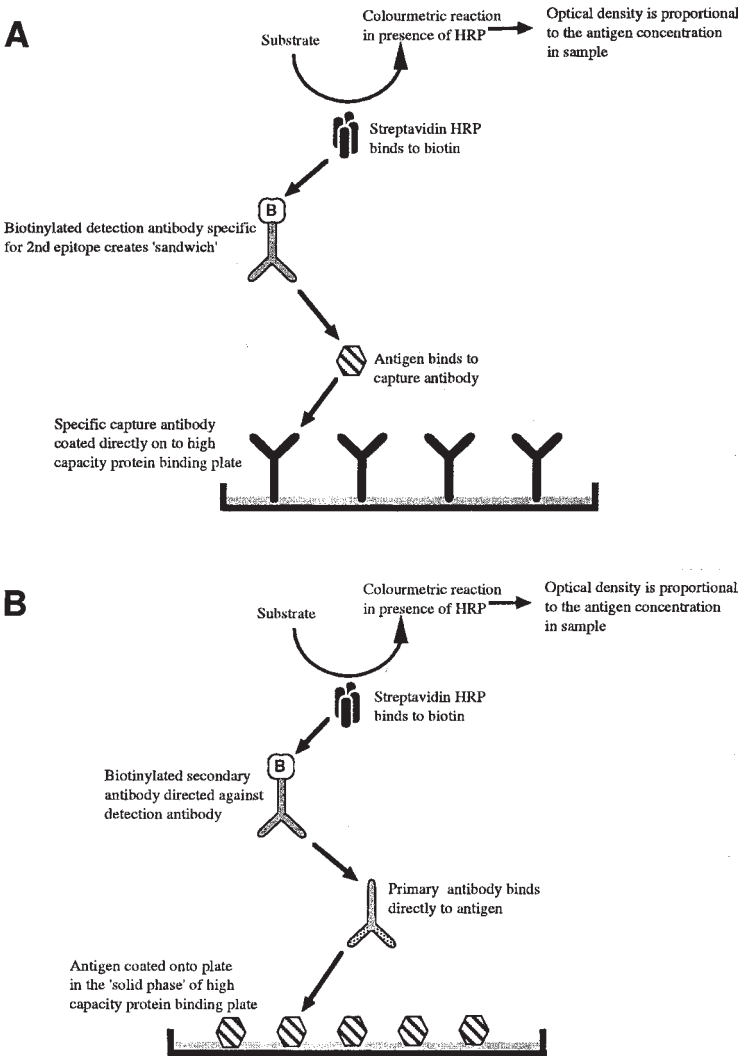

Fig. 1. The indirect sandwich ELISA.

resulting optical density (OD) relating directly to the amount of antigen present within the sample.

1.2. The Indirect ELISA

In some cases, however, only one specific antibody may be available, and in such a small quantity that directly conjugating it to biotin would be impractical. In this situation a direct ELISA should be used. During the direct ELISA

the sample itself is coated directly onto the microtiter plate and is then detected using the specific antibody. If this antibody is biotinylated, then the procedure can then proceed as in the indirect ELISA; if not, then a secondary biotinylated antibody directed against the species of the detecting antibody itself can be used. **Figure 1B** demonstrates this technique.

To set up a reliable and durable ELISA it is essential to first optimize a number of the parameters mentioned previously. The level of optimization will, of course, depend on exactly what is required from the assay. In some cases a simple "yes-or-no" answer is desired and a simple standard procedure may be sufficient. If, however, high sensitivity is the aim with accurate quantatation of the molecule in question, then carefully setting up the optimal conditions in advance will pay dividends and save a great deal of time in the long term.

2. Materials

1. Antibodies (*see* **Note 1**): For the indirect ELISA, antibody pairs can often be bought commercially and consist of a capture antibody and a biotinylated detection antibody. Both antibodies are specific for the molecule in question, with the detection antibody being directly biotinylated, and able to recognize the sample molecule when it is bound to the capture antibody on the plate. For the direct ELISA, one specific detection antibody is required, preferably biotinylated, but if not a secondary biotinylated antibody specific for the detection antibody is also needed. Aliquot and freeze at −20°C or lower in small, usable quantities with a carrier protein at such as 10% FCS or 1% BSA.
2. Blocking buffer: Phosphate-buffered saline (PBS), pH 7.4, supplemented with either 1% fatty acid free BSA or filtered 10% FCS. If measuring in tissue culture samples, substitute the FCS with protein representing that within the culture conditions, that is, 10% FCS; in effect the sample will have been preabsorbed with this during culture and thus any non-specific binding to the blocking buffer is avoided.
3. Carbonate coating buffer: 8.41 g Na_2HCO_3 in 1 L freshly made PBS. Dissolve and adjust to desired pH with HCl or NaOH. Store for no more than 1 mo at 4°C (*see* **Note 2**).
4. High-capacity protein binding 96-well microtiter plates: There are a large number of suitable makes including Maxisorp (Nunc), Immunoware (Pierce), Immunlon II (Dynatech), and Costar (*see* **Note 3**).
5. PBS–Tween–10% FCS: Add 0.05 mL of Tween 20 to 90 mL of PBS, pH 7.4, and 10 mL of filtered FCS. Make up fresh as required.
6. Plate sealers or cling film wrap.
7. Plate washing apparatus: Adequate washing is a vital element of achieving a successful ELISA. Although a number of automatic plate washers are available, they are expensive and the use of a wash bottle with good pressure is perfectly suitable, although a little more time consuming.
8. Samples/standards: Standards of known amounts are required for positive controls, and for estimation of levels within samples (via comparison to a titration of known

amounts). All standards should be diluted in medium as near as, or identical to that of the sample solution. Standards are best obtained from a reliable commercial source having been mass calibrated and should be frozen in small, concentrated aliquots at −20°C or lower. Repeated freeze–thaw cycles must be avoided.
9. Spectrophotometer: Any suitable microplate reader able to measure absorbance at the appropriate wavelength.
10. Stop solution: 0.5 *M* H_2SO_4.
11. Streptavidin HRP (*see* **Note 4**): Use in accordance to manufacturer's instructions. Sources of streptavidin HRP include Sigma, Biosource, Pierce, and Zymed.
12. Substrate: One-step TMB (Zymed). Although many other substrates are available for HRP, TMB has high sensitivity with a quick development time. OD can be monitored at 650 nm while the color develops, then at 450 nm when the reaction is stopped with H_2SO_4. TMB may also be obtained in a lyophilized state and made up fresh with hydrogen peroxidase.
13. Washing buffer: Add 0.5 mL of Tween 20 to 1 L of PBS, pH 7.4. Make up fresh as required.

3. Methods

3.1. Basic Sandwich ELISA Protocol

1. Dilute the capture antibody to 1 µg/mL is coating buffer, pH 9.5. Add 100 µL to each well of a high-capacity protein binding 96-well microtiter plate.
2. Seal the plate to avoid evaporation and incubate overnight (12–18 h) at 2–8°C.
3. Wash plate: Discard unbound antibody by inverting and flicking the plate over a sink. Fill each well with washing buffer and leave for at least 10 s before discarding once more. Ensure all liquid has been removed between each wash by repeatedly tapping the plate onto clean paper towels. Repeat 3×.
4. Add 200 µL of blocking buffer to each well. Seal plate and incubate for at least 2 h at room temperature.
5. Discard blocking buffer. Wash plate 3× as described in **step 3**.
6. Prepare a titration series of known standards (e.g., in 1.5-mL Eppendorf tubes) diluted in a matrix representing that of the samples (e.g., culture medium or human serum). Include a negative control such as culture medium only. Transfer samples and antigen standards to the ELISA plate in duplicate at 100 µL/well. Seal plate and incubate at room temperature for at least 2 h, or overnight at 4°C for increased sensitivity.
7. Wash plate 3× as described in **step 3**.
8. Dilute biotinylated detection antibody to 1 µg/mL in PBS, pH 7.4. Add 50 µL/well. Incubate at room temperature for 2 h. If problems with nonspecific binding of the biotinylated antibody to the plate occur, dilute the antibody in PBS–Tween–10% FCS rather than just PBS.
9. Wash plate 3× as described in **step 3**.
10. Dilute streptavidin HRP according to manufacturer's instructions. Add 100 µL/well. Incubate at room temperature for 30 min. Again, if problems with nonspecific binding of the biotinylated antibody to the plate occur, dilute the antibody in PBS-Tween-10% FCS rather than just PBS.

11. Wash plate 4× as described in **step 3**.
12. Add 100 µL/well of "one step" TMB. Allow color to develop for 10–60 min (20 min is usually sufficient). OD may be monitored at this stage at 650 nm as the color develops.
13. Add 100 µL of 0.5 *M* H_2SO_4 to each well to stop the reaction. Read OD at 450 nm.
14. Estimate amount of antigen within samples by comparing ODs to those of known standards.

3.2. Direct ELISA Protocol

1. Make serial dilutions of samples from neat to 1 : 16 in coating buffer, pH 9.5. Add 100 µL to each well of a high-capacity protein binding microtiter plate. Also set up wells with antigen standards and a negative control diluted in the same coating buffer.
2. Seal the plate with an acetate plate sealer or cling film wrap to avoid evaporation and incubate overnight (12–18 h) at 2–8°C.
3. Wash plate: Discard unbound antibody by inverting and flicking the plate over a sink. Fill each well with washing buffer leave for at least 10 s and discard once more. Ensure all liquid has been removed between each wash by repeatedly tapping the plate onto clean paper towels. Repeat 3×.
4. Add 200 µL of blocking buffer to each well. Seal plate and incubate for at least 2 h at room temperature.
5. Discard blocking buffer. Wash plate 3× as described in **step 3**.
6. Dilute detection antibody to 2 µg/mL in PBS. Add 50 µL/well. Incubate at room temperature for 2 h. If the antibody is biotinylated proceed to **step 9**.
7. Wash plate 3× as described in **step 3**.
8. Add secondary antibody (100 µL, 2 µg/mL) specific for the detection antibody (i.e., if the detection antibody is mouse, use biotinylated rabbit anti-mouse Ig).
9. Wash plate 3× as described in **step 3**.
10. Dilute streptavidin HRP according to the manufacturer's instructions. Add 100 µL/well. Incubate at room temperature for 30 min.
11. Wash plate 4× as described in **step 3**.
12. Add 100 µL/well of "one-step" TMB. Allow color to develop for 10–60 min (20 min is usually sufficient). OD may be monitored at this stage at 650 nm, as the color develops.
13. Add 100 µL of 0.5 *M* H_2SO_4 to each well to stop the reaction. Read OD at 450 nm.
14. Estimate amount of antigen within samples by comparing ODs to those of known standards of sample.

3.3. Optimization of ELISA

At this stage the ELISA may be more than adequate, although optimization of the following parameters is usually required:

1. pH of carbonate coating buffer (pH 7.0–pH 10.0). Also try PBS at pH 7.4.
2. Concentration of capture antibody (0.5–10.0 µg/mL).

3. Concentration of secondary antibody (indirect ELISA, 0.5–4.0 µg/mL).
4. Concentration of biotinylated detection antibody (0.1–2.0 µg/mL).
5. Concentration of streptavidin–HRP conjugate (usually between 1 : 1000 and 1 : 10,000).

4. Notes

1. The quality of the antibodies used is perhaps the most important aspect in seting up a good ELISA. Antibodies need to have a high affinity for the sample to be measured, reducing the chance of being "washed off" during the assay. The indirect ELISA relies on two specific antibodies and thus the increased specificity increases sensitivity of the assay by reducing background.
2. The pH of the coating buffer can have a great effect on the amount of antibody that will bind to the plate and thus to the ELISA as a whole. Basically, a higher pH will result in more antibody binding but may have a detrimental effect on its immunoreactivity. Thus a pH must be found that is suitable for the antibody in question, and this can vary dramatically. When beginning optimization of the assay, test a range of carbonate buffers from pH 7.0 to 10.0 as well as PBS, pH 7.4. We usually find a carbonate buffer pH of 9.5 gives good results. In some cases we have found commercially available coating antibodies recommended by the manufacturer to be adsorbed onto the plate at pH 7.4 to be far more effective at higher pH values, improving the sensitivity by up to 10-fold. This can allow the coating concentration to be vastly reduced, creating an extremely cost-effective assay.
3. There can be a significant difference between the protein binding capability of different makes, and even batches of microtiter plates. Some appear to be extremely good for binding antibodies, whereas others more useful for other proteins. The only real way to choose a suitable plate is by trial and error, or using a recommended make known to bind the protein you intend to coat.
4. Although the HRP–TMB system represents a good, reliable, and sensitive combination, HRP has a number of alternative substrates that can be used *(2)*. These include o-phenylene diamine (OPD) or 2,2′-azino-di(3-ethylbenzthiazoline-6-sulfonic acid (ABTS). There are also a number of options for the enzyme used other than HRP, such as alkaline phosphatase (AP) which can be used in combination with the substrate *p*-nitrophenyl phosphate (p-NPP) or phenolphthalein monophosphate (PMP). The choice of enzyme–substrate system depends on a number of factors including price, sensitivity, and whether a filter is available for the substrate specific wavelength to be measured.

5. The use of biotinylated secondary antibodies (or detection antibody in the indirect sandwich ELISA) in conjunction with enzyme-conjugated streptavidin (or avidin, extravidin, etc.) both increase sensitivity and save time in that a further step is eliminated from the assay and therefore another step of optimization is eliminated.
6. If the major aim of the ELISA is to obtain quantitation of substances present in extremely low concentrations a number of adaptations to the technique can be used. Such techniques often use AP enzyme systems which can be utilized, for example, to lock into a circular redox cycle producing an end product such as red formazan which is greatly amplified in comparison to standard amplification methods ***(3)***. Chemiluminescent amplified ELISA principles have also been shown to give very high sensitivity ***(4)*** and can be optimized to measure as little as 1 zeptomol (about 350 molecules!) of AP ***(5)***. Although extremely sensitive, such techniques are time consuming to set up and optimize, and are far more expensive than the simple colormetric ELISAs described in this chapter.
7. In some cases, molecules present in a sample are masked by the solution that they are in. This problem can sometimes be solved by diluting the samples in PBS–Tween–10% FCS. If this is performed, remember to make similar adjustments to the solution used for the standards. Possible interference molecules within samples such as soluble receptors for the antigen can also cause a problem. Commercially available matched antibody pairs for molecules should have been pretested and guaranteed against being affected by such problems.

Enhanced Chemiluminescence Immunoassay

Richard A. W. Stott

1. Introduction

Chemiluminescence results from reactions with a very high energy yield, which produce a potentially fluorescent product molecule; reaction energy passed to the product may result in an excited state and subsequent production of a single photon of light. The light yield is usually low, but can approach one photon per molecule in bioluminescent reactions catalyzed by dedicated enzymes.

A wide variety of immunoassay systems that use chemiluminescence or bioluminescence have been developed with the aim of detecting low concentrations of biologically active molecules. Even when emission efficiencies are <1%, chemiluminescence is a sensitive label detection method compared with isotopic methods in which very large numbers of molecules must be present for each detected disintegration (e.g., about 1×10^7 atoms of ^{125}I give 1 count/s). The production of light against a low background permits detection of small numbers of reacting molecules by measuring total light output. Luminescent emissions can be measured over a range of at least six orders of magnitude by all but the simplest luminometers. This is in marked contrast to fluorescent or spectrophotometric detection of reaction products, where sensitivity and instrument linear range are limited by the stability of light sources and wavelength selection. For example, a good spectrophotometer may achieve a linear range slightly greater than three orders of magnitude.

Directly labeled chemiluminescent systems produce <1 photon/label and require complex chemical synthesis to produce each new labeled molecule ***(1, 2)***. In contrast, chemiluminescent detection of enzyme labels combines the advantages of a high specific activity label with the convenience of relatively simple coupling chemistries, which use commercial reagents. A number of enzyme labels can be detected via chemiluminescent or bioluminescent

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

reactions, including β-galactosidase *(3)*, alkaline phosphatase *(4)*, peroxidase, luciferin and a variety of enzymes indirectly linked via production of ATP or NADH *(5)*. Systems that use alkaline phosphatase and peroxidase have the additional advantage of commercial availability of a wide range of labeled molecules and complete assay kits suitable for adaptation to luminescent detection.

Enhanced chemiluminescence is based on the reaction of luminol (3-aminophthalhydrazide) with an oxidizing agent, such as hydrogen peroxide or sodium perborate. This reaction is catalyzed by metal ions at high pH, resulting in emission of blue light (emission peak about 425 nm). At lower pH, the reaction is catalyzed by hemecontaining enzymes, such as horseradish peroxidase, catalase, cytochrome C, and hemoglobin (**Fig. 1**). However, the light output is low with a half-life of a few seconds. The presence of any one of a series of "enhancer molecules" increases the light emission from horseradish peroxidase by 1000-fold or more, and alters the kinetics so that a steady glow is produced lasting several hours *(6, 7)*. Microparticles, plastic beads, plastic tubes, microtiter plates, membranes, and plastic pins have all been used successfully as solid supports in a wide range of enhanced chemiluminescence assays, including competitive immunoassays, immunometric assays, and RNA and DNA binding assays *(6, 8, 9)*.

In common with all other sensitive detection systems, maintenance of the label enzyme in its active state is important. The precautions detailed in **Notes 1–3** should be observed to maximize the sensitivity achieved. Reagents for enhanced chemiluminescence can be prepared in the laboratory or are available commercially (*see* **Note 4**). The purity of the substrate solution is important in achieving maximum sensitivity. Therefore, the precautions detailed in **Notes 5–7** should be followed if preparing substrate solutions. The free base form of luminol undergoes rearrangement to a mixture of luminol and a series of contaminants. Therefore, luminol should be purified by recrystallization as the sodium salt before use (*see* **Note 8**).

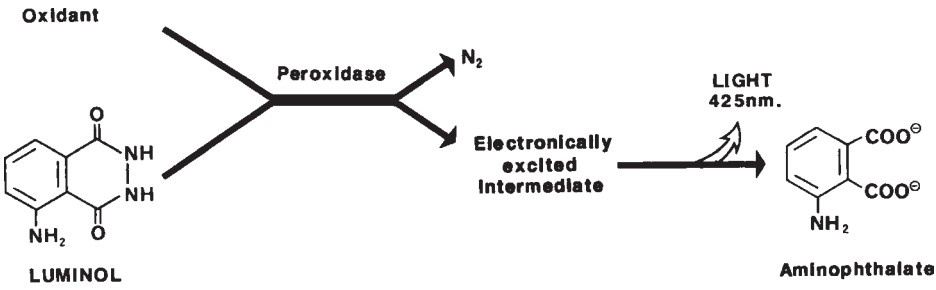

Fig 1. Chemiluminescent oxidation of luminol by peroxidase.

1.1. Light Measurement Instruments (Luminometers)

Commercial luminometers range from low-cost manual single tube instruments to fully automated high-capacity machines and have been reviewed previously ***(10)***. However, application-specific requirements are rarely discussed, and the first-time user will require some guidance in matching an instrument to the chemistry or chemistries to be used.

There is normally no requirement for wavelength selection, because very few reactions produce significant light output. Therefore, a simple luminometer can consist of a detector and some means of presenting a sample or samples in a light-tight compartment. There may also be a system for adding reagents to the sample while in the chamber. The detector is usually a photomultiplier tube for sensitive instruments, but can be a photodiode in a portable instrument ***(7, 11)*** or photographic film, if a semiquantitative result is sufficient ***(2, 12)***.

Luminometers designed for use with short-lived reactions have complex high-precision reagent injection systems. There may also be a short measurement prior to reagent injection to correct for background owing to light leaks, phosphorescence, and scintillation from sample tubes. Photon-counting and cooled detectors may also be used to achieve maximal light-detection sensitivity. None of these features is essential for use with enhanced chemiluminescence.

Relatively high light intensities and prolonged emission are produced by enhanced chemiluminescence detection of peroxidase and the substituted dioxetane-based detection reactions for alkaline phosphatase or β-galactosidase ***(3, 4)***. These reactions require a short stabilizing time before reading and are conveniently performed by adding the reagents before the sample reaches the measuring position. This can only be done if any preinjection blank measurement can be disabled. It is also practical to handle large numbers of samples using a timed reagent addition outside the instrument, completely eliminating the need for automatic reagent handling. High light output can lead to "pulse pileup" in photon-counting electronics, resulting in nonlinearity and eventually zero apparent signal ***(13)***. Linearity can be improved via mathematical correction for the dead time or insertion of a neutral density filter.

Although light output from individual transparent microtiter wells can be measured in a luminometer designed for tubes, it is more convenient to use opaque microtiter plate wells and one of the purpose-designed readers. Prolonged light output makes it possible to start the reaction outside the instrument in the same pattern as the light emission is read. However, the presence of other glowing wells introduces the possibility of light carryover into the well being read. Carryover is important if the dynamic range of light emissions from a plate is expected to be higher than three orders of magnitude; in this case, there is a risk of false-positive results owing to a fraction of a percent of the emission from a very high sample being transmitted to a low one as much as three positions away (**Table 1**).

Table 1
Carryover from a Single Glowing Well in a Rigid[a] Black Microtiter Plate Measured Using a Prototype Luminometer

0.02%	0.01%	0.007%	ND	ND
0.04%	0.035%	0.018%	0.005%	ND
0.71%	0.075%	0.034%	0.007%	ND
Source	0.1%	0.03%	0.007%	ND
0.045%	0.034%	0.025%	0.006%	ND
0.03%	0.025%	0.013%	0.005%	ND
0.009%	0.009%	0.006%	ND	ND

[a]Data represent the mean of several readings obtained for empty wells expressed as a percentage of the mean light output of the source well. Positions marked ND gave readings that were not significantly different from the photomultiplier background.

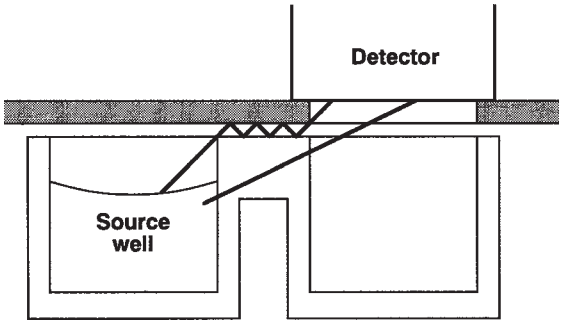

Fig. 2. Origin of light carryover between wells of an "opaque" microtiter plate.

Both white and black microtiter plates are available in single-well, strip, and plate formats. The plastic is made opaque by incorporating colored particles into transparent plastic. Therefore, some light can pass through the plastic. The light transmission differs considerably between formats and individual manufacturers. However the greatest carryover occurs via external reflection from the shiny top surface (**Fig. 2**). Carryover is least for black plastic, although the loss of reflection within the well also reduces the signal available to the detector. Multiwell strips have higher carryover along the strip than between adjacent strips owing to the plastic web that links the wells. Similarly, individual wells have lower carryover than joined ones.

Carryover varies considerably between instruments, but it is particularly low if the instrument has an antireflection mask between the plate and detector. Individual instruments should be assessed for carryover using the type of plates that will be used with it. The pattern of carryover should be determined by reading light output from all wells of a plate containing a single glowing well with a

light output, which represents the highest expected from the assay. The location of this well may affect the results, and carryover should be assessed using each corner well and one close to the center of the plate.

2. Materials

1. High-quality deionized water (*see* **Note 3**).
2. Luminol stock solution: 1.25 m*M* luminol in 0.1 *M* Tris-HCl, pH 8.6. Store at 4°C in the dark. Make up fresh each week. Luminol should be recrystallized as the sodium salt before use (*see* **Note 8**).
3. Hydrogen peroxide: 30% (w/v). Store at 4°C.
4. p-Iodophenol stock solution: p-iodophenol, 1 mg/mL in dimethyl sulfoxide (DMSO). Make up fresh each day.
5. Microfluor "B" microtiter plates (Dynatech Laboratories, Chantilly, VA).
6. Coating buffer: 0.1 *M* glycine, pH 8.8. Adjust pH using NaOH. Store at 4°C, and make up fresh each week.
7. Rabbit anti-α fetoprotein (AFP) (Dako [Glostrup, Denmark]).
8. Phosphate-buffered saline (PBS), pH 7.2: 0.14 *M* NaCl, 2.7 m*M* KCl, 1.5 m*M* KH_2PO_4, and 8.1 m*M* Na_2HPO_4. Store at 4°C, and make fresh each week.
9. Blocking solution: PBS containing Bovine serum albumin (BSA) 0.1% (w/v). Make up fresh each day.
10. PBS-Tween: PBS containing Tween-20, 0.05% (v/v). Make an additional batch using high-quality deionized water (*see* **Note 3**). Store at 4°C, and make fresh each week.
11. Assay diluent: PBS-Tween containing BSA 0.5% (w/v). Make up fresh each day.
12. Working standards concentration range 0–800 ng/mL made fresh for each assay batch by serial dilution of stock standard using normal human serum. Stock standard (1600 ng/mL) is made by diluting AFP standard serum (Dako cat. no. X900 or Boehring Diagnostics [Westwood, MA] cat. no. OTOD 02/03) in human serum containing 0.05% (w/v) sodium azide. Store frozen as 1-mL aliquots.
13. Peroxidase-conjugated anti-AFP (Dako cat. no. P128) diluted 1/1000 in assay diluent. Make up fresh for each assay batch.
14. Working enhanced chemiluminescence substrate solution (*see* **Note 9**)—either:
    a. p-iodophenol-enhanced substrate: 1.25 m*M* luminol, 4 μ*M* p-iodophenol, 2.7 m*M* H_2O_2. Add 15 μL of stock hydrogen peroxide and 40 mL of p-iodophenol stock solution to 50 mL of stock substrate: solution, and mix well. Make up daily using high-quality deionized water (*see* **Note 3**), and store in the dark when not in use, or
    b. p-Hydroxycinnamic acid-enhanced substrate: 1.25 m*M* luminol, 30 μ*M* p-hydroxycinnamic acid, 2.7 m*M* H_2O_2. Add 15 mL of stock hydrogen peroxide and 1 mg of p-hydroxycinnamic acid (alternative names: p-coumaric acid or 4-hydroxycinnamic acid, e.g., Aldrich [Gillingham, UK]) to 50 mL of stock substrate solution. Mix for 30 min before using. Make up daily using high-quality deionized water (*see* **Note 3**), and store in the dark when not in use.

3. Method

1. Coat the wells of a microtiter plate with 100 mL of anti-AFP (1/1000 in coating buffer). Allow the protein to bind for either 2 h at room temperature or overnight at 4°C (*see* **Note 10**).
2. Empty the wells, and wash off any unbound antibody by filling each well with PBS and shaking the plate to re-empty. Repeat the wash and block unbound sites by incubating with 200 mL/well of blocking solution for 30 min at room temperature.
3. Empty the wells, and wash the plate twice (as described in **step 2**) with PBS-Tween to remove any unbound albumin.
4. Prepare 1/20 dilutions of samples, standards, and quality control specimens using assay diluent, and add 150 µL to each of the microtiter plate wells. Cover the plate with plastic film, and incubate at 37°C for 1 h.
5. Empty the wells, and wash the plate three times with PBS-Tween. Shake the plate over a sink to ensure complete removal of wash solution. Add 150 µL of working conjugate to each well, cover, and incubate at 37°C for 1 h.
6. Empty the wells, and wash the plate three times with PBS-Tween made using high-quality deionized water (*see* **Note 3**).
7. Add 150 µL of enhanced chemiluminescent substrate to each well in the same order and preferably with the same timing as used by the plate reader. Allow at least 2 min for the light output to stabilize before reading the plate.
8. Obtain unknown specimen results either by reading off a plotted calibration curve or use a computer program to calculate from a fitted curve.

4. Notes

1. Peroxidase is inactivated by anions and certain antimicrobial agents, including azide, cyanide, and thiomersal. Antimicrobial agents may be present in concentrated enzyme label solutions and assay buffers at typically active concentrations, but must not be present in wash solutions or substrate. The latter reagents must be freshly made each day from concentrated stocks.
2. Powerful oxidizing or reducing agents may interfere with any peroxidase detection reaction by inactivating peroxidase, oxidizing the substrates or reducing the oxidants in the reagents. There are potentially many of these in the laboratory environment, including chlorine in water, disinfectants, paper dust, laboratory coats, skin, and so forth. Care should be taken to avoid contamination of individual assay wells or equipment.
3. For best possible sensitivity, the final assay wash (**step 6**) and all substrate reagents should be made up in water of the highest possible purity. Trace contamination with bacteria, algae, organic compounds, and chlorine is a particular problem. Laboratory-grade distilled or reverse osmosis water should be further treated using a deionization cartridge. The water plant must be well maintained to avoid bacterial growth in deionization columns,

plumbing, and storage tanks. Alternatively, commercial HPLC-grade water has been found to be satisfactory.

4. Amerlite signal reagent (Johnson and Johnson Clinical Diagnostics) is supplied as separate bottles of buffer and substrate tablets. One "A" and one "B" substrate tablet (cat. no. LAN.4401) are dissolved in each bottle of substrate buffer (cat. no. LAN. 4402) prior to use. This reagent is stable for a day at room temperature providing it is kept in the dark glass bottle.
5. In order to ensure stable concentrations, the anhydrous form of sodium luminol is preferred molecular weight 199.1. This should be stored over silica gel in the dark. Luminol solutions should be stored in the dark at 4°C. Stock solutions must be made up at least weekly and working substrate daily.
6. DMSO is a colorless, odorless compound. However, it is hygroscopic and acquires an onion-like smell. DMSO in this state has been found to be inhibitory in the enhanced chemiluminescent reaction. Therefore, the highest available grade should be purchased in small amounts and carefully stored to minimize water uptake.
7. Hydrogen peroxide is a powerful oxidant, but gradually loses activity. The highest available grade should be purchased in small amounts, and stored at 4°C.
8. Luminol is available as the free base under alternative chemical names from several chemical suppliers, including:

   a. 5-Amino-2, 3-dihydro-1, 4-phthalazinedione (Sigma [St. Louis, MO]).
   b. 3-Aminophthalhydrazide (Aldrich).

   There is considerable batch to batch variability in commercial luminol. The purity of the original material is only important in determining how many recrystallization steps are required. Recrystallization gives a consistently high activity product and may be performed as follows (for further details, *see* **ref. *7***):

   a. Dissolve luminol in 5% (w/v) sodium hydroxide at room temperature until close to saturation (about 200 g/L). The color of this solution will depend on the original luminol. Cool the solution in an ice bath and allow to crystallize for 4 h. Recover the sodium luminol crystals using suction filtration on a glass fiber filter disk (Whatman GFA or similar), and wash using a small volume of ice-cold 5% sodium hydroxide. The crystals should be white or only slightly discolored. Sodium luminol should be recrystallized at least twice after a white product is obtained.
   b. Dissolve the sodium luminol in a minimum volume of 5% sodium hydroxide at room temperature. Allow to crystallize on an ice bath for 18 h. A refrigerator can be used as an alternative, although crystallization may be slower and yield may be low. Recover the crystals by filtration as above.

The initial crystalline form is the hexa-hydrate, which converts to an anhydrous powder on drying over silica gel. Sodium luminol is stable to heat (melting point >400°C), but Sodium luminol has recently become available from Sigma (cat. no. A 4685). The author has no experience with this product.

9. The substrate solutions detailed here (**Subheading 2, item 14**) are essentially interchangeable with no sensitivity advantage for either. Both systems are optimized for a reasonably steady light output at a peroxidase concentrations typically encountered in immunoassays. Use of final peroxidase activities that are markedly higher will result in declining light output owing to substrate exhaustion. This cannot be avoided by alteration of the reaction conditions. Slight reduction in enhancer concentration may give more stable light output for assays with atypically low peroxidase activity.
10. For best results, plates should be coated with the IgG fraction of an antiserum, this can be conveniently prepared using caprylic acid precipitation (*see* Chapter 180 and **ref. *15***). Where this is not possible, indirect capture may be used, such as antispecies antibody on the plate, or the streptavidin–biotin system. Any indirect capture system must be compatible with the final label, e.g., labeled antigen or different species antisera with no cross-reaction with the indirect coating antibody.
11. Safety data (from **ref. *16***):
    a. Luminol (commercial-grade): Irritating to eyes, respiratory system, and skin. No specific information is available for pure luminol or for the sodium salt.
    b. Hydrogen peroxide: Contact with combustible materials may cause fire. Causes burns. Keep in a cool place. After contact with skin, wash immediately with plenty of water.
    c. DMSO: Irritant to eyes, skin, and respiratory system. Harmful by inhalation, skin contact, and if swallowed. May cause sensitization by inhalation or skin contact.
    d. *p*-Iodophenol: Irritant to eyes, skin, and respiratory system.
    e. *p*-Hydroxycinnamic acid: Irritant to eyes, skin, and respiratory system.

Immunoprecipitation and Blotting

The Visualization of Small Amounts of Antigens Using Antibodies and Lectins

Stephen Thompson

1. Introduction

Immunoprecipitation and blotting both use antibodies (normally, but not exclusively monoclonal antibodies) to detect and quantitate specific protein antigens in complex cellular or protein mixtures. Immunoprecipitation has an advantage in that the antigens are allowed to react with the antibodies in their native conformation prior to their subsequent separation and quantification. A further advantage is that a protein at a very low concentration can be concentrated from the relatively large volume of 1–2 mL. The major disadvantage is that the proteins normally have to be radiolabeled to facilitate their detection. In Western blotting the proteins do not have to be labeled, but they have to be separated by electrophoresis in polyacrylamide gels prior to their transfer to either nitrocellulose, polyvinyldifluoride (PVDF), or nylon membranes. This seriously restricts the size of the sample, and hence the protein antigen has to be present at higher concentrations. A further disadvantage is that the antigen is not normally in its native conformation when it reacts with the antibody, because the electrophoresis usually being carried out in the presence of sodium dodecyl sulfate (SDS) to maximize the resolution of the separated proteins. If an antibody has a lower affinity for an antigen, it may well immunoprecipitate an antigen but not react with it on a Western blot. This is the reason why some workers slot-blot their protein mixtures rather than separate them by electrophoresis. This maintains their native conformation. The main problem encountered here is that crossreactions of the primary antibody with all the other proteins in the mixture can outweigh the antigen-specific binding. An unlabeled antigen is often therefore prepurified using an immobilized lectin or even immunoprecipitation itself

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

prior to its quantitation on a slot-blot. Such a combination of lectin and antibody techniques has tremendous potential both in more precise analysis of cellular antigens and in the characterization of disease progression.

This chapter therefore discusses the following major steps involved in immunoprecipitation:

1. The labeling and lysis of cells.
2. The formation of antibody–antigen complexes.
3. The removal and separation of the complexes.
4. The quantitation of the separated antigens.

This is followed by a shorter second section discussing Western and slot-blotting. The actual processes involved in Western blotting are not covered in great detail. This has recently been excellently reviewed ***(1)***. However, common practical problems are addressed.

Finally, a third and final section then discusses the use of lectins in both of the above techniques. This section is included because post-translational glycosylation of proteins is becoming increasingly recognized as an important factor in determining the course of many diseases including cancer.

2. Materials

All chemicals were of the purest grade possible (analar grade). All enzymes and second-layer antibodies were purchased from Sigma unless otherwise stated.

2.1. Immunoprecipitation

1. Radioactive amino acids (20–200 µCi), sugars or $^{32}PO_4$.
2. Minimal essential medium (MEM) depleted of the appropriate amino acid.
3. Fetal calf serum (FCS).
4. Phosphate-buffered saline (PBS).
5. Glucose: 0.5 *M* in PBS.
6. Lactoperoxidase: 1 mg/mL in PBS (stored in frozen aliquots).
7. KI: 100 µ*M* in PBS.
8. Glucose oxidase: 10 µL in 10 mL PBS (make up just before use).
9. $Na^{125}I$: 100–200 µCi.
10. Cell lysis buffer: 25 m*M* Tris-HCl buffer, pH 8.0, 150 m*M* NaCl, 1 m*M* $MgCl_2$ (TBS), 0.5–1.0% Nonidet P-40 (NP-40), 0.1 m*M* phenylmethylsulfonyl fluoride (PMSF; made up as 100 m*M* stock solution in ethanol).
11. CNBr-activated Sepharose beads (Pharmacia).
12. Primary antibody.
13. LP3: 3 mL round-bottomed plastic tubes.
14. Primary monoclonal or polyclonal antisera
15. Protein A-Sepharose beads: washed in TBS to remove preservatives and kept as a 50% suspension.

16. Second-layer sheep or rabbit polyclonal anti-antibody if your primary antibody is a mouse or rat antibody (*see* **Note 9**).
17. SDS: 5–10%.
18. Light-proof film cassettes.
19. X-ray film.
20. Flash gun with filters to presensitize the film.
21. Calcium tungstate scintillation screens (enhanced autoradiography).
22. 2,5-Diphenyloxazole (PPO).
23. Dimethylsulphoxide (DMSO, fluorography).
24. Gel drier.
25. Scanners or densitometers.

2.2. Blotting

1. Nitrocellulose or nylon membranes.
2. Polyoxyethylenesorbitan monolaurate (Tween-20).
3. Apparatus to suck the samples onto a membrane under vacuum (slot-blotting).

2.3. Precipitation and Blotting with Lectins

1. Lectins coupled to Sepharose beads: commercially available or made in an identical procedure to that given for antibodies in **Subheading 3.1.2.1.**
2. Labeled cellular antigens or complex protein mixtures.
3. Dioxigenin (DIG)-coupled lectins (Boehringer Mannheim, Germany).
4. Alkaline phosphate (AP)-labeled anti-DIG antibody second layer.
5. Proteins with known glycosylation structures as positive and negative controls.
6. Biotinylated lectins.
7. Anti-biotin-AP or avidin-AP second layer.

3. Methods

3.1. Immunoprecipitation

3.1.1. The Labeling and Lysis of Cells

There are two main methods of labeling cellular antigens: (1) metabolic labeling and (2) cell surface labeling. Metabolic labeling is normally carried out for at least 16 h in an attempt to label all the cellular proteins, even those with low turnover rates. Cell surface labeling allows an accurate analysis of the surface of a cell at any given time. Metabolic labeling is performed as follows:

1. Add approx 20 µCi/mL ^{35}S, ^{14}C, or ^{3}H amino acids to near confluent cell cultures for 16–18 h in MEM depleted of the appropriate amino acid ***(2,3)***. A typical flask would contain between 5×10^5 and 10^7 adherent cells (*see* **Notes 1–3**).
2. Wash adherent cells once with PBS.
3. Remove cells by treatment with 0.02% EDTA or EGTA for 5–10 min followed by two further washes with PBS (*see* **Note 4**).
4. Wash nonadherent cells three times with PBS to remove surplus radioactivity.

Many techniques have been developed to label the surface of cells, but those utilizing radioactive iodine have proved to be the most popular, probably because of the ease of detection of radioactive iodine in labeled proteins after their separation in polyacrylamide gels. The most commonly used technique is the lactoperoxidase-catalyzed iodination procedure using H_2O_2 generated by the glucose–glucose oxidase system ***(4)***. I have found this technique to be very reliable ***(5–7)***, and it can also be used to iodinate protein mixtures with a very high efficiency (around 95%). The procedure is given below.

1. Wash adherent cells once with PBS.
2. Remove cells by treatment with 0.02% EDTA or EGTA for 5–10 min followed by two further washes with PBS.
3. Resuspend the cells immediately in 1 mL PBS.
4. Add 10 µL glucose, 10 µL glucose oxidase, 5 µL KI, 10 µL lactoperoxidase, and 1–2 µL $Na^{125}I$ (100–200 µCi) (*see* **Subheading 2.1.** and **Note 5**).
5. Leave to react for 20–30 min at 37°C.
6. Wash away any unbound ^{125}I by three further washes with PBS containing 5 µ*M* KI (*see* **Subheading 2.1** and **Note 5**).

Many procedures can be used to lyse labeled cells. These all utilize isotonic buffers with pH values from 7.4 to 8.0 containing 0.5–1.0% nonionic detergent to solubilize the cell membranes. Some workers include EDTA at concentrations up to 10 m*M*, whereas others prefer to add Ca and Mg ions. Cell lysis buffer pH8.0, as described in **Subheading 2.1**, works well and will give good immunoprecipitates with most antibodies from cell lysates solubilized in this buffer. However, antibodies will often not give immunoprecipitates if PBS or Tris buffers at pH 7.4 with the same additives are used as lysis buffers.

1. Collect labeled cells by centrifugation.
2. Solubilize the cell pellet in 500 µL to 1 mL of the cell lysis buffer for 30 min at 4°C with repeated vortexing (*see* **Note 6**).
3. Separate the solubilized components from residual cellular debris by microcentrifugation at 13,000 *g* for 10 min. The solubilized extracts can be used immediately or can be stored frozen at −70°C until required.

3.1.2. Formation of Antibody–Antigen Complexes

Antigens can be immunoprecipitated by direct or indirect methods. The direct method uses the antibody directly coupled to Sepharose beads. In the indirect method the protein mixture is incubated with the antibody, and then the antigen–antibody complexes are removed using Protein A immobilized on Sepharose beads. The indirect method is more commonly used, as the antibody binding is not constrained by its immobilization to beads.

3.1.2.1. Direct Precipitation

The antibody has to be bound to activated-Sepharose beads before it can be used. This is a very simple procedure:

1. Place 0.3 g of CNBr-activated Sepharose in 100 mL of 1 m*M* HCl and allow to swell (to give approx 1 mL of beads).
2. Decant the clear supernatant after 30 min.
3. Gently resuspend the beads in another 100 mL of 1 m*M* HCl to remove the preservatives.
4. After 1 h decant the supernatant again (by suction).
5. Wash the beads rapidly in 10 mL 0.1 *M* sodium bicarbonate and pack by minimal centrifugation (30 s at 500 *g*).
6. Add immediately 1–2 mg (1 mg/mL in bicarbonate) of antibody to 1 mL of beads and mix gently overnight at 4°C.
7. Leave the beads to settle out. Remove the supernatant and measure its absorbance. The OD of the supernatant should be close to zero if the coupling has worked.
8. Add 5–10 mL of a 0.2 *M* glycine solution for 2 h to block residual active groups.
9. Wash the antibody-coated beads twice in 0.1 *M* bicarbonate and PBS. They are then ready for use.
10. For immunoprecipitation, add 25–50 µL of beads (50–100 µL of a 50% bead suspension) to a LP3 tube and add up to 0.5 mL of cell lysate or protein mixture.
11. Leave with gentle mixing for 1 h at room temperature for complexes to form.
12. Wash away unbound proteins (5 × 2 mL; *see* **Note 7**).
13. Dissociate the immune complexes from the beads (see below).

3.1.2.2. Indirect Precipitation

1. For indirect immunoprecipitation add the antibody to up to 1 mL of cell lysate (more often 100–200 µL) and incubate the mixture for 30–40 min at room temperature for anti-gen–antibody complexes to form (*see* **Note 8**).
2. Add 50 µL of a 50% suspension of Protein-A Sepharose to each sample to bind to the antigen-antibody complexes (*see* **Note 9**).
3. After a further 1 h of incubation with frequent gentle mixing, wash the beads five or six times, by gravity or very gentle centrifugation (*see* **Note 7**), with 2.5 mL TBS/NP-40 to remove unbound proteins.

3.1.3. Removal and Separation of the Complexes

1. Remove the immunoprecipitates from the small Sepharose-bead pellets by the direct addition of 50 µL of double-strength SDS-PAGE sample buffer. The ionic detergent totally disrupts the antigen–antibody complexes (*see* **Note 10**).
2. Harvest the solubilized antigen in the supernatant after microcentrifugation (*see* **Note 11**).
3. Add 5% (v/v) 2-mercaptoethanol to reduce the sample.
4. Boil for 5 min to ensure complete solubilization of the proteins.

5. Separate the immunoprecipitates by SDS-PAGE. The discontinuous system of Laemmli ***(5,8)*** gives the best resolution of proteins.

3.1.4. Quantitation of the Separated Antigens

Separated antigens are normally quantitated by autoradiography or fluorography of the dried polyacrylamide gels followed by densitometry of the developed X-ray film.

3.1.4.1. Autoradiography

This is the simplest procedure, as the polyacrylamide gel is simply dried onto filter paper and placed directly in contact with X-ray film. It is not very sensitive, with bands needing to contain more than 1500 dpm of ^{35}S or ^{14}C to allow their detection in 24 h. Much lower levels of ^{125}I or ^{32}P can be detected owing to their stronger γ and β emissions. Their irradiation is so strong it penetrates completely though the X-ray film. This has allowed the development of an ultrasensitive sandwich detection technique in which a sensitized X-ray film is placed between the dried gel and a calcium tungstate intensifying screen ***(10)***. Emissions pass through the X-ray film and hit the screen, and multiple photons of visible light are emitted that superimpose a photographic image on top of the autoradiographic image. The X-ray film is preexposed to a brief flash of light (*see* **Note 12**), and autoradiography is carried out at −70°C to maximize the detection of the emitted photons ***(10)***.

An indirect autoradiograph of $pp60^{src}$ immunoprecipitates is shown in **Fig. 1**. The pp60 kinase band is clearly visible in the positive control virally transformed cell line (lane 4) but is not visible in the untransformed parent cell line (lane 2) or the normal rabbit serum control lanes (lanes 1 and 3). The antibody in the precipitate is also phosphorylated by the kinase but at a much lower level in the parental cell line. Unlabeled lysates of cells (500 µL) were immunoprecipitated as above using 3 µL of antibody or normal rabbit serum and 25 µL of Protein A beads; 2 µCi (4 µL) of [γ-^{32}P]ATP were then added to the immunoprecipitate, and it was left to phosphorylate for 30 min. After washing to remove excess ATP, the immunoprecipitates were solubilized by SDS and separated by PAGE in a 13% polyacrylamide gel.

3.1.4.2. Fluorography

This technique also utilizes the detection of photons/light emitted by scintillators to detect the presence of low levels of ^{35}S or ^{14}C ***(11)***. It can also be used to increase massively the detection limits of ^{3}H, a very weak α emitter. It is possible to measure as low an amount as 300 dpm of ^{3}H in a band in 24 h ***(12)***. The

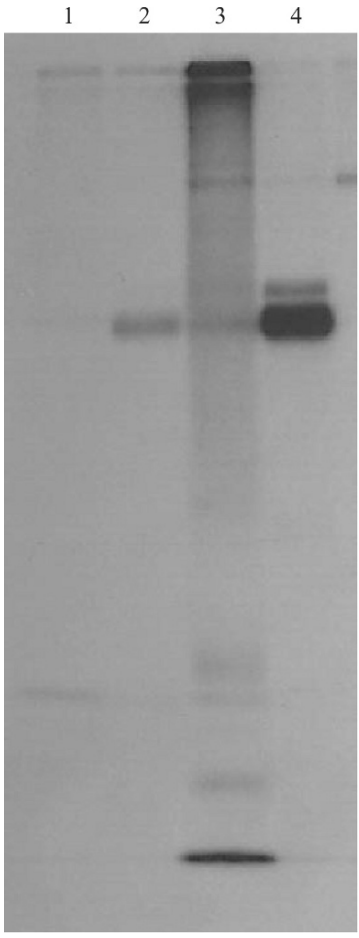

Fig. 1. A pp60src immunoprecipitate of rat fibroblasts (lanes1 and 2) and their virally transformed (A23) counterparts (lanes 3 and 4). Lanes 1 and 3 were control normal serum, lanes 2 and 4 were immunoprecipitated with pp60src antibody.

principles are exactly the same as those described for enhanced autoradiography. However, here the radioactive emissions are not strong enough to pass out of the dried gel and through the film to reach a scintillation screen. The scintillant has instead to be impregnated directly into the gel, as follows:

1. Totally dehydrate fixed gels by two 30-min to 1-h immersions in a 20X excess of dimethylsulfoxide (DMSO).
2. Immerse the gel in a saturated solution of the scintillator PPO (20% w/v) in DMSO for 1 h with gentle shaking.
3. Remove and place into a large excess of water where the scintillant immediately precipitates.
4. After 1 h, dry the gel normally and expose against preexposed X-ray film at −70°C.

3.2. Blotting

As mentioned in **Subheading 1**, blotting is described elsewhere in detail. Briefly, blotting is performed by the following steps:

1. Separate the protein mixture by SDS-PAGE and blot transversely onto a nitrocellulose or nylon membrane (*see* **Note 13**).
2. Block spare sites on the membrane (*see* **Note 14**).
3. Add the primary antibody (*see* **Note 15**).
4. After 1 h, wash the blot and add an enzyme-labeled anti-antibody (*see* **Note 16**).
5. Perform further washes and add a colored enzyme substrate. The substrate is precipitated onto the antigen by the enzyme ***(1,13)***. Dried blots (or photographs) can then be scanned for quantitation purposes.

3.2.1. Slot-Dot Blotting

To avoid the problems associated with denaturing the antigen you want to quantitate, it is possible to absorb a sample directly onto nitrocellulose by vacuum in either dots or slots. As either of the primary and secondary antibodies could be crossreacting with other components in the mixture and giving a false signal, it is essential to check that your antibodies are highly specific. This is carried out by using negative and positive control slots. These should contain a mixture of proteins that are known to be negative and a highly positive protein. Even then, artifactual results can occur. A more correct control experiment is to add varying amounts of your positive control in the presence of the same large amount of your negative control. The staining of the slots should then be in a linear relationship to the amount of positive sample added.

3.3. Precipitation and Blotting with Lectins

Precipitation with lectins is performed with microbatch lectin-affinity chromatography ***(14)***. This is used to take all the proteins with a given state of glycosylation out of a complex mixture prior to silver staining or blotting or ELISA quantitation. This could be used to study the glycosylated states of cellular antigens. Alternatively, it can be used to examine body fluids. I have used this procedure to study the fucosylation of serum glycoproteins in cancer progression ***(15–17)***, active and inactive arthritis ***(18)***, and inflammatory bowel disease ***(19)*** and have found similar changes in haptoglobin in the sera of "healthy" blood donors who smoke, compared with those found in cancer patients ***(20)***. This may be useful as a serum marker of risk of liver disease and/or cancer for the "healthy" population that smokes/drinks.

Figure 2 shows the serum glycoproteins precipitated from patients with five diseases by three lectins and demonstrates some of the major changes that can occur. When the fucose-specific *Lotus* lectin is used, cancer sera are characterized by strong bands around 43 kDa (lanes 2 and 3) and occasionally at

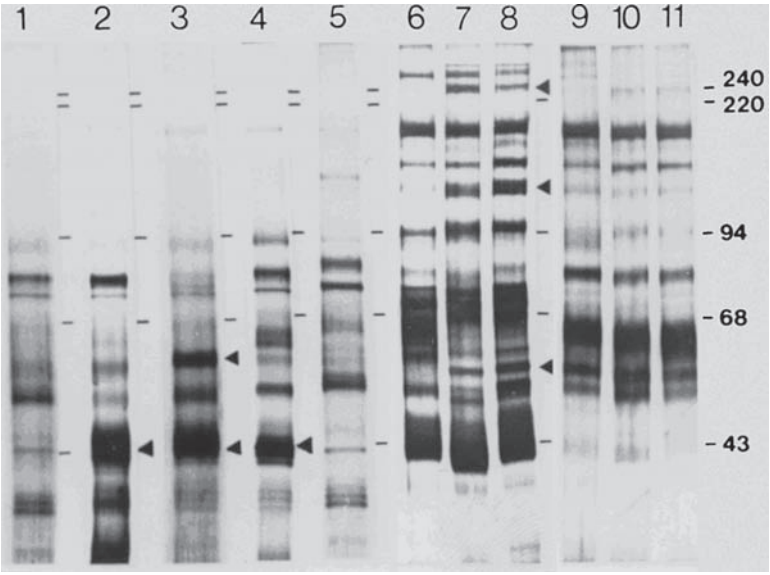

Fig. 2. Silver stained SDS-PAGE patterns of sera extracted with *Lotus* (lanes 1–5), WGA (lanes 6–8), or lentil (lanes 9–11) lectins. Lanes1, 6, and 9, healthy individuals; lane 2, advanced hepatoma, lane 3, recurrent cancer; lane 4, active rheumatoid arthritis; lane 5, bronchopneumonia; lanes 7 and 10, renal failure, lanes 8 and 11, liver cirrhosis.

57 kDa. These are haptoglobin and α_1-antitrypsin, the former being related to tumor burden ***(16)***and the latter to tumor progression ***(17)***. Active rheumatoid sera (lane 4) also contain abnormal haptoglobin, but this is of a lower molecular weight than that obtained in cancer sera ***(15)*** and is associated with high serum haptoglobin levels (4–6 g/L). Surprisingly, fucosylated haptoglobin is not detected in untreated broncopneumonia patients even when the total haptoglobin level is highly elevated (7–8 g/L). Changes could also be seen in these specimens when the N-acetylglucosamine-specific lectin wheat germ agglutinin (WGA) was used, but they were not as marked as those found with *Lotus* lectin. WGA extracts of renal failure (lane 7) and cirrhosis patients (lane 8) did give characteristically altered patterns that were highly reproducible. Here, however, very little change was found using lentil (lanes 9–11) or *Lotus* lectins. The altered proteins were identified by blotting as described above.

Figure 3 shows an α_1-antitrypsin blot of *Lotus* extracts from serial serum samples of a cancer patient that were collected at roughly 3-mo intervals. The fucosylated α_1-antitrypsin levels increased as her disease progressed. A weakly stained second band can also be seen just under the antitrypsin band, owing to the heavy chain human serum immunoglobulins crossreacting weakly with the

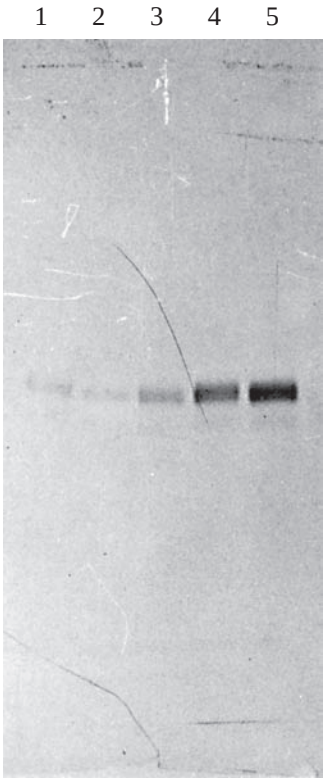

Fig. 3. An a1-antitrypsin western blot of fucosylated serum proteins extracted from a terminally ill cancer patient. Lanes 1–5 represented samples taken 0, 3, 6, 9, and 12 months after the commencement of treatment respectively.

AP-labeled sheep antirabbit second layer. A polyclonal rabbit antiserum (5 µL) was used at 1:1000 dilution followed by 5 µL of a second-layer AP-labeled sheep-anti-rabbit antiserum (1:2000).

Blotting with lectins requires the lectin to be coupled to another molecule such as digoxigenin. Your purified protein (or mixture of proteins) is slot or Western blotted, the blot is blocked (with nonionic detergent), and the lectin is added in the same manner as a first-layer antibody (*see* **Note 17**). After incubation with gentle shaking for up to 2 h, the blot is washed and an AP- or horseradish peroxidase-labeled antidigoxigenin antibody is added. Chemiluminescence can increase the sensitivity of this procedure and allow blots to be reprobed with different lectins ***(21)***. An alternative and now more commonly used procedure is to utilize biotinylated lectins. They are relatively easy to prepare, and many commercial antibiotin or AP-avidin second layers are available. They are often used to compare the glycosylation of recombinant proteins with their natural products and have also been used to study the expression of cell surface proteins in parasites ***(22)***.

4. Notes

1. $^{32}PO_4$ can also be used as a metabolic label for the specific labeling of phosphoproteins and measurement of kinase activity. However, here it is often more correct to label the cell lysates or even the specific kinase immunoprecipitates with [γ-^{32}P] ATP. This not only reduces the problems encountered because $^{32}PO_4$ also labels DNA and RNA but also minimizes the amount of ^{32}P required for protein labeling.
2. Do not label confluent cell cultures, as they will have a slower turnover rate than nonconfluent cultures. The cells may also run out of the labeling amino acid.
3. Low levels of dialyzed FCS (1–5%) are normally retained to maintain essential growth factors. Nonadherent cells are normally labeled at around 10^7 cells/mL.
4. Do not use trypsin to remove attached cells as you will alter cell surface protein expression. If labeled cells do not detach with EDTA, they should be washed *in situ* and then removed by rubbing them off the surface of the plate in the presence of lysis buffer.
5. It is essential to add nonradioactive KI; if this is not done, the radioactive ^{125}I sticks ionically to the surface of the cells and subsequently washes off in the washing steps. The addition of 0.5 µ*M* "cold" KI, *before* the ^{125}I, saturates the cell surface, and all the ^{125}I is then available for labeling. Higher levels of "cold" KI reduce the efficiency of labeling.
6. If ^{32}PO4 is used as a metabolic label, it is essential to include large amounts of DNAase and RNAse and possibly micrococcal nucleases to digest small labeled pieces of DNA and RNA sticking to the proteins. Otherwise numerous artifactually phosphorylated proteins will be present in your mixture.
7. In both direct and indirect precipitation, the most critical factor is how the beads are washed after antibody–antigen complexes have been formed. If the beads are spun at any speed, the complexes split off the surface of the beads and are washed away. Furthermore, proteins stick nonspecifically to the newly revealed surface. I demonstrated this in 1982. Two identical immunoprecipitates were washed, one by gravity and one using a microfuge. A very clean precipitate with one band of the correct molecular weight was obtained with the beads that were allowed to settle out under gravity. However, numerous background bands with only a faintly visible correct band were obtained with the centrifuged immunoprecipitate.
8. Enough antibody has to be added to precipitate all the antigen present. Five microliters of polyclonal antisera, 5 µL of monoclonal ascites, or 50 µL of hybridoma tissue culture supernatant should easily be sufficient. The same amount of nonimmune sera or ascites should also be incubated with a second aliquot as a negative control.

9. In indirect precipitation, occasionally your antibody will not react very well with the protein A-Sepharose beads, and hence the antigen–antibody complex will not be precipitated properly. This is especially true with some subclasses of mice antibodies. It is possible to use alternative antibody binders with different binding specificities such as protein G-Sepharose. A simpler solution is to add 2 or 3 µL of a polyclonal sheep (or rabbit) anti-mouse antibody for a further 30 min after the initial antigen–antibody binding step ***(6,7)***. Sheep (and rabbit) antibodies bind very well to protein A and carry the mouse antibody-antigen complex onto the protein A. Rat monclonals may also be helped to immunoprecipitate with a sheep anti-rat second antibody.
10. If further chemical analysis of a purified immunoprecipitated antigen is required, the antigen can be released from the beads by the addition of a high (>9) or low (<4) pH buffer followed by centrifugation and immediate neutralization. Here direct immunoprecipitation is required or the purified antigen will be contaminated with the antibody ***(9)***. Trifluoroacetic acid (TFA; 0.1 *M*) instantly solubilizes purified antigens from antibody-coated beads without removing any antibody ***(9)*** from the beads.
11. The microcentrifugation step after addition of the SDS sample buffer can be omitted. The presence of a few microliters of Sepharose beads in a sample well does not have any deleterious effect on the migration of the immunoprecipitated proteins in discontinuous SDS-PAGE.
12. In both indirect autoradiography and fluorography, preexposed X-ray film is required to permit a linear detection of photons. It is very easy to do this. A flash gun is taken, and a red filter is taped over the flash. A strip of X-ray film is flashed from between 18 and 24 in. away (from above). This ensures a fairly even spread of the flash over the film. Normally the light is still far too strong. This can be further reduced by taping a piece of Whatman No. 1 filter paper over the filter followed by several layers of colored plastic tape. After each layer of tape is added, a strip of film is exposed and the film is developed until a background film OD of 0.15 is reached ***(12)***. X-ray film is two-sided; the side closest to the flash is placed against the scintillation screen or the impregnated gel.
13. There are two obvious major problems with Western blotting. The first is that a relatively high level of antigen is required in the sample, as most polyacrylamide gels have a maximum sample well size of 50 µL. Protein mixtures (serum samples, culture supernatants, and so on) are often preconcentrated by immunoprecipitation ***(9)*** or with lectins bound to Sepharose prior to blotting ***(14, 15)*** to circumvent this problem.
14. I always block remaining sites on the membrane with 0.5% Tween-20 after transfer. This can have the fortuitous effect of renaturing the antigen by displacing the SDS as well as blocking remaining active sites of the mem-

brane. I have also found that the alternative blocking reagents of 0.5% BSA or milk powder can cause very high backgrounds, especially when used in conjunction with nylon membranes, owing to nonspecific crossreactions with either or both the antibody preparations.

15. A primary antibody may sometimes crossreact with other proteins. More commonly it will not react at all due to the denatured nature of the antigen.
16. If an antibody has a high specificity but low avidity (as is the case with many antibodies to glycosylated antigens), the antibody/antibody–second antibody complexes will often fall off the blot during the washing steps, and no color will appear. This effect can be minimized or cured by two simple practical precautions:
    a. Use only an Fc-specific enzyme-labeled secondary antibody. This will then not interfere with the primary antigen–antibody reaction in the Fab region.
    b. The secondary anti-Fc antibody can be preincubated with the primary antibody for 1 h, and this primary-secondary complex can then be added in one step. Try to use anti-Fc-specific second-layer antibodies; this is especially important when blotting with first-layer monoclonals. Remember to preincubate the primary and secondary antibodies if the primary is suspected of having a low affinity. Not a lot else can be done about nonspecific crossreactions of either the primary or secondary antibodies. Samples should always be blotted in duplicate with one blot containing an irrelevant primary antibody raised in the same species as the correct primary. Specific staining is then guaranteed, especially if the staining is at the correct molecular weight.
17. Most if not all lectins require the presence of Ca^{2+} and Mg^{2+} ions. Most buffers for lectin immunoprecipitation ***(16)*** contain 5 m*M* Ca and Mg ions in isotonic Tris-HCl buffers (50 m*M*, pH 7.4). Blotting solutions are similar to those used with antibodies but always contain 1 m*M* Ca^{2+} and Mg^{2+}.

Determination of Epitopes by Mass Spectrometry

Christine Hager-Braun and Kenneth B. Tomer

1. Introduction

According to the World Health Organization's AIDS Epidemic Update Report for December 2006 ***(1)***, somewhere between 34 to 47 million people worldwide are infected with the human immunodeficiency virus (HIV) and from 2.5 to 3.5 million people died from the disease in 2006. An epidemic like this makes it necessary to investigate the infection and its subsequent steps at the biochemical level in order to understand the process and to find means to prevent or interfere with an infection. As a response to an infection, the immune system develops antibodies that recognize regions, antigenic structures or epitopes, on proteins of the infectious agent. Determination of the epitopes provides invaluable knowledge for understanding the pathogenesis and developing of vaccines against HIV.

Mapping the epitope on the gp41 glycoprotein of the human immunodeficiency virus recognized by the human neutralizing monoclonal antibody 2F5 ***(2)*** illustrates an approach that is also applicable to other antigen/antibody complexes in characterizing immune responses or autoimmune diseases. Briefly, the antigen-recognizing primary antibody is covalently coupled to an immobilized Fc-specific secondary antibody. Subsequently, the antigen is bound to the primary antibody and proteolytically digested. The individual steps are monitored by matrix-assisted laser ionization mass spectrometry (MALDI/MS). The peptide that remains affinity-bound throughout the digestion steps reflects the epitope ***(2,3)***. A schematic outline of this approach is depicted in **Fig. 1**.

Although a variety of alternative techniques, such as peptide reactivity assays, mutation analyses, antigen proteolysis, crystallography, or nuclear magnetic resonance (NMR) spectroscopy, are available to determine epitopes ***(4–12)***, limitations to these approaches reduce the rate of success. Crystallography requires high concentrations of antigen and antibody and the formation of diffracting

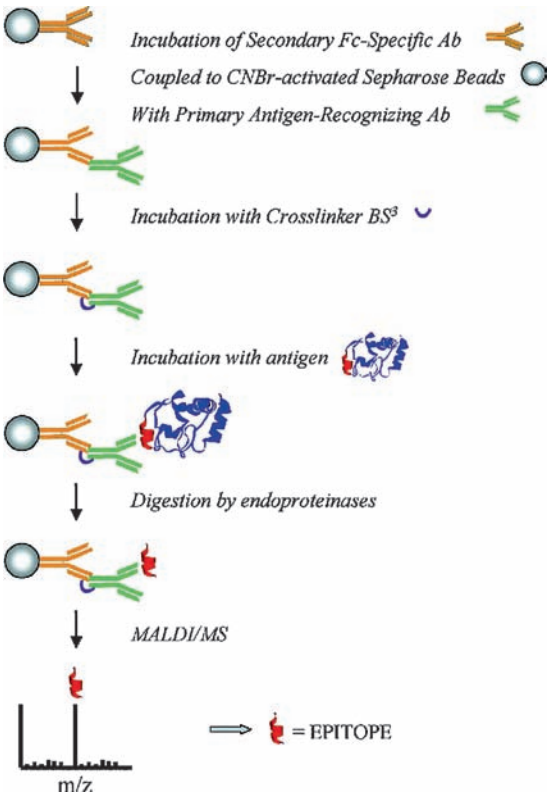

Fig. 1. Schematic outline of the epitope excision method followed by mass spectrometry. Ab, antibody; BS^3, *bis*(sulfosuccinimidly) suberate; CNBr, cyanogen bromide; MALDI/MS, matrix-assisted laser desorption/ionization mass spectrometry.

crystals. For NMR spectroscopy, the complex of antibody and antigen often exceeds the mass that can be analyzed. Peptide reactivity assays, either based on enzyme-linked immunosorbent assay (ELISA) or surface plasmon resonance imaging, are only applicable to linear epitopes but not to discontinuous epitopes or to antigens containing post-translational modifications. Mutation analyses focus only on specific amino acids by point mutations and are, therefore, tedious. Moreover, an altered binding affinity of the antigen to the antibody can be a false positive, when a distant mutation results in a conformational change of the antigenic structure. Other mass spectrometry-based approaches include epitope extraction ***(13–18)***, hydrogen/deuterium exchange ***(19,20)*** and differential surface modification ***(21–23)***. Epitope extraction is primarily useful for linear epitopes, but not for conformational or discontinuous epitopes. Differential surface modification and hydrogen/deuterium exchange are useful for discontinuous epitope characterization.

The method of enzymatic proteolysis of the antibody-bound antigen followed by MALDI/MS analysis as described here allows mapping of linear epitopes with three-dimensional conformation or post-translational modification with low sample consumption ***(2,24–34)***.

2. Materials

1. Cyanogen bromide (CNBr)-activated Sepharose 4B beads (Pharmacia Biotech, Piscataway, NJ).
2. Compact Reaction Columns (CRCs) with 35-µm column filters (USB, Cleveland, OH).
3. 1 m*M* HCl.
4. 0.1 *M* $NaHCO_3$, pH 8.2.
5. Coupling buffer: 0.1 *M* $NaHCO_3$, 150 m*M* NaCl, pH 8.2.
6. Anti-human Fc-specific IgG antibody (Sigma, St. Louis, MO) as secondary antibody.
7. Quenching buffer: 0.1 *M* Tris-HCl, pH 8.0.
8. 0.1 *M* sodium acetate, 0.5 *M* NaCl, pH 4.0.
9. Monoclonal antibody 2F5, IgG1 isotype, κ-chain (AIDS Research and Reference Reagent Program, Division of AIDS, National Institute of Allergy and Infectious Diseases, National Institutes of Health) as the primary antibody.
10. Phosphate-buffered saline (PBS), PBS, pH 7.2: 100 m*M* Na-phosphate buffer, 150 m*M* NaCl, pH 7.2.
11. 10 m*M* *bis*(sulfosuccinimidyl)suberate (BS^3; Pierce, Rockford, IL) in PBS, pH 7.2.
12. SOSgp140 (JR-FL) glycoprotein, expressed as a gp120 glycoprotein covalently linked to the ectodomain of gp41 (gift from N. Schülke, Progenics Pharmaceuticals, Tarrytown, NY; ***16***).
13. Endoproteinase Lys-C (Wako, Dallas, TX).
14. 50 m*M* Tris-HCl, pH 8.0.
15. Carboxypeptidase Y (Roche Diagnostics, Indianapolis, IN).
16. PBS, pH 6.1: 100 m*M* Na-phosphate buffer, 150 m*M* NaCl, pH 6.1.
17. Aminopeptidase M (Roche Diagnostics).
18. Saturated solution of recrystallized α-cyano-4-hydroxycinnamic acid in ethanol/water/concentrated formic acid 45/45/10 (v/v/v).

3. Methods

3.1. Preparation of Immobilized Antibody Columns

1. Fill approx 0.2 g of dry CNBr-activated Sepharose 4B beads into a Falcon tube.
2. Mix the beads gently with 10 mL 1 m*M* HCl (*see* **Note 1**). Let the slurry equilibrate at room temperature for about 15 min, and then decant most of the supernatant.
3. Transfer 20 µL of beads slurry into each of two compact reaction columns (CRC).
4. Wash both CNBr-activated Sepharose columns with 6X 0.8 mL 1 m*M* HCl and 6X 0.4 mL 0.1 *M* $NaHCO_3$, pH 8.2.

5. To the drained beads in each CRC add 80 µL of 0.1 *M* $NaHCO_3$/150 m*M* NaCl, pH 8.2, and 20 µL of anti-human Fc-specific secondary antibody (48 µg) (*see* **Note 2**). Incubate at room temperature with slow rotation for 1.5 h (*see* **Note 3**).
6. Drain the beads and block any unreacted sites with 0.1 *M* Tris-HCl, pH 8.0, by rinsing the beads once with 0.4 mL and then incubating them in 0.4 mL for 1 h at room temperature with slow rotation.
7. Remove any antibody not covalently linked to the beads by a sequence of washing steps thereby alternating between 0.1 *M* sodium acetate/0.5 *M* NaCl, pH 4.0, and 0.1 *M* Tris-HCl, pH 8.0 with a volume of 0.4 mL each for three times. Finally, wash three times with 0.4 mL PBS.
8. Obtain a MALDI spectrum of the beads. Essentially, no ions should be detected at this point as the secondary antibody is covalently linked to the Sepharose beads (**Fig. 2A**).
9. Add 50 µL equivalent to 50 µg of the primary antibody 2F5 to one of the anti-human Fc-specific secondary antibodies containing CRC (= vial "Fc-specific Ab + 2F5"). To the other CRC, which will serve as the control (= vial "Fc-specific Ab"), add 50 µL PBS. Incubate both CRCs for 1 h at room temperature with slow rotation (*see* **Note 3**).
10. Drain the beads and save the drain in case the yield of captured primary antibody is low and a longer incubation time would be necessary.
11. Wash the beads three times with 0.4 mL PBS.
12. Check a 0.5 µL-aliquot of the beads by MALDI/MS to determine whether or not the primary antibody was successfully affinity-bound to the secondary antibody (**Fig. 2B**; *see* **Note 4**).
13. To stabilize the complex between the anti-human Fc-specific secondary antibody and the 2F5 primary antibody, the proteins are crosslinked. For this, add 10 µL of freshly prepared 10 m*M* BS^3 in PBS to vial "Fc-specific Ab + 2F5" and treat the control vial "Fc-specific Ab" the same way. Incubate both CRCs for 45 min at room temperature in the dark with slow rotation (*see* **Note 5**).
14. To quench the crosslinking reaction, drain the beads and wash twice with 100 µL 0.1 *M* Tris-HCl, pH 8.0.
15. Wash the beads three times with 0.4 mL PBS and obtain a spectrum of a 0.5 µL-aliquot of the beads by MALDI/MS. As the secondary and the primary antibody in the vial "Fc-specific Ab + 2F5" are now covalently linked, no ions from the antibodies should be observed in the spectrum (**Fig. 2C**).
16. From vial "Fc-specific Ab + 2F5," now crosslinked, transfer about one-fourth of the beads into a new CRC and add 50 µL of PBS. This vial will serve as the control for the proteolysis experiments.
17. Incubate the remaining beads of the vial "Fc-specific Ab + 2F5" with the antigen SOSgp140 using 50 µg of antigen solution (200 µL). Rotate slowly at room temperature for at least 2 h with up to overnight incubation if needed. In parallel, incubate the control beads without antigen.
18. Drain the beads and rinse three times with 0.4 mL PBS.
19. Obtain a MALDI/MS spectrum of a 0.5 µL-aliquot of the antigen-containing beads and of the control beads (**Fig. 2D**).

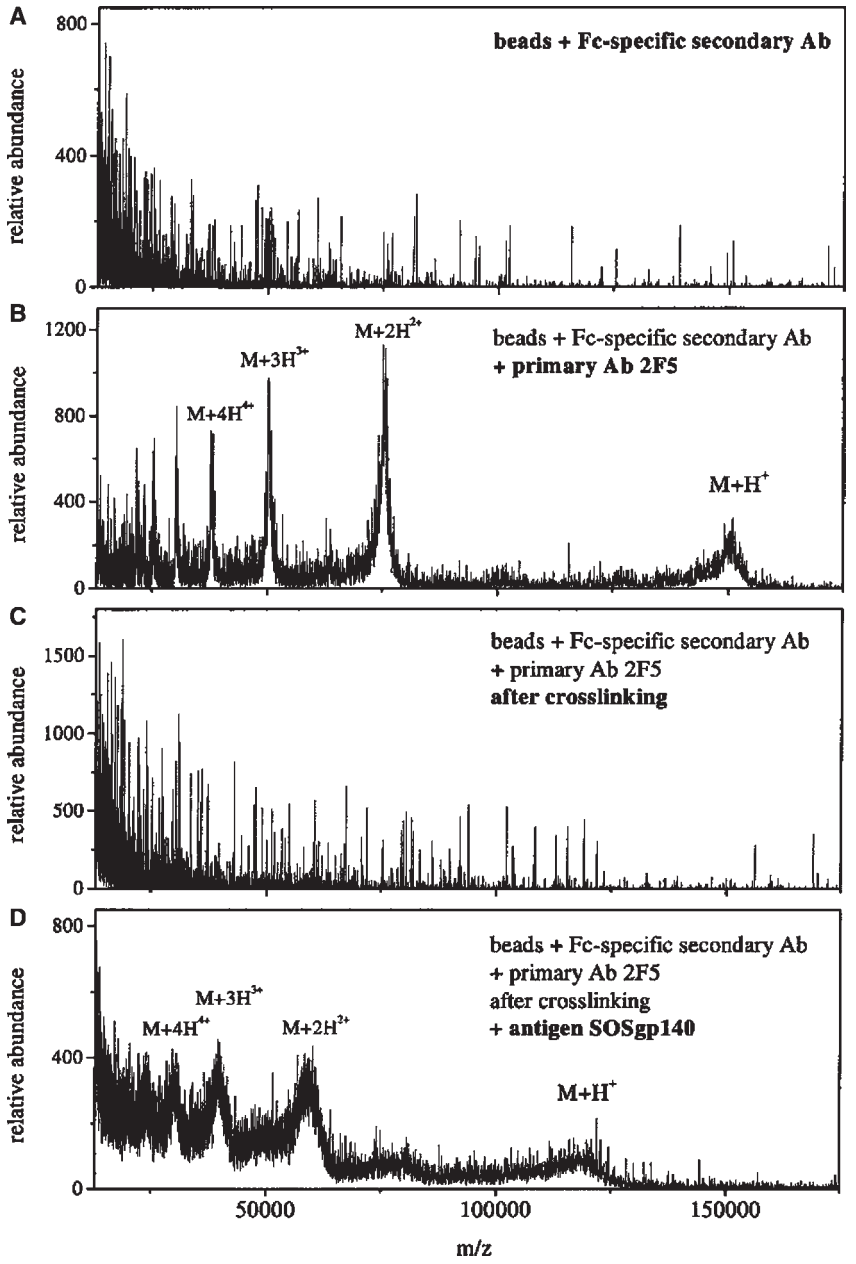

Fig. 2. MALDI/MS spectra of the Fc-specific secondary antibody (Ab) coupled to the CNBractivated Sepharose beads **(A)** followed by the addition of the primary antibody 2F5 before **(B)** and after **(C)** crosslinking with BS^3. **(D)** MALDI/MS spectrum of the affinity-bound antigen SOSgp140. The spectra were recorded in linear mode. (Adapted with permission from ***ref. 2***. Copyright 2001 American Society for Microbiology.)

3.2. Proteolysis of the Affinity-Bound Antigen SOSgp140

3.2.1. Endoproteinase LysC

1. Prepare a fresh solution of endoproteinase LysC (0.1 µg/µL) in 50 m*M* Tris-HCl, pH 8.0, and store it at 0°C (*see* **Note 6**).
2. Resuspend the beads containing the antigen as well as the control beads in 50 µL 50 m*M* Tris-HCl, pH 8.0 (*see* **Note 7**).
3. Add 50 µL of LysC solution (5 µg) to both CRCs.
4. Incubate both CRCs for 2.5 h at 37°C with slow rotation.
5. Wash the beads three times with 0.4 mL PBS.
6. Analyze a 0.5 µL-aliquot of both the antigen-containing beads and the control beads by MALDI/MS.

3.2.2. Carboxypeptidase Y

1. Prepare a stock solution of carboxypeptidase Y with a concentration of 0.5 µg/µL in deionized water just prior to use and store it on ice.
2. Resuspend the beads containing the antigen as well as the control beads in 50 µL PBS, pH 6.1.
3. Add 50 µL of carboxypeptidase Y solution to both CRCs.
4. Incubate both vials at 37°C with slow rotation.
5. After a 1-min incubation, drain the beads, wash them three times with PBS, pH 6.1, resuspend them in 50 µL PBS, pH 6.1, and remove a 0.5-µL aliquot of the beads for immediate MALDI/MS analysis.
6. Add fresh buffer (50 µL PBS, pH 6.1) and carboxypeptidase Y (50 µL) to the beads, continue incubation, and remove aliquots of washed beads at various time points like 1-min intervals (here: 2, 3, 4, 5, and 6 min) for MALDI/MS analyses. Although during the first 5 min a progress in digestion could be monitored (**Fig. 3**), at 6 min of incubation with carboxypeptidase Y, further digestion products were not detected (spectrum not shown). **Table 1** lists the ions observed in the MALDI/MS spectrum after 5 min of carboxypeptidase Y incubation and the corresponding amino acid sequences.

3.2.3. Aminopeptidase M

1. Wash beads containing the epitope and the control beads three times with 0.4 mL PBS, pH 7.2.
2. Resuspend the beads of both CRCs in 49 µL PBS, pH 7.2.
3. Add 1 µL of 5 µg/µL aminopeptidase M stock solution (as supplied by the manufacturer in ammonium sulfate solution) to both vials.
4. Incubate at 37°C with slow rotation.
5. At various time points like 1-h intervals (here: 1, 4, and 7 h), wash the beads with PBS and remove an aliquot for MALDI/MS analysis (**Fig. 4**). After the analysis, add new buffer and aminopeptidase to the beads and continue incubation. **Table 2** gives an overview of the ions found by MALDI/MS after 7 h of digestion and the assignments to the amino acid sequences.

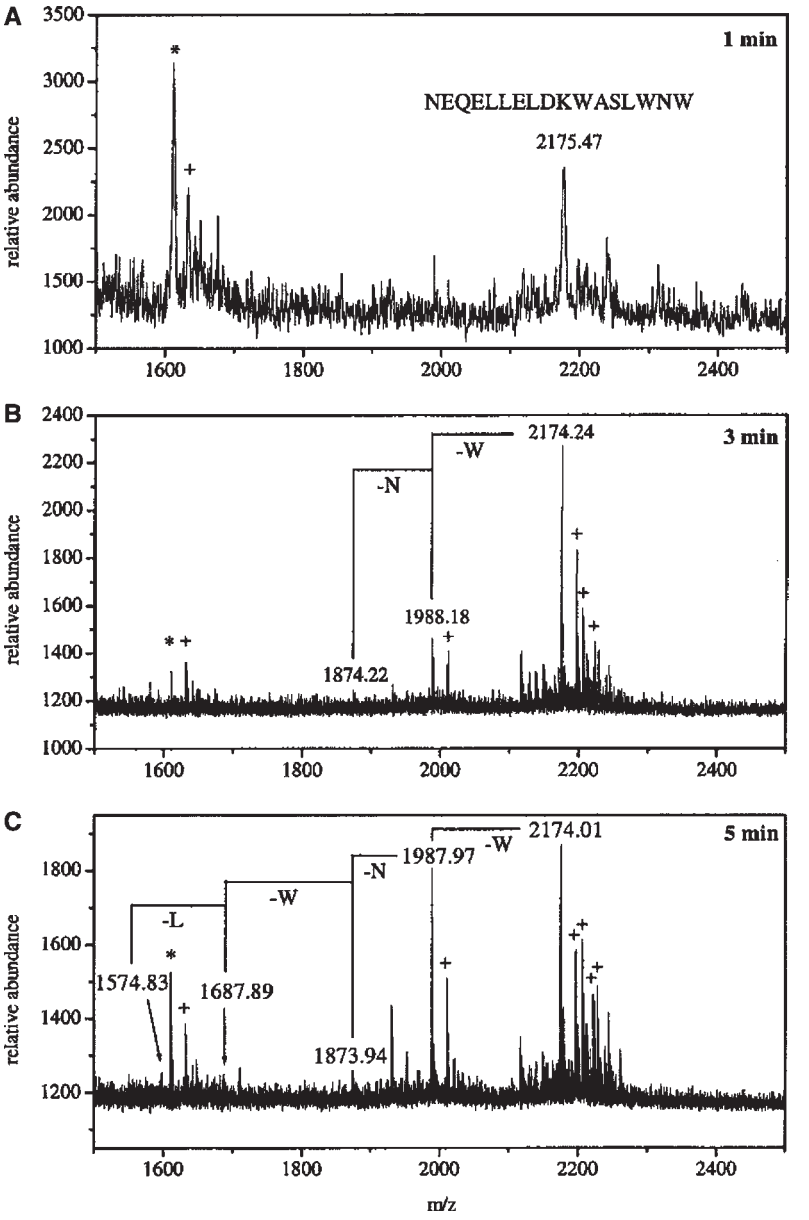

Fig. 3. MALDI/MS spectra obtained from the rinsed beads after digestion of affinity-bound SOSgp140 with endoproteinase LysC for 2.5 h followed by digestion with carboxypeptidase Y for 1 min **(A)**, 3 min **(B)**, and 5 min **(C)** to determine the fine structure of the epitope on the C-terminal end. Spectrum A was recorded in linear mode and spectra B and C in reflector mode of the MALDI instrument. The ion labeled with an asterisk represents a background ion, and ions labeled with a + represent Na^+-adducts and/or oxidized ions. (Adapted with permission from ***ref. 2***. Copyright 2001 American Society for Microbiology.)

Table 1
Products Found after Digestion of the Affinity-Bound SOSgp140 with LysC for 2.5 h Followed by Carboxypeptidase Y for 5 Min as Detected by MALDI/MS[a]

Amino acid sequence	Calculated M+H$^+$	Measured M+H$^+$
NEQELLELDKWASLWNW	2174.06	2174.01
NEQELLELDKWASLWN	1987.98	1987.97
NEQELLELDKWASLW	1873.94	1873.94
NEQELLELDKWASL	1687.86	1687.89

[a]*See* **Fig. 3C**.

Table 2
Products Found after Digestion of the Affinity-Bound SOSgp140 with LysC for 2.5 h Followed by Carboxypeptidase Y for 6 Min and Aminopeptidase M for 7 h as Detected by MALDI/MS[a]

Amino acid sequence	Calculated M+H$^+$	Measured M+H$^+$
NEQELLELDKWASLW*	1873.94	1874.17
NEQELLELDKWASLWN*	1987.98	1988.23
NEQELLELDKWASLWNW	2174.06	2174.30
EQELLELDKWASLWN	1873.94	1874.17
EQELLELDKWASLW	1759.89	1760.16

[a]*See* **Fig. 4B**. The amino acid sequences marked with an asterisk were already detected after the carboxypeptidase Y digest.

3.3. Mass Spectrometric Analysis

A 0.5-μL aliquot of the bead slurry or the drained liquid was spotted on a stainless-steel target and mixed with an equal volume of the saturated α-cyano-4-hydroxycinnamic acid solution. The target was left at room temperature to dry in air. MALDI mass spectra were recorded on a Voyager DE-STR (Applied Biosystems, Framingham, MA). Similar results should be obtained with similar equipment. External calibration of the mass range of interest was used.

3.4. Data Interpretation

1. Knowing the amino acid sequence of the antigen under investigation allows the researcher to determine which endoproteinase is best for digestion. A computer-based *in silico* digest gives a list of expected peptides with a molecular weight assigned. Choose the most suitable proteinase based on these *in silico* digest masses to allow MALDI/MS measurements with high mass accuracy on your specific instrument.
2. The amino acid sequence that contains the epitope should be protected by the antibody. Cleavage sites within the antigenic structure should not be accessible

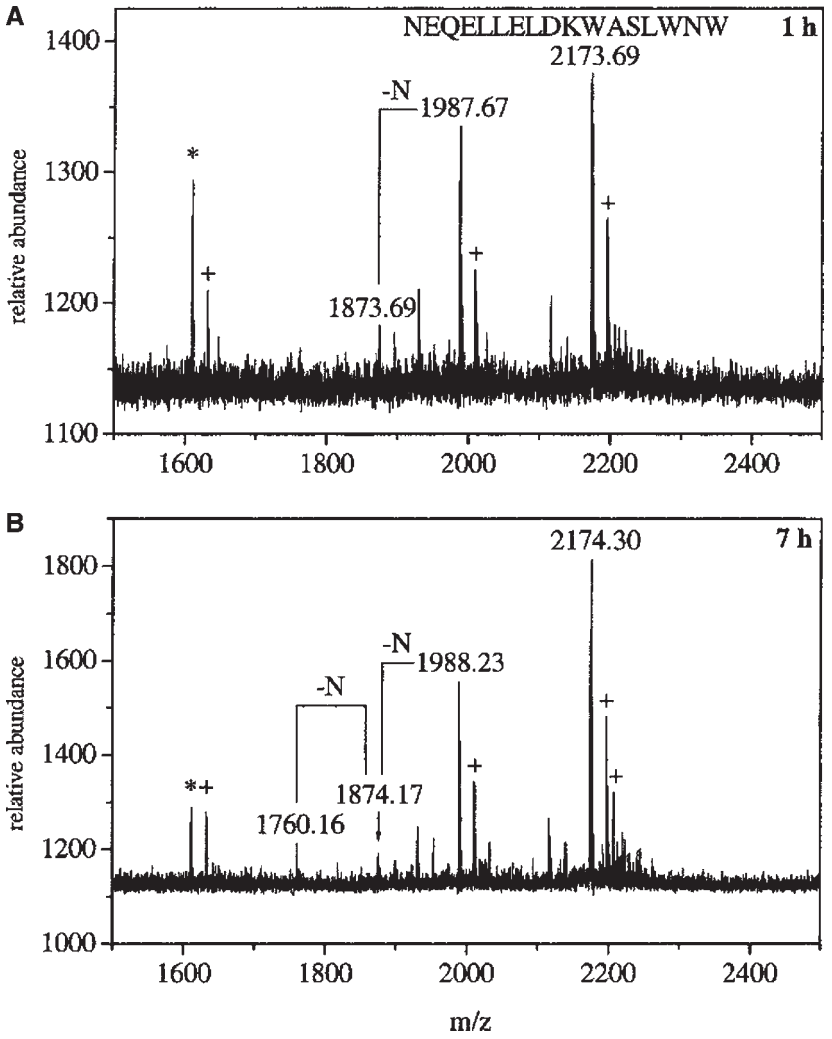

Fig. 4. MALDI/MS spectra obtained from the rinsed beads after digestion of affinity-bound SOSgp140 with endoproteinase LysC for 2.5 h followed by digestion with carboxypeptidase Y for 6 min and subsequent digestion with aminopeptidase M for 1 h **(A)** and 7 h **(B)** to determine the fine structure of the epitope on the N-terminal end. The spectra were recorded in reflector mode. The ion labeled with an asterisk represents a background ion, and ions labeled with a + represent Na^+-adducts and/or oxidized ions. (Adapted with permission from ***ref. 2***. Copyright 2001 American Society for Microbiology.)

to the endoproteinases, and, therefore, only adjacent cleavage sites will be used. To determine the fine structure of the epitope, digestion with carboxypeptidase Y will give information about the C-terminal end of the epitope, whereas digestion with aminopeptidase M will characterize the N-terminal side. The exoproteinases should only cleave "overhanging" ends of the affinity-bound peptide.

3. The ion detected in the MALDI spectrum after 2.5 h of LysC digestion and 1 min of carboxypeptidase Y digestion could be assigned to the amino acid sequence NEQELLELDKWASLWNW (**Fig. 3A**). Further incubation with carboxypeptidase showed the loss of W, N, W, and L from the C-terminus (**Fig. 3B** and **C**). The low abundances of the ions after the loss of N, W, and L, respectively, compared with the high abundance of the ion at *m/z* 1987.97 after the initial loss of W indicates that amino acids N, W, and L are partially protected by the antibody against proteolysis.
4. Using a heterogeneous sample after the carboxypeptidase Y digest for subsequent characterization of the N-terminus of the epitope results in a relatively complicated interpretation of the MALDI spectra. The ion at 1874.17 in **Fig. 4B** could be the result of the carboxypeptidase Y digest (NEQELLELDKWASLW) or could reflect the loss of the N-terminal asparagine residue from the ion at 1988.23 (NEQELLELDKWASLWN → EQELLELDKWASLWN) by the activity of the aminopeptidase M. The ion at 1760.16 indicates the removal of asparagine from the N-terminus of the peptide NEQELL ELDKWASLW with *m/z* = 1874.17 originating from the carboxypeptidase Y digest.
5. Based on the LysC digest, the carboxypeptidase Y digest, and the aminopeptidase M digest, the epitope recognized by the monoclonal antibody 2F5 is NEQELL ELDKWASLWN and is located near the C-terminus of gp41.

4. Notes

1. Handle the beads gently. Avoid any shaking, vortexing, or fast centrifugation, which might cause the beads to crush. All centrifugation steps to drain the beads are carried out in an Eppendorf (Westburg, NY) microcentrifuge at low force only (2–3 min at approx 80 *g*). For MALDI/MS analysis, only 10–20 beads are necessary to give sufficient results, although more may be used if required. Check under a microscope if enough beads were spotted for analysis.
2. The CNBr-activated Sepharose beads will react with primary amines such as the C-terminus of the heavy and light chains of the antibody as well as the ε-amines in lysine residues. Reactions are also possible with amines from buffers such as Tris, so in some cases it may be necessary to exchange the buffer of the antibody solution, for example, by gel filtration.
3. In some cases incubation times may need to be doubled.
4. In the MALDI spectrum, IgG molecules will give a singly charged ion at about 150 kDa. However, doubly and triply charged ions will be more abundant. Do not use dithiothreitol to reduce disulfide bridges as this will

cause the antibody to dissociate into its heavy and light chains. In case no ions can be detected in the MALDI spectrum of the beads, check the drain for presence of the antibody. If most of the antibody is detected in the drain, add the drain to the beads and continue to incubate at room temperature with slow rotation.

5. BS^3 [*bis*(sulfosuccinimidyl)suberate] is a homobifunctional *N*-hydroxysuccinimide ester that reacts with the α-amine at the N-terminus of a protein and the ε-amine of lysine residues. This crosslinker is water-soluble, and the storage of a stock solution is not recommended.
6. If using a different endoproteinase, a normally suggested protein/substrate ratio of 1:20 or higher is recommended. This ratio is higher than for in-solution digests but takes into consideration the possibility that the cleavage sites of the affinity-bound antigen in its native conformation are less accessible than in solution under denaturing conditions. Nevertheless, test the activity of the endoproteinase with the antigen in solution (or a readily available protein with similar molecular weight) to determine the rate of digestion.
7. In general you should wash the beads with the buffer that is recommended for the proteinase that you use. However, compatible components should be substituted for buffers and additives that are incompatible with subsequent MALDI/MS analysis. Avoid high concentrations of salt, as this can result in poor MALDI/MS signals, avoid glycerol, which will interfere with the formation of crystals for MALDI/MS analysis, and avoid the use of detergents because their presence will result in MALDI/MS ions with high abundance over a wide mass range, possibly suppressing the ions of the peptides of interest.

Immunogen Preparation and Immunization Procedures for Rats and Mice

Mark Page and Robin Thorpe

1. Introduction

A high-titer antibody response usually requires use of an adjuvant for the first (priming) immunization. For most purposes, the immunogen is prepared by emulsification in a mineral oil containing heat-killed mycobacterium (Freund's complete adjuvant—FCA). The emulsion ensures that the antigen is released slowly into the animal's circulation, and the bacteria stimulate the animal's T-helper cell arm of the immune system. Further booster (secondary) immunizations are almost always necessary for production of high antibody levels, and these are given either in phosphate-buffered saline (PBS) or as an oil emulsion (bacteria are not normally included in the boosting injections; a suitable oil adjuvant is Freund's incomplete adjuvant—FIA). A large number of alternative adjuvants are available, but FCA/FIA (for priming and boosting respectively) usually produces maximal immune responses. However, FCA in particular can produce adverse effects in some cases and is not normally recommended for use in humans or primates Alum adjuvants are often chosen as an alternative and can be used in humans. Immunization with substances with molecular weights <3000 (such as peptides) are not normally immunogenic and will require conjugation to a carrier protein (*see* **ref. *1*** and Chapters 172–173), such as purified protein derivative (PPD) or keyhole limpet hemocyanin (KLH).

2. Materials

1. Freund's complete adjuvant (FCA).
2. Freund's incomplete adjuvant (FIA).
3. Phosphate-buffered saline (PBS).
4. Immunogen preparation.
5. 2-mL glass Luer lock syringes (two).

Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

6. Syringe coupler, Luer lock with female inlet and outlet ports (Sigma, St. Louis, MO).
7. Rat/mouse.

3. Methods

3.1. Immunogen Preparation (*see* Notes 1–5)

1. Dilute immunogen in physiological buffer (e.g., PBS without sodium azide) so that the preparation will contain 10–100 µg of protein in approx 300–600 µL/animal (Note: the final quantity will be 5–50 µg, since the preparation will be diluted with an equal volume of adjuvant). Mix the immunogen solution with an equal volume of FCA and draw up into a glass syringe or prepare directly in the syringe barrel.
2. Remove excess air from the syringe barrel, and connect to a second glass syringe with its plunger fully depressed via a double-hub connector.
3. Ensure the connections are tight and not leaking, and transfer the oil and immunogen solutions from one syringe to the other. Continue this action until the mixture is fully emulsified when it should appear as a creamy, white thick liquid.
4. Transfer emulsion into one of the glass syringes, remove from double-hub connector and empty syringe, and fit a small-diameter needle (the size of which will depend on the animal to be immunized and route of immunization).

3.2. Immunization Procedure

1. Prime mice or rats by immunizing with immunogen subcutaneously on the flanks and neck (0.1 mL/site, 3–5 sites). Do his by raising the skin between thumb and forefinger, and inserting the needle into the raised area at a shallow angle. A short narrow-diameter needle is preferred (0.4 × 27 mm) to avoid injection into the deeper body layers/cavities. The result should be a discrete lump under the skin.
2. Boost intraperitoneally after 14–28 d using the immunogen prepared in PBS via a short narrow-diameter needle. Administer the immunogen at one site in no more than 0.5 mL using the same total dose as that used for priming (usually 5–50 µg).
3. Three days after the booster immunization, withdraw blood from the tail vein with a needle (0.4 mm) and syringe, and use this as a positive control in screening assays during hybridoma production and as a check on the success of the immunization. Sacrifice mouse, and remove spleen aseptically.

4. Notes

1. Shake the complete adjuvant before use to disperse the Mycobacterium particles fully.
2. The emulsion is very difficult to recover completely from the walls of vessels, and so forth; therefore, it is inevitable that some will be lost during preparation. To minimize this, prepare the emulsion in glass syringes, one of which can be used for the immunization. If possible, prepare slightly

more than required to compensate for losses, which normally amount to around 10%.

3. If Luer connectors are not available, the emulsion can be prepared by vigorous shaking or mixing using a whirlimixer. This is less efficient at producing an emulsion and requires larger volumes of immunogen.
4. When using connected syringes, keep the hub connector as short as possible to avoid emulsion loss.
5. Use glass syringes to prepare the emulsion since the rubber seals of plastic syringes are not compatible with the mineral oil of the adjuvant.

199

Making Hybridomas

Robert Burns

1. Introduction

In 1975 Kohler and Milstein reported ***(1)*** that immortal cell lines secreting antibody of a single specificity could be produced by the artificial fusion of splenocytes derived from immune mice and a tumour cell line derived from a murine myeloma. They called these cell lines hybridomas and the product from them monoclonal antibodies. The development of monoclonal antibodies opened up huge possibilities in all areas of antibody use as reagents could be created with specificity to a single epitope on the target protein. Additionally, antibodies could be generated to compounds that had previously been regarded as impossible when using conventional serum production. Monoclonal antibodies should however be seen as complementary to those derived from animal serum as each has its place in immunochemistry. The unique specificity, defined affinity and avidity of the monoclonal antibody are very desirable when looking at cell surface markers or single epitopes on a viral protein. In contrast, the broad specificity of polyclonal antibodies is a characteristic that may be desirable when screening for multiple strains of a virus or in techniques such as immunoaffinity purification.

The techniques for generating hybridoma cell lines have not changed much from the early work of Kohler and Milstein. Original work ***(2)*** used mice as donor animals and the mouse myeloma line NS-1 or its derivative NS-O (*see* **Note 1**) as the fusion partner. The murine system is probably still the most prevalent today although rats may be used for some antigens. Most murine hybridomas are produced from the physical fusion of spleen and tumour cells using low speed centrifugation and polyethylene glycol ***(3)***. Recombinant hybridoma cells are selectively grown as only they have the necessary characteristics of immortality derived from myeloma cells, and a salvage pathway for purine nucleotide (Hypoxanthine-guanine

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

phospho rybosyltransferase, HPRT) inherited from the splenocytes (*see* **Note 2**). Unfused spleen cells have a limited natural life span in tissue culture and the myeloma cell line lacks the purine nucleotide salvage pathway necessary for survival in the presence of the purine biosynthesis inhibitors (Aminopterin) contained in the selective medium (Hypoxanthine Aminopterin Thymidine, HAT).

Techniques such as electroporation and transfection have successfully been used for hybridoma production but are much less commonly used than fusion assisted by polyethylene glycol. Hybridomas may be unstable, as the techniques used to create them are fairly crude and may lead to a loss of cellular and genetic integrity. Instability is characterized by cell death after a few divisions or a loss or change in specificity. It is vitally important to test the hybridomas repeatedly to ensure that loss of specificity or ability to secrete has not occurred. The desirable qualities of monoclonal antibodies hinge on the fact that they are the products of a cell line derived from single parent cell. To ensure that this is the case it is important to aggressively clone the cells until a cloning efficiency of close to 100%, based on the quality of the antibody is achieved.

The vast majority of hybridomas generated in laboratories are destined to be discarded, as they will not have the desired qualities of antibody specificity, growth characteristics or cloning ability required. In most cases, it is more practical to derive a new cell line rather than try to continue with one that is less than ideal. It is very important to have in mind the qualities of the cell line that are required along with the characteristics of the antibody that are needed prior to embarking on hybridoma production.

Other species hybridomas, including human have been produced but are generally created by the use of viruses conferring cellular immortality. Artificial immunization of the donor is often not practical or ethical and so cell lines are often derived from peripheral lymphocytes obtained from individuals naturally immune to the target substance. Some human monoclonal antibody secreting cell lines have been derived from spontaneously occurring myelomas but this line of approach is frequently unrewarding as the probability that the antibody will be one of interest is remote.

Nonsecretory myeloma fusion partners with defective purine nucleotide biosynthesis pathways do now exist for a number of species including humans and so hybridoma production by cell fusion using PEG is now a possibility.

Hybridoma production can be broken down into four processes, immunization of donor animals, cell fusion, cell selection and expansion and each of these stages is important for the quality of the final product. Antigens used to immunize animals must be representative of the target substance (*see* **Note 3**) or the likelihood of producing cell lines with the correct specificity is remote. Cell fusions must generate hybridomas but steps must be taken to ensure that neither too few nor too many are generated. Cell lines must be selected using strict criteria to ensure

that desirable qualities in both cell growth and stability are present along with the specificity, avidity and affinity required for the final testing format. It is always advisable to screen primary cell lines using the assay format envisaged for the final test (*see* **Note 4**). Monoclonal antibodies may perform perfectly well in one assay format but may not for one reason or another convert to another.

2. Materials

1. 4 female Balb-c mice (*see* **Note 5**).
2. NS-O myeloma cell line.
3. Basal RPMI 1640 medium requires supplementation with sodium pyruvate, L-glutamine and Penicillin/Streptomycin before use. The supplements are supplied as concentrates of X50 or X100 and the appropriate amounts should be added. Standard tissue culture media for hybridoma production contain 5%, 10%, or 15% FBS (*see* **Note 6**). Sufficient quantities should be prepared in advance and a sterility check should be performed on them prior to use.

   All prepared media should be stored at −20°C until required and used within 28 days of thawing. L-Glutamine has an effective lifespan of about 28 days in prepared medium and will degrade giving rise to ammonia after this time.
4. HAT medium: Add 5 mls HAT supplement to 500 ml RPMI 1640 medium containing 15% FBS. Check sterility prior to use. Store at −20°C.
5. Allogeneic mixed thymocyte medium (MTM) is a conditioned medium used to aid cells recover from the fusion process. It also encourages division of hybridoma cells following dilution cloning when colonies derived from single cells are required. Rat thymi are used for this purpose to minimize the number of animals required to produce adequate numbers of cells. The medium contains a number of "helper" cytokines produced by the thymocytes. It is important that the thymocytes used are derived from two different rat strains as this causes co-stimulation and enhanced cytokine secretion by the cells. MTM must always be diluted with RPMI 1640 medium containing 15% FBS and is usually used at a dilution of 10%–15%. A number of proprietary supplements are available which can be used in the place of MTM. All of these contain cytokines derived from a variety of sources which provide the necessary stimulation for hybridoma cell division.
6. Allogeneic mixed thymocyte conditioned medium: Obtain two 6-week-old rats of two different strains (e.g., Sprague and Wistar). Kill rats humanely and remove the thymus glands aseptically. Homogenize the thymus glands using the frosted ends of glass microscope slides (see method for spleen homogenization) and suspend in 10 ml PBS. Wash by centrifugation 400 g and resuspend in 10 ml PBS. Add the thymocyte suspension to 1 litre RPMI 1640 medium containing 15% FBS and distribute into 4 X 225 cm T flasks. Incubate the cells for 30 to 40 h 37C/5% CO_2 (it is important that incubation is not longer than 40 h or undesirable cytokines will be produced). Harvest the conditioned medium is by centrifugation 500 g. The medium should be tested for sterility and stored at −20°C in 20 ml aliquots.

7. Freezing medium: Add 50 ml DMSO to 500 ml FBS Dispense in to 20 ml aliquots. Test sterility. Store at −20°C.
8. PEG medium for cell fusions (*see* **Note 7**): Autoclave 20 g PEG 4000 MW in a glass universal 121C/24 min. When cool enough to handle quickly add 20 ml RPMI 1640 without FBS. Mix well and dispense in 2 ml aliquots. Check sterility. Store RT in dark (*see* **Note 6**).
9. 96 well tissue culture plates.
10. 24 well tissue culture plates.
11. 25 cm "T" tissue culture flasks.
12. Freezing medium.
13. Cryovials.
14. Sterile glass petri dish and one pair of sterile "frosted end" glass microscope slides.

3. Methods

3.1. Immunizations

Mice should be obtained from a reputable source and should have be maintained under standard condition as required by local animal welfare legislation. Female mice can be housed together and it is usual to indelibly mark individuals by tattoo, ear punch, or electronic chip, so that the immune response for each individual animal can be monitored.

1. Prepare antigens at approximately 1 mg/ml in physiological saline.
2. Inject the mice intraperitoneally with 0.1 µl of antigen mixed with an appropriate adjuvant on days 0, 14, 28 and 44. Take a test bleed on day 51 and assess the serum for the presence of circulating antibody to the antigen.
3. If the immune response is good (*see* **Note 8**) rest the animals for a minimum of 8–10 weeks prior to cell fusion work. If the immune response is poor give another immunization on day 61 and assess the circulating antibody level on day 68.
4. Prior to carrying out a fusion, give the mouse with the highest antibody titre a booster dose of 50–100 µl antigen *without* adjuvant intraperitoneally. Three days later kill the mouse by cervical dislocation and remove spleen aseptically.
5. If all mice have responded well to the immunizations give all of them a booster dose, harvest the spleens, and cryogenically store the splenocytes for use at a later date (*see* **Note 9**). Store the spleen cells cryogenically as described in 3.6.

3.2. Preparation of the Myeloma Cells

NS-O myeloma cells are normally kept stored cryogenically and so should be resuscitated 3 days prior to carrying out the fusion.

1. Quickly thaw a frozen aliquot of NS-O cells either in a 37°C water bath or between the palms of the hands. Once the pellet has melted add 1 ml 37°C RPMI 1640 medium supplemented with 10% FBS and draw up into a Pasteur pipette. Transfer

the cells to a 225 cm "T" flask and add 50 mls RPMI 1640 medium containing 5% FBS and place in a tissue culture incubator 37°C/5% CO_2.
2. Inspect the cells on day 2, they should be semiconfluent and adherent to the flask base. Increase the volume of RPMI 1640/5% FBS medium to 75 ml and return to the incubator.
3. Inspect the cells on day three, they should be almost fully confluent on the flask base. Discard the medium, add 10 ml cold PBS containing 0.02% EDTA and leave for a few min to allow the cells to detach. Split the cells equally between 2 flasks and add 75 ml RPMI 1640 medium/5% FBS to each flask and return to the incubator.
4. On day four remove the medium from each flask and replaced with 20 ml cold PBS containing 0.02% EDTA. After a few min the cells will detach from the flask surface. Harvest the cells by gently tapping the flask and pouring the cell suspension in to sterile universal containers. Wash the cells by centrifugation 300 g and resuspend in 10 ml cold PBS.

3.3. Preparation of Splenocytes

Keep the spleen on ice, in RPMI 1640 medium without FBS until the splenocytes are harvested. Spleens can kept in this way for 1–2 h without significant loss of splenocyte viability.

1. Decant the spleen in to the sterile glass petri dish and gently dissociated by rubbing between the frosted ends of the glass microscope slides. It is sometimes necessary to break up the spleen a little prior to dissociating using either the ends of the microscope slides or a pair of dissecting scissors. After dissociation there will be fibrous tissue remaining from the spleen capsule and a red liquid containing the splenocytes.
2. Aspirate the red liquid from the fibrous tissue and place into a sterile universal container. Allow the contents of the universal container to settle for a few min then aspirate or "pour off" the supernatant from the residual tissue fragments (*see* **Note 10**).
3. Wash the splenocytes with PBS by centrifugation at 400 g and resuspend the pellet in 10 mls of cold PBS.
4. Remove 2.5 mls of splenocyte suspension for cell fusion.
5. Harvest the remaining cells by centrifugation, resuspend in freezing medium (2 ml spleen) and dispense into cryotubes in 0.5 ml aliquots. Freeze the cells and store cryogenically.

3.4. Cell Fusion

1. Mix the washed NS-0 cells harvested from the 2 T flasks with one quarter of the splenocytes from one spleen.
2. Pellet cells by centrifugation 400 g 5 min.
3. Discard supernatant and slowly add 1 ml PEG/RPMI mixture.
4. Gently resuspend the pellet by swirling.

5. Pellet cells by centrifugation 250 g 5 min.
6. Slowly overlay cell/peg layer with 5 mls RPMI 1640 with no FBS and then gently swirl to create a cell suspension.
7. Pellet cells by centrifugation 400 g 5 min.
8. Discard PEG/RPMI mixture and replace with 5 mls HAT medium, do not disturb the cell pellet then incubate the cell pellet for 5–10 min at 37°C.
9. Resuspend the cells by swirling and add 7.5 mls HAT and 7.5 mls Allogeneic Mixed Thymocyte Medium.
10. Dispense cells suspension into 96 well tissue culture plates (0.2 ml/well) (*see* **Note 11**).
11. Place in 37°C/5% CO_2 incubator.
12. After 7 days examine the wells for the presence of hybridomas and given an additional 0.1 ml HAT medium.
13. Test wells exhibiting growth for the presence of monoclonal antibodies when the hybridoma growth covers approximately 25% of the base of the cell well. The assay system used should mimic the final test format required. Commonly, TAS ELISA is use for screening hybridomas for specific antibody. It is important when testing hybridomas that a suitable negative is included as background antibody activity from unfused spleen cells may give apparently positive results. Up to 200 µl of medium can be harvested from each cell well, which can be split to assay against specific antigen and a suitable negative.

3.5. Stabilizing Hybridomas

Wells testing positive for specific antibody should be assayed more than once to ensure that activity continues over the course of a few days. The health of the cells should be checked daily to ensure that overcrowding does not occur and once the cells are confluent in the cell well they should be subcultured into 24 well plates. The cells must also be cloned by limiting dilution at this stage and plated out at 1 cell/well. It is useful to test the isotype of the secreted antibody when the cells are growing in the 24 well plates. This can be accomplished using a number of "dip stick" assays giving results in a matter of a few min. The isotype of the antibody is important for development of the antibody if purification and reagent development will be required. Antibodies of the sub classes G1, G2a, and G2b are the most desirable for further development as they are readily purified and are relatively stable. Antibodies with the G3 isotype, most commonly produced from bacterial antigens may be inherently unstable and liable to spontaneous aggregation.

Approximately 50% of hybridomas will secret antibody of the M subclass. IgM is a large molecule that does not readily purify but may be used for TAS ELISA. Some antigens will only give rise to IgM secreting hybridomas and are know as anamnestic antigens. These substances are frequently highly glycosylated and do not invoke a "memory" response in the immune system.

The result of this is that B-lymphocytes never mature beyond the production of IgM regardless of the number of immunizations the animal is given.

3.5.1. Limiting Dilution Cloning

1. Agitate the contents of the cell well using a Pasteur pipette and then using a pipette with sterile tip draw up 2X 10 ul aliquots of cells. Add one aliquot to 1 ml warm RPMI 1640 medium with 15% FBS. Add the other aliquot to 10 µl of Trypan blue dye and count the cells using a Neubauer counting chamber.
2. Calculate the cell count in the 1 ml tube using the formula: (total cell count/number of grid squares counted) × 10^4 × 2 = cells/ml.
3. Calculate the volume of cell suspension from the 1 ml tube that would contain 60 cells.
4. Transfer the appropriate volume of the medium and cells from the 1 ml tube to the 9 ml cloning medium and dispense 150 µl/well in 60 wells of the cloning plate.
5. Place the cloning plate into the tissue culture incubator 37°C/5% CO_2 for one week and then inspect for growth. Most cell wells should have single hybridoma colonies growing in them. **It is important at this stage to record the wells containing single colonies**. Give each of the cell wells 50–100 µl of cloning medium and reincubate until cella are between 30–50% confluent.
6. Test the wells which originally contained single colonies for specific activity; and record the numbers which are positive.
7. Subclone the cells using the method above until 100% of the clones are positive for the specific antibody. Occasionally some cell lines will not achieve a cloning efficiency of 100% regardless of the number of subcloning attempts. In these cases a final clone should be selected, rapidly multiplied and cryogenically stored. Cells from these stores should never be used to produce additional cell stocks without subcloning again.
8. Choose one of the clones from the final cloning as the cell line, expand it in tissue culture and cryogenically preserve stocks of it as the master cell bank (at least 12 vials).

3.6. Preserving Cells Cryogenically (Freezing)

1. Keep flasks of cells in log phase of growth by subdividing when almost confluent.
2. Make sure that caps are tightened on flasks and then sharply tap to dislodge cells.
3. Pour off cell suspension into a sterile plastic universal container.
4. Pellet cells at 400 g for 5 min.
5. Pour off medium, add 200 µl 1% Sodium azide solution and retain for assessment of antibody activity.
6. Tap the cell pellet and add 0.5 ml **cold** freezing medium.
7. Aspirate with Pasteur pipette to resuspend pellet then transfer to a 2 ml cryogenic vial.

8. Cells must be frozen at approximately 1°C/min and this can be achieved by putting the cryovials into an expanded polystyrene container with a wall thickness of 0.5 cm and then placing them in a −70°C freezer.
9. Transfer the cells to liquid nitrogen storage within 3 days of freezing at −70°C, they will remain viable for many years.

4. Notes

1. It is preferable to use NS-0 as a fusion partner, it does not secrete a constitutive antibody but has the ability to produce monoclonal antibodies once fused to an immune spleen cell. NS-1 has a constitutive antibody which may cause interference in screening assays for recombinant hybridoma cells.
2. Cell lines are available which have other defective pathways, aminopterin cannot be used to select for their growth and an alternative agent must be used.
3. Antigens must be representative but do not need to be identical to the target substance. Synthetic peptides modelling single epitopes and fusion proteins containing homologous regions to the target can be used very effectively as antigens.
4. It is not always possible to use exactly the same format for screening as will be used in the final assay but it is advisable to attempt to ensure that the "position" that the Mab will occupy in the final format is the position that is used for screening. For example mabs which will eventually be conjugated to enzymes and used in DAS ELISA should be screened for using TAS ELISA. This ensures that the epitope-binding portion of the antibody is in the same position as it will be in the final test format with the analyte bound to the coating antibody.
5. Balb-c mice are normally used for mab production, partly because they are the strain of mouse that the NS-0 cell was derived from and also because they are easily handled and the females can be communally housed.
6. Batches of FBS vary enormously in their ability to support cell growth and it is important to establish that the batch you are buying will be suitable. Most suppliers will allow you to reserve quantities from a batch and will provide small samples for testing. Usually a few batches are tested at the same time and the best performer then selected. Testing is carried out by cloning an established hybridoma line by limiting dilution in medium containing the test FBS and then observing numbers of resulting colonies.
7. Polyethylene glycol 4000 MW is normally use for cell fusions. Batches may vary in their ability to produce viable hybridomas and it is wise to test a few batches from different sources prior to undertaking hybridoma project work. A number of biochemical suppliers now produce ready-to-

use PEG/media solutions in sterile ampoules, which workers may find is a more practical source.

8. If the antigen to be used is derived from fungal mycelium, bacterial cell walls or is known to be highly glycosylated then repeated immunization is of no value. Antigens of this type are known to be anamnestic and do not produce "memory" B-lymphocytes. The animal sees each immunization as a primary challenge and the likelihood of producing an IgG response is remote.
9. Frozen spleen cells work well for cell fusions and this approach allows a greater degree of flexibility in performing fusions than using splenocytes directly *ex vivo*. The vial of spleen cells should be rapidly thawed in a 37°C water batch or between the palms of the hands. 1 ml of PBS is then added to the vial and the contents aspirated and added to 5 ml PBS. The cells are washed once by centrifugation 400 g and resuspended in 5 ml cold PBS; they should then be stored on ice until required. Spleen cells that have been frozen may have a tendency to clump and the pellet will look very pale. This does not affect their ability to produce viable hybridomas.
10. Disposable cell strainers that fit into the top of universal containers may be used to remove large fragments of spleen tissue.
11. The volumes of media used during cell fusion and subsequent plating in to tissue culture wells do not need to be accurately measured. Disposable Pasteur pipettes can be used to approximate volumes and most manufacturers publish specifications including drop volume for dispensing cells and medium.

Growing Hybridomas

Gary Entrican, Catherine Jepson, and David Deane

1. Introduction

The fusion of antigen-primed B cells with transformed myeloma cells results in immortalized hybridomas that secrete antibodies. The subsequent cloning of the hybridomas gives rise to cell lines secreting monoclonal antibodies (MAbs) of a single specificity ***(1)***. This technology has had a tremendous impact on research and medicine, with MAbs being used to identify and characterize the biological significance of myriads of molecules. The outcome has been the development of diagnostic tests and therapies for the detection and management of disease ***(2)***. The amount and purity of a MAb required for any given purpose can vary greatly. Here we describe the procedures involved in the maintenance and management of hybridomas and suggest techniques for maximising yields.

2. Materials

1. RPMI 1640 1× liquid without L-glutamine, without HEPES, stored at 4°C (Gibco Invitrogen Corporation, Inchinnan Business Park, Paisley, UK).
2. 100 mM L-glutamine solution, stored at −20°C (Sigma, Poole, Dorset, UK).
3. 1 *M* HEPES solution, stored at 4°C (Sigma).
4. Nutrient broth No. 2 (NB): 25 g dissolved in 1 liter of sterile H_2O, stored at 4°C (Oxoid Ltd, Basingstoke, Hampshire, UK).
5. Oxaloacetate, pyruvate insulin (OPI) media supplement solution: 1 vial dissolved in 10 ml sterile H_2O, stored at −20°C (Sigma).
6. Penicillin/streptomycin solution, stored at −20°C: 10,000 International Units/ml benzypenicillin sodium BP (Britannia Pharmaceuticals, Surrey, UK) and 10,000 µg/ml streptomycin sulphate (Gibco Invitrogen Corporation).
7. Fetal bovine serum (FBS), heat-inactivated at 56°C for 30 min to destroy complement and stored at −20°C (Gibco Invitrogen Corporation).

8. Costar/Corning 96- and 48-well tissue culture plates (Corning Incorporated, New York).
9. Corning 25 cm^2, 75 cm^2, 225 cm^2 vented sterile tissue culture flasks (Corning Incorporated).
10. Costar/Corning 5 ml, 10 ml, 25 ml disposable sterile pipettes (Corning Incorporated).
11. MiniPERM classic kit, molecular weight cutoff 12.5 KDa. Kit includes twelve miniPERM bioreactors (Greiner Bio-One Ltd, Gloucestershire, UK).
12. CellPROTECT, anti-shearing agent for high-density culture (Greiner Bio-One Ltd).
13. AntiFOAMa (Greiner Bio-One).
14. Universal turning device, holds four miniPERM bioreactors (Greiner Bio-One Ltd).
15. Disposable hypodermic syringe, 50 ml Luer (Greiner Bio-One Ltd).
16. Disposable hypodermic syringe, 2 ml Luer (Greiner Bio-One Ltd).
17. Spare Luer-Lock screw caps for production modules. Six caps per case, autoclavable (Greiner Bio-One Ltd).
18. Spare filter screw cap for nutrient module: thirty caps per case, autoclavable (Greiner Bio-One Ltd).
19. MiniPERM stand, for mounting the miniPERM bioreactor during inoculation, sampling and cell harvest: Four stands per case (Greiner Bio-One Ltd).
20. Neubauer haemocytometer (Fisher Scientific UK, Bishop Meadow Road, Loughborough, Leicestershire, UK).
21. Cryopreservation tubes (Nunc A/S, DK-4000 Roskilde, Denmark).
22. DMSO Hybrimax (Sigma).
23. 'Mr Frosty' cryopreservation 1°C freezing container (Nalgene, Nalge Europe Ltd, Thorn Business Park, Hereford, UK).
24. 2-propanol (Rathburn Chemicals, Walkerburn, Scotland, UK).
25. Nigrosin, dissolved to a final concentration of 0.1% w/v in PBS containing 2% FBS, filter-sterilized and stored at 4°C (Sigma).
26. RPMI is used as the standard base medium for culturing hybridoma cell lines. The following supplements are added to each 500 ml bottle of RPMI: 10 ml penicillin/streptomycin (*see* **Note 1**), 10 ml glutamine (*see* **Note 2**), 5 ml HEPES and 50 ml FBS (*see* **Note 3**). The contents should be mixed by swirling, not by inversion, thereby avoiding leakage and contamination. Hereafter this mixture is referred to as complete medium (CM). Two × 1 ml aliquots of CM should be removed and added to 2 × 5 ml aliquots of nutrient broth (NB) for sterility testing. Keep one NB at room temperature for 3 days and incubate the other at 37°C for 3 days. Check the NBs for evidence of microbial contamination prior to using the CM for the first time. Store CM at 4°C and use within 2 weeks of preparation (*see* **Note 2**).

3. Methods

The methods in the following sections describe (1) the growth of cloned hybridoma cell lines, (2) high-density culture systems required for bulk production of MAbs, and (3) the generation of validated cell banks where hybridomas can be stored for future retrieval. All procedures that involve manipulation of cell lines are conducted within the confines of a Class II microbiological safety cabinet using sterile equipment. Cell cultures are maintained at 37°C in an atmosphere of 5% CO_2 in air and 100% humidity. It is preferable to use tissue culture flasks that have filter-vented caps to minimize the chances of contamination. Several hybridoma cell lines were used in the following procedures: 36F ***(3)***; VPM 20, VPM 21, VPM 22 ***(4)***; 73B ***(5)***; 3C2 and 8D8 ***(6)***. These cell lines have individual characteristics, but the procedures described here are generic in nature and can be applied to all hybridoma cell lines, taking into account the comments under **Subheading 4**.

3.1. Expansion of Cloned Hybridomas

1. Transfer hybridoma cells from the 96-well cloning culture plate to a 48-well culture plate in 0.4 ml fresh CM (*see* **Note 4**), using gentle pipetting to dislodge the cells from the plastic (*see* **Note 5**).
2. Two days later transfer the cells to a 25 cm^2 flask in 2 ml fresh CM (*see* **Note 6**). Next day, add 3 ml CM to feed the cells.
3. The following day, gently pipette the 5 ml of medium in the flask several times several to dislodge the cells and transfer the total volume to a 75 cm^2 flask. Add a further 5 ml fresh CM immediately to the flask to feed the cells. Add 10 ml fresh CM 24 h later.
4. The next day transfer the 20 ml containing the cells to a 225 cm^2 flask using gentle pipetting as before, then 30 ml fresh CM is added immediately.
5. The following day dislodge the cells from the flask by pipetting and add 10 ml of the resulting suspension to each of five 225 cm^2 flasks. Add 40 ml fresh CM per flask. This protocol of passaging 10 ml of cell suspension at a 1:5 ratio can be followed for expansion of hybridomas either for generating cells for high density cultures (***3.2***) or for preparation of cell banks (***3.3***). Check the cells for *Mycoplasma* contamination (*see* **Note 7**) and analyse the supernatant for antibody production (*see* **Note 8**) before progressing to either of the next stages.

3.2. High Density Culture

There are multiple means by which high density hybridoma cultures can be achieved. The objective is to maintain cloned hybridomas in a healthy condition in the lowest possible volume of CM to maximize antibody production and facilitate downstream antibody purification. There are various products on the market such as multi-layered tissue culture flasks, dual-chamber flasks

Fig. 1. The MiniPERM bioreactor.

with semi-permeable membranes and fermentation systems. Flasks tend to be cultured statically whereas fermentation requires mechanical agitation of the cells. The MiniPERM bioreactor is our method of choice for the high-density culture of hybridoma cells (**Fig. 1**).

3.2.1. The MiniPERM Bioreactor

The modular system, consisting of a 40 ml disposable culture chamber and a 550 ml reusable nutrient module separated by a dialysis membrane (12.5 kD molecular weight cut-off), allows for the production of a low-volume, high-density cell population with a correspondingly high antibody yield.

The hybridomas and secreted antibody are retained in the production module (**Fig. 2**). Depending on the cell line, cell densities can reach upward of 1×10^7 cells/ml. The MiniPERM bioreactor is rotated on a universal turning device that allows four MiniPERM bioreactors to be run simultaneously for larger production runs of one hybridoma or production of different hybridomas. This motion speeds the distribution of nutrients to the cells and facilitates the removal of metabolic waste products and CO_2-processes that rely on passive diffusion in static

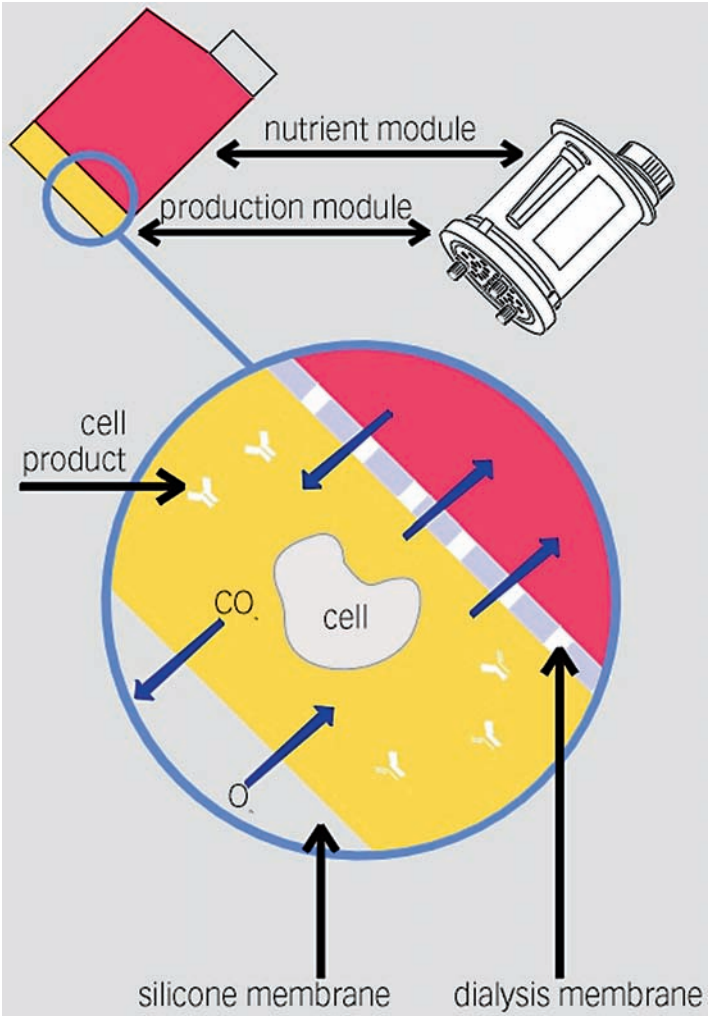

Fig. 2. The MiniPERM production module.

bioreactors. Sample collection and harvesting is via Luer-Lock connections on the production module. The MiniPERM is a continuously fed culture system that allows cultures to be maintained for several weeks.

3.2.2. Inoculation of the Bioreactor

Assemble the MiniPERM bioreactor according to the manufacturer's instructions (*see* **Note 9**), disinfect the universal roller and install in a CO_2 incubator. Media for the production module (production medium) and the nutrient module

(nutrient medium) should be prepared prior to inoculation (*see* **Notes 1–4**). The production medium is complete medium as described previously but supplemented with a further 5% FBS and 0.1% v/v CellPROTECT (*see* **Note 10**). The nutrient medium contains the same components as complete medium, with the exceptions of 5% FBS instead of 10% FBS and with the addition of 0.2% v/v AntiFOAMa (*see* **Note 11**). Both the nutrient media and the production media are prewarmed to 37°C to prevent expansion of the MiniPERM membrane when introduced into the incubator.

1. Detach the hybridoma cells by tapping and gentle pipetting from a 225 cm^2 tissue culture flask, wash by centrifugation at 300 × g for 10 min and resuspend the resulting cell pellet in 5 ml production medium.
2. Calculate the cell density by diluting 10 µl of suspension in 90 µl Nigrosin then count the cells using a haemocytometer. Adjust the density to 5×10^5 cells/ml in production medium and inoculate the reactor with 35 ml of this suspension using the following procedure (*see* **Note 12**).
3. Draw the suspension slowly up into a 50 ml hypodermic syringe (*see* **Note 13**). Unscrew the two Luer-Locks on the assembled MiniPERM and inject the cell suspension carefully into the production module while the module is slowly rotated (*see* **Note 14**). This ensures that displaced air is expelled through the open Luer-Lock.
4. Replace both Luer-Locks then add 400 ml of nutrient medium to the nutrient module. Close the cap and place the MiniPERM module inside an incubator on the Universal turning device set at 5 rpm (*see* **Note 15**).

3.2.3. Sampling and Harvesting

1. Remove 1 ml samples daily using a 2 ml syringe to assess the culture (*see* **Note 16**). To do this, put the MiniPERM on a stand and turn it so that a Luer-Lock sampling port is at 12 o'clock. Open the port and insert the 2 ml syringe (*see* **Note 17**). Rotate the device 120 degrees clockwise so that another port is at 12 o'clock and the sample port used for withdrawal is now at 4 o'clock.
2. Assess cell viability using Nigrosin exclusion (*see* **Note 18**).
3. Harvesting is performed using the method described for sampling, with the exception that a larger quantity of medium is removed using a 50 ml syringe. Harvest 20 ml either when the cell viability falls below 50% or when the cell density exceeds 2×10^7 cells/ml. The remaining 15 ml of cell suspension allows for repopulation of the production module following the addition of 20 ml fresh production medium.
4. Change the medium in the nutrient module every 2 to 4 days (*see* **Note 19**). Proceed with harvesting and replacement of nutrient media in a cyclic manner.
5. After sampling and harvesting the Luer-Locks must be wiped down with 70% ethanol to prevent infection being introduced to the production module (*see* **Note 20**). Periodical measurement of cell-density, viability, and antibody production over the course of the production run will help in the planning of future production runs.

3.3. Storage of Hybridomas

3.3.1. Cryopreservation

Prepare freezing mix (FM) in advance of the procedure. To do this, mix 10 ml FBS with 8 ml CM and 2 ml DMSO and store at 4°C (*see* **Note 21**).

1. Harvest the cells and supernatant from five 225 cm^2 flasks one day after being seeded (*see* **Note 22**) and pool the resulting cell suspension.
2. Remove 2 ml of this suspension and add to a 25 cm^2 flask. Supplement with 3 ml fresh CM and place the flask in the incubator (*see* **Note 23**).
3. Centrifuge the remaining suspension at 300 × *g* for 10 min at 4°C. Retain the supernatant for antibody analysis. From this stage onward all reagents should be used at 4°C. Recover the cell pellets, pool the cells, resuspend in 50 ml CM and wash by centrifugation at 300 × *g* as before.
4. Discard the wash supernatant and resuspend the cell pellet in 20 ml fresh CM. Calculate the cell density by diluting 10 µl of suspension in 90 µl Nigrosin and counting the cells using a haemocytometer.
5. Centrifuge the cells as before then finally resuspend the pellet to a density of 5×10^6 viable cells/ml in FM and 1 ml added to each cryovial.
6. Place the vials in a Nalgene freezing tub filled with 2-propanol then place in a −70°C freezer overnight (*see* **Note 24**).
7. Transfer the vials to LN_2 for long-term storage (*see* **Note 25**).

3.3.2. Resuscitation of Frozen Cells

1. Remove one vial from the cell bank in LN_2 after 24 h of storage and immediately thaw by immersion in a water bath at 37°C (*see* **Note 26**).
2. As the last of the ice disappears, transfer the suspension to a centrifuge tube (*see* **Note 27**). Slowly add 10 ml CM at 4°C to the cells with gentle mixing and centrifuge the suspension at 300 × *g* for 10 min at 4°C.
3. Wash the cells by resuspending the pellet in 10 ml CM at 4°C and then centrifuging as before.
4. Finally resuspend the cells in 1 ml CM and count as described in **Subheading 3.3.1**.
5. Adjust the cell concentration to 2×10^5/ml in CM, add to a 25 cm^2 flask and incubate as described in **Subheading 3.1.2** (*see* **Note 28**).
6. Visually monitor the cells daily for growth and lack of contamination. Expansion of the cells can be taken as evidence of a viable cell bank and also that no microbial contamination of the cells occurred during the freezing/resuscitation process (*see* **Note 29**).

3.3.3. Management of a Cell Bank

Validated cell banks are essential for the long-term survival of hybridomas. Ideally, databases should be set up to manage the banks and to record information about the cells. An example of useful fields for a database are set out in

Hybridoma identification code		
Specificity		
Isotype		
Cloning history		
Passage number		
Result of *Mycoplasma* screen		
Date frozen		
Cell density per vial		
Number of vials in bank		
	Date	Viability
Resuscitation (1 week)		
Resuscitation (1 month)		
Resuscitation (6 months)		
Resuscitation (1 year)		
Resuscitation (2 years)		
Resuscitation (3 year)		
Resuscitation (4 years)		
Resuscitation (5 years)		

Fig. 3. Recommended fields for management of hybridoma cell banks.

Fig. 3. One vial of cells should be resuscitated after one week, one month, six months and then annually and checked for viability following the procedure set out in **Subheading 3.3.2**. A new cell bank should be made if there is concern about the viability of the stock. It is recommended to have vials stored in more than one container to safeguard against loss as a result of mechanical failure of the storage system.

4. Notes

1. It is not desirable to routinely use antibiotics in tissue culture. Antibiotics may limit growth of contaminants without eradicating them, ultimately having a detrimental effect on the cells. Sound tissue culture technique

conducted in suitable facilities with appropriate equipment is sufficient to maintain established cell lines. However, hybridomas are expensive to produce and are often unique, so the inclusion of antibiotics in the early expansion stages acts as an added safeguard against contamination.

2. CM should be prepared at least three days before use to allow for sterility checking. CM can be stored for two weeks at 4°C, after which time the components will deteriorate. Glutamine is notably labile, hence storage of the concentrated stock at −20°C. It is possible to purchase a formulation of glutamine supplement that is stable (cat. no. 35050-038; Glutamax™, Gibco Invitrogen Corporation).
3. Selection of appropriate FBS is crucial for successful growth. Batches of FBS should be screened prior to selection for their ability to support hybridoma cloning and growth. Antibody content of FBS tends to be low, however batches of FBS may contain antibodies to ruminant pestiviruses and other transplacental pathogens. In the vast majority of cases this will not present a problem unless the hybridomas are producing MAbs to be used for pestivirus diagnosis or research. If the FBS contains pestivirus itself, this will create problems if the MAbs are used for research involving ruminant cells that can be infected by virus that then establishes a persistent infection and cannot be eradicated *(7)*.
4. Hybridomas vary in their growth characteristics and different lines will multiply at different rates. The expansion of hybridomas after they have been cloned requires careful monitoring to ensure that the cells have suitable growth conditions and an adequate supply of nutrients. Daily examination is desirable, with good note-keeping to record growth patterns. Cell populations are expanded by a gradual step-wise increase in the size of the culture vessel and volume of medium as the cell number increases. A change in the colour of the medium from orange to pale yellow signifies a drop in pH as the cells metabolize. This is accompanied by an increase in cell density and indicates that the cells can be moved to a larger culture vessel with fresh medium. If the medium becomes bright yellow the cells require urgent attention. CM should be warmed to 37°C before being added to cells. If cells are at low density and/or showing signs of poor growth, CM can be temporarily supplemented with OPI solution to a final concentration of 2% to encourage cell growth. Cell counts should be performed if required (*see* **Subheading 3.2.2**). Hybridoma growth can be modulated by altering the concentration of FBS in the CM, with lower concentrations reducing the rate of growth. This may be appropriate if daily monitoring is not feasible, but this may not be suitable for every hybridoma.
5. Hybridomas vary in their ability to adhere to plastic and to each other. It is important to avoid subjecting the cells to excessive mechanical stress such

as vigorous pipetting or foaming of the medium that can cause damage and cell death when removing them from plastic or disrupting clumps.

6. Culture flasks with vented filter caps allow for gaseous exchange between the culture and the incubator while protecting the cells from airborne microbial contamination.
7. There are various methods for detecting *Mycoplasma* contamination of cell culture. A sensitive PCR test with broad specificity for *Mycoplasma* species is available ***(8)***. Our method of choice is an enzyme immunoassay that detects four species of *Mycoplasma* (cat. no. 1296744; Roche Diagnostics Ltd, Charles Avenue, Burgess Hill, UK). There are several products available for the eradication of *Mycoplasma* species from cell lines. The effectiveness of the treatment will depend on the cells and involves trial-and-error. This is because some cell lines are very sensitive to the chemicals used to eradicate *Mycoplasma* and may become static or die during treatment. We use *Mycoplasma* removal agent (MRA) according to the manufacturer's instructions (BUF035; AbD Serotec, Langford Business Park, Kidlington, Oxford, UK).
8. Once hybridomas cell lines have been cloned they tend to have a stable phenotype. However, they do divide rapidly and can spontaneously change. Cells that do not produce antibody can arise from cloned populations, albeit at a low frequency. The growth properties of non-producing cells may not be the same as that of the parent clone, potentially outgrowing the producing cells which would resulting in loss of the hybridoma line. An important rule to remember is that different hybridoma lines should never be handled simultaneously in tissue culture. There is the risk of cross-contamination and if this does occur, it may not be immediately apparent if the lines are phenotypically similar (e.g., adherence properties etc). As with reverting clones, contamination may only become apparent when the supernatant is tested for MAb content. Hybridoma lines can be safeguarded by ensuring that cells are cryopreserved at an early stage after cloning (**Subheading 3.3**), by routine checking for MAb production, isotyping and sub-cloning if required. Mouse monoclonal antibody isotyping kits can be obtained from Roche (cat. no. 1 493 027; Roche Diagnostics Ltd).
9. Pre-assembled sterile bioreactors are available from the manufacturer. With the classic kit the production modules are sterile and can be used just once, the nutrient module needs to be assembled and sterilized by autoclaving.
10. Some hybridomas require a higher concentration of FBS, up to 15%. As the cells in the production module are subject to shearing forces due to the rotation of the bioreactor, CellPROTECT can be used as an antishearing supplement.
11. Nutrient medium is supplemented with 5% foetal bovine serum. Low molecular weight serum proteins diffuse across the dialysis membrane

between the nutrient and production modules. A reservoir of low molecular proteins is required in the nutrient module to maintain the equilibrium for hybridoma growth and survival. Accumulation of foam in the nutrient module can be a problem. To counteract foaming, do not exceed a concentration of 5% FBS in the nutrient module and add AntiFOAMa anti foaming agent. Do not fill the nutrient module with more than 400 ml of nutrient medium. An air space is required within the module to ensure successful hybridoma growth.

12. Hybridomas for inoculation into the MiniPERM bulk culture device should be greater than 90% viable and free from infection with *Mycoplasma* or other microbial agents. Ideally, a concentration of 5×10^5 cells/ml is required for the 35 ml inoculum, although the density can be increased to 2×10^6 cells/ml if the culture fails to seed at the lower density.
13. Do not use a needle for loading the syringe since the shearing forces can damage the cells.
14. Work on the MiniPERM should be carried out promptly in order that the cells do not settle and clump together impairing their viability. This is particularly important to bear in mind when high densities are reached as these populations will rapidly exhaust nutrients and oxygen when static. In addition the localized build up of metabolic products will have a toxic effect on the cells. A stand is available to aid this procedure.
15. Mouse hybridomas can be turned at speeds of 5–20 rpm. Cells sensitive to shearing forces should be turned at lower rpm.
16. To maintain the optimum cell density, cell viability and maximize the antibody yield within the cell chamber it is necessary to sample the cell population at regular intervals. The frequency of harvesting is dependent on the growth properties of the hybridoma being cultured so sampling should initially be performed daily to assess the culture.
17. Pressure within the module can cause the cell-culture medium to spurt out when the Luer-Locks are opened. If the rubber membrane of the production module is distended stand the MiniPERM upright and release the cap of the nutrient module and gently push the membrane into a flat position.
18. Cells often take a time to adjust to the bioreactor and a small initial drop in viability is normal. If the cells are not growing and the viability has dropped below 50%, and contamination has been ruled out, there are several options to try: (a) reseed the bioreactor at a higher cell density; (b) adjust the rolling speed; (c) increase the serum concentration in the nutrient module; (d) add OPI at 1/50 to promote cell growth.
19. Low-density cultures (e.g., 5×10^5 cells/ml) will require fresh nutrient media less frequently than high-density (e.g., 5×10^6 cells/ml) cultures. A change in the colour of the medium from orange to yellow indicates that the medium requires to be changed.

20. Replacement sterile caps for the nutrient module Luer-Locks can be used to reduce the chances of contamination.
21. The components of FM (FBS, CM, DMSO) are used in the ratio of 5:4:1. It is preferable to prepare fresh FM for each cell bank and chill to 4°C. DMSO can be purchased in 10 ml units. Once a vial has been opened, any unused DMSO can be stored at 4°C in a sealed container. Undiluted DMSO crystallizes at 4°C, so it is recommended to store aliquots in suitable working volumes to avoid repeat thawing of the stock.
22. Cells are in optimal condition for cryopreservation when they are in log-phase growth. This occurs when the cells are at low-to-medium density in CM that is not exhausted of nutrients.
23. It is advisable to maintain a small culture of cells until the viability of the cell bank is validated. This ensures survival of the line should the freezing procedure fail.
24. To avoid cell damage due to rapid formation of ice crystals a freezing rate of 1°C per min is optimal. If Nalgene tubs are not available, vials can be wrapped loosely in cotton wool to achieve a similar effect, but this has a more variable success rate.
25. Appropriate safety procedures must always be followed when dealing with LN_2 storage. Cells can be stored in liquid phase or vapour phase, or in ultra-cool freezers. Prevention of ice-crystal formation is essential for successful long-term storage and the vials should be protected from temperature fluctuations wherever possible. Temperature fluctuations can damage cells when frozen, even if they do not result in the contents of the vial thawing out.
26. Cells are vulnerable in the transition period from freezing to resuscitation. Rapid thawing in a water bath is advisable to limit cell damage. The vial should never be submerged to the level of the seal on the cap, otherwise contamination will occur.
27. It is important not to allow the cells to remain in the water bath since they need to be washed free of freezing mix as soon as possible after they have thawed.
28. It is desirable to have a cell bank containing a high percentage of viable cells upon thawing. If the viability is less than 70%, another cell bank can be produced from the cells that have been kept in culture (**Subheading 3.3.1,** *see* **Note 23**). Hybridomas with low viability can be resuscitated into 96-well culture plates (1×10^5 cells/well), allowed to settle for 24 h, then the CM changed to remove intracellular products of dead cells that can inhibit the growth of the surviving cells. Alternatively, freshly-isolated syngeneic peritoneal mouse macrophages can be used as feeder cells for cell banks that prove difficult to resuscitate. The macrophages should be seeded at a

density of 5×10^3/well in a 96-well culture plate 24 h before resuscitation of the hybridoma. The macrophages will ingest cellular debris and release growth factors for the hybridoma.

29. If microbial contamination is observed, another vial should be resuscitated from the bank to confirm whether or not the contamination is unique to one vial. If contamination is found in other vials the bank should be discarded.

Acknowledgments

The authors thank Joachim Lücke for permission to reproduce the miniPERM images. GE, CJ and DD are supported by the Scottish Executive Environment and Rural Affairs Department (SEERAD). This work was conducted in conjunction with the BBSRC/SEERAD Toolbox.

Mouse Hybridomas as an Entryway to Monoclonal Antibody Design and Production

Eugene Mechetner

1. Introduction

Over the last 30 years, significant progress was made in the development of monoclonal antibodies (mAbs) initiated by the pioneer studies of Caesar Milstein on the structure and genetics of immunoglobulins in the 1960s and 1970s. **Table 1** summarizes the most significant advancements in the hybridoma field since the first publication by Kohler and Milstein in 1976 ***(1)***. The variety of research and diagnostic mAbs was expanded from "classic" mouse-mouse monohybridomas through the use of rat-rat, hamster-hamster and increasingly popular rabbit-rabbit monohybridomas ***(2–4)***, as well as relatively simple to make and efficient mouse-rat and rat-mouse heterohybridomas ***(2)***. After many years of persistent development complicated by difficulties in identifying reliable fusion partner cell lines, chicken ***(5)*** and, especially, human ***(6)*** monohybridomas are also coming closer to fruition. In the therapeutic arena, human mAb versions originated in transgenic mice ***(7)*** and recombinant mAbs expressed in vitro using phage displays ***(8)***, ribosome displays ***(9)*** and baculovirus expression vectors ***(10)*** are now playing a major role in the discovery and clinical applications of new immunotherapeutic agents. A new and rapidly evolving approach with a very promising future in multiple biomedical ventures is mAb manufacturing in non-animal system, including yeast ***(11)*** and plant ***(12)*** cells. Finally, fully synthetic mAbs prepared using amino acid ***(13)*** and nonamino acid ***(14)*** diversity platforms have been added to the arsenal of research, diagnostic and therapeutic mAbs.

However, the major challenge facing a neophyte is not in the selection of a specific source of antibodies or an expression system, but rather in gaining an overall understanding of the design and in circumventing experimental pitfalls

Table 1
Brief summary of the monoclonal antibody field

Type of mAb	Description	Source	Reference
Animal, cell fusion based monohybridomas	mAbs produced by hybrids of immune cells and fusion cell line partner from the same animal species	mouse	(1)
		rat	(2)
		rabbit	(3)
		hamster	(4)
		chicken	(5)
		human	(6)
Animal, cell fusion based heterohybridomas	mouse or rat mAbs produced by hybrids of the two species	mouse/rat, rat/mouse	(2)
Animal recombinant, in vivo	human mAbs produced in mice using antibody gene loci inserted in mouse germ line	mouse/human	(7)
Recombinant mAbs and their fragments (minibodies)	mAbs expressed in living E.coli	phage display	(8)
	mAbs expressed in bacterial or animal cell lysates	ribosome displays	(9)
	mAbs expressed and produced in vitro in the baculovirus system	insect	(10)
Non-animal (fungibodies, plantibodies)	mAbs produced by yeast cells in vitro	yeast	(11)
	transgenic mAbs produced in algae or higher plants (e.g., tobacco)	plants	(12)
Synthetic (multibodies)	mAb multimers created through chemical processes from multivalent recombinant fragments	amino acid based	(13)
	aptamers engineered synthetically using RNA or DNA ligands	non-amino acid based	(14)

common for beginners in the mAb trade. In this context, the original approach reported in 1976 ***(1)*** and virtually unchanged since then, remains a mainstay for the field and serves as a prime example of how a successful mAb ought to be

developed. Consequently, this chapter is centered on the mouse monohybridoma methodology and its major objectives and limitations.

2. Materials

2.1. Animals

1. Host animals: BALB/c mice, 20- to 30-weeks old
2. Immunization: Complete Freund's Adjuvant (Sigma) and Incomplete Freund's Adjuvant (Sigma, St. Louis, MO)
3. Production of ascites: Pristane (2,6,10,14-Tetramethylpentadecane; Sigma)

2.2. Hybridoma Selection and Expansion

1. Myeloma fusion partner: P3X63Ag8.653 mouse myeloma (ATTC accession number CRL-1580)
2. Medium for routine cell maintenance: Iscove's (IMDM) or Dulbecco's (DMEM) Modified Eagle Medium, supplemented with 15% fetal calf serum, 4 mM L-glutamine, 1 mM sodium pyruvate, 50 µM beta-mercaproehtanole, non-essential amino acids, and antibiotics of choice (e.g., penicillin/streptomycin, 50 units/50µg) (all from Invitrogen, Carlsbad, CA)
3. Medium for P3X63Ag8.653 before cell fusion: normal maintenance medium plus 8-azaguanine (Sigma, St. Louis, MO) at 15 µg/ml
4. Medium for routine protein-free production: PFHM II (Invitrogen) or UltraDOMA-PF (Cambrex, East Rutherford, NJ)
5. Medium for difficult-to-grow hybridoma clones: HybriCare Cell Culture Medium (ATCC, Manassas, VA).
6. Medium for hybridoma selection: normal maintenance medium plus HAT or HT using 500× concentrates of HAT and HT (69-X and 71-X, respectively; ATCC)
7. Cell fusion: polyethylene glycol solution (PEG) 40%–50 % (w/v), mol wt 1,450 (P7181; Sigma) in a protein-free medium or phosphate buffer saline (PBS)
8. Cell count: 0.4% Trypan Blue solution (Sigma)
9. Cell cryopreservation: hybridoma grade DMSO (dimethyl sulfoxide; Sigma)
10. Plastic ware: sterile 96-well plates, tissue culture flasks, Petri dishes, conical tubes (15 and 50 ml)

2.3. Monoclonal Antibody Characterization and Production

1. mAb isotyping: antibody-capturing strips kit (ISO1, Sigma)
2. mAb quantification: Standard Vectastatin ABC kit (PK-4000, Vector Labs, Burlingame, CA)
3. For complement-fixation testing: Low-tox rabbit complement (Cedarlane Laboratories, Hornby, ON, Canada)
4. mAb concentration: for IgG supernatants, AMICON Centriprep 100 concentration units (Millipore, Billerica, MA)
5. Affinity chromatography: application specific mAb purification kits (Pierce Biotechnology, Inc., Rockford, IL)

Table 2
Timetable and example of immunization schedule

Day	Procedure	Route
0	Primary immunization	i.p.
14	First boost	s.c.
28	Second boost	s.c.
36	Serum collection; titration	from retroorbital sinus
42	Third boost	s.c.
56	Final boost	i.v.
59	Serum collection; cell fusion	total bleeding; spleen removal

3. Methods

3.1. Immunization

1. Immunization protocols may vary depending on the experimental model and objectives. A generic exemplar immunization schedule is shown in **Table 2**. Initial immunization: i.p. administration of 0.5 ml of Complete Freund's Adjuvant mixed at 1:1 (v/v) with antigen solution (5–100 µg of the antigen or 10^6–10^7 cells) (*see* **Note 1**).
2. Booster injections: s.c. administration (to increase the immune response, at multiple sites) of 0.5–1 ml of Incomplete Freund's Adjuvant mixed with 1–50 µg of protein or 10^5–10^6 cells.
3. Blood samples for subsequent serum titration are collected from the retroorbital sinus.
4. The total number of boost injections before the fusion should be determined using serum titration results.
5. Final boost: slow (to avoid anaphylactic shock) i.v. administration of 50–100 µl of purified antigen dissolved in PBS, or i.p. injection of the antigen.

3.2. Cell Fusion and Screening

1. Prepare P3X63Ag8.653 mouse myeloma in advance through propagating cells in flasks or roller bottles.
2. Grow myeloma cells in the presence of 8-azaguanine for at least 3 weeks (*see* **Note 2**).
3. Maintain myeloma cells in 8-azaguanine-free medium for 7 days before fusion.
4. Refresh medium 24 h before fusion. Harvest and wash the cells immediately before fusion, wash twice in ice-cold serum-free medium and keep on ice until adding PEG. Keep P3X63Ag8.653 cells viable and completely free of protein in the medium.
5. Keep 1.5 ml of 50% PEG solution in serum-free DMEM at 37°C until fusion.
6. After sacrificing the animal, collect blood through total bleeding, prepare serum samples, and keep 100 µl aliquots at −20°C for further analysis.
7. Remove and transfer the spleen into a sterile Petri dish with 10 ml of cold DMEM. Wash the spleen in two additional Petri dishes containing 10 ml of cold DMEM.

8. Use crusher/homogenizer containing 5–7 ml of cold DMEM to squeeze splenocytes from the spleen. Avoid circular motions of the pestle to maintain cell viability.
9. Remove the splenocyte suspension into a conical tube with ice-cold DMEM, gently pipet on the tube wall to break down large cell clumps, and collect debris-free splenocytes.
10. Wash twice at 200 g for 10 min with ice-cold DMEM.
11. Resuspend prewashed P3X63Ag8.653 myeloma and splenocytes cell pellets in 10 ml of cold DMEM and count cells using a hemocytometer.
12. Although different ranges of splenocyte-to-myeloma cells ratios and cell numbers have been reported, the approximately 1:1–1:5 ratios and a total of 5×10^7–10^8 cells per fusion worked best in our hands.
13. Combine splenocytes and myeloma cells in a 50-ml conical tube, resuspend in prewarmed to 37°C protein-free DMEM and spin down in a bucket rotor centrifuge at 200 g for 10 min to obtain a loose cell pellet (*see* **Note 3**).
14. Quickly aspirate the supernatant and dissociate the cell pellet by gently flicking on the bottom of the tube. Slowly add 1 ml of prewarmed PEG solution to the cell pellet, while gently tapping on the bottom to mix the cells with PEG.
15. Slowly add 40–45 ml of prewarmed at 37°C serum-free DMEM while gently swirling the tube after every 5 ml of DMEM added.
16. Wash once at 200 g for 10 min, remove the supernatant, gently pipet in 10 ml of prewarmed at 37°C complete HAT medium, and transfer into a container with another 190 ml of warm complete HAT medium.
17. Transfer the cells into 10 96-well flat-bottom plates, 0.2 ml per well (*see* **Note 4**).
18. Incubate at 37°C in 5% CO_2; replace one half of the well volume with complete HAT medium every two or three days.
19. Start screening 12 days after fusion or when wells containing hybridoma clones are 50% confluent. The screening procedure should yield prompt and definitive results to avoid excessive growth of hybridoma clones in their initial wells.

3.3. Hybridoma Cloning, Expansion, and Storage

1. Use at least three consecutive rounds of cloning.
2. Clone all positive wells after fusion in the initial 96-well plates.
3. Utilize the largest single colonies in subsequent rounds of cloning. For each initial colony, at least 15–20 single colonies should be tested and at least 10 best single colonies should be re-cloned, each into one flat-bottom 96-well plate (*see* **Note 5**).
4. Use Trypan Blue to determine the concentration and total number of viable hybridoma cells.
5. After 8–12 days of growth, select the largest 15–20 colonies and repeat the re-cloning procedure.
6. Cryopreserve all best colonies before the next round of cloning.
7. Utilize complete HAT medium for the first round of cloning (i.e., cloning of initial hybridoma colonies).
8. In the second round of cloning, start replacing 50% of the well volume with complete HT medium every 2–3 days.

9. In the third round of recloning, start replacing 50% of the well volume with normal complete DMEM using the same timetable.
10. Repeat testing of the supernatants and cell cryopreservation at each recloning step (*see* **Note 6**).
11. To expand the best hybridomas, transfer cells into 24-well plates and, when stable growth is achieved, into T25 and T75 flasks. Test and cryopreserve clones from each selection/adaptation cell culture step.
12. After stable growth of hybridoma population is well established, proceed to mass production in multiwell plates, tissue culture flasks, roller bottles, cell factories, etc.
13. Hybridomas are cryopreserved using standard freezing procedure in 90% fetal bovine serum mixed with 10% DMSO, 10^6–10^7 viable cells per vial.
14. Thaw hybridoma cultures at 37°C, followed by a transfer of cells into conical tubes, drop-wise addition of complete hybridoma medium, gentle centrifugation at 200 g for 10 min, and addition of 2 ml of complete medium to cell pellets. Transfer resulting cell suspension into 24-well plates containing full hybridoma medium.

3.4. Isotype Determination

1. The isotype of a mAb is a major parameter to consider its performance in end-use applications. mAb candidates should be isotyped at early stages of the hybridoma selection/expansion process.
2. Various isotyping kits available commercially can be used for primary and advanced hybridoma screening. We recommend a quick (1 h) and sufficiently sensitive (1 µg/ml) Immunotype ISO1 Mouse Monoclonal Antibody Isotyping Kit (Sigma) based on the treatment of nitrocellulose strips with 2 ml of a hybridoma supernatant.
3. Although over 90% of murine immunoglobulins contain kappa light chains, the kappa vs lambda light chain composition of each candidate mAb should be also determined.

3.5. Complement Fixation Testing

1. Use Rabbit Low-Tox-M Complement to test the ability of mAb candidates to fix and activate complement.
2. mAb concentration in the tested material should be equal or greater than 1 µg/ml, as determined by ELISA based Standard Vectastatin ABC kit.
3. Adjust 1 ml of mAb solution in serum-free hybridoma medium to pH 7.2–7.4 and incubate with 10^6 washed target cells at 4°C for 1 h. Wash twice with serum-free medium, incubate pre-treated cells with 1 ml of pre-diluted rabbit complement for an additional 1 h at 37°C, and calculate the percentage of dead cells treated with the mAb vs negative control (hybridoma medium with no mAb). Repeat two to three times using different lots and concentrations of the complement.

3.6. Ascitic Fluid Production

1. Inoculate (i.p.) BALB/c mice with 0.5 ml of Pristane.
2. Seven days after Pristane injection, inject (i.p.) 5×10^6 to 5×10^7 hybridoma cells pre-washed in serum-free medium.
3. Subsequently, check inoculated mice for abdominal distension every 3 days until the abdomen is filled with ascitic fluid.
4. Drain ascitic fluid from the abdomen.
5. Centrifuge the fluid at 500 g for 10 min and remove the fat and clotted material (*see* **Note 7**).
6. Aliquot and keep at −20°C until further analysis.
7. One BALB/c mouse can produce up to 10 ml of ascitic fluid, with mAb concentration of 5–10 mg/ml (*see* **Note 8**).

3.7. Antibody Production in Protein-Free Medium

1. After the third round of cloning and subsequent clone expansion, gradually replace the original hybridoma medium with PFHM II supplemented with 15% fetal calf serum. Culture cells in 25 or 75 ml flasks.
2. Gradually reduce the concentration of fetal calf serum to 0% by replacing complete PFHM II with serum-free PFHM II.
3. Re-clone the hybridoma population by serial dilution in serum-free PFHM II in 96-well plates, re-test for mAb production, expand and cryopreserve the best clones.
4. To achieve high mAb titers (up to 0.5 mg/ml), passage in PFHM II medium in plastic flasks, cell factories or roller bottles (*see* **Note 9**).

3.8. Antibody Purification

1. Depending on the experimental system and intended end-use applications, commercially available purification kits, mostly protein A, G and L based, are used to purify mAbs from hybridoma supernatants and ascites. Proteins A and G absorb the Fc portion of mouse mAbs, at pH 8.2 (Protein A) and pH 5 (Protein G).
2. All mouse IgG subclasses, except IgG1, can be purified using either of these two systems. Because of better stability of mouse mAbs at slightly basic pH, Protein A based purification systems are more advantageous than those based on Protein G.
3. Mouse IgG1 and IgM mAbs can be isolated using Protein L based kits.
4. Refer to Pierce's Web site www.piercenet.com for many useful mAb purification protocols.

4. Notes

1. An efficient immunization protocol, which avoids the neutralization of the antigen by circulating antibodies and thereby resulting in high numbers of proliferating antibody-secreting B-cells is essential in generating high-quality mAbs. Immunization schedules have to be optimized for each

antigen and end-use application, based on intermediate titration data and cell fusion outcomes.

2. It is critical that P3X63Ag8.653 cells remain resistant to 8-azaguanine and not capable of producing HGPRT to re-utilize hypoxanthine contained in hybridoma selection media. To eliminate HGPRT revertants and facilitate after-fusion growth of hybridoma clones, culture P3X63Ag8.653 cells in a medium supplemented with 8-Azaguanine and (in some protocols) HT.
3. Avoid protein contamination of PEG stock solutions and thoroughly wash splenocytes and P3X63Ag8.653 cells in protein-free medium. Free protein adversely affects the cell fusion process.
4. Unused mouse splenocytes can be cryopreserved and utilized later in additional cell fusions to improve end-use parameters of the desired mAb. Furthermore, additional fusions can be used to create heterohybridomas with myeloma cell lines from different animal species.
5. Re-test hybridoma clones periodically to retain mAb production and prevent overgrowing by hybridoma revertants which produce no mAb. Continued (over two months) expansion of pre-selected hybridomas is not recommended. Instead, new rounds of mass hybridoma expansion should be initiated using confirmed frozen cells from earlier passages.
6. As is the case with immunization schedules, all mAb screening protocols and procedures have to be optimized in preliminary experiments. It is imperative that screening be performed to address the intended end-use application. For example, if you need a mAb for flow cytometry staining of cell surface epitopes, it would not make sense to use western blotting or ELISA to select hybridoma clones. Such seemingly straightforward strategies rarely work well in real life, resulting in developing hybridomas producing superfluous mAbs.
7. After separation from ascitic fluids, living ascitic cells can be cryopreserved and used to generate more ascites. However, because of potential overgrowth by non-producing clones, ascitic cell populations cannot be passaged more than twice.
8. Although still hugely popular, production of large amounts of mAbs from mouse ascitic fluids is not, in most cases, the best possible approach. Manufacturing mAbs from tissue culture supernatants, especially using serum- or protein-free media, is a better alternative resulting in large-scale mAb preparations free of non-specific mouse immunoglobulins.
9. In many situations, it is worth investing additional effort in selecting hybridomas which can grow as suspension cultures. This ability makes hybridoma cell lines particularly suitable for industrial-scale production and, if needed, for using tissue culture supernatants without additional concentration and purification.

Potential Pitfalls in Monoclonal Antibody Development and Applications

Eugene Mechetner

1. Introduction

The field of monoclonal antibodies (mAbs) continues to expand upon its phenomenal success in producing valuable research tools and clinically potent immunological drugs with enhanced therapeutic window. In 2006, the worldwide revenues of clinical mAbs reached $20.6 billion. Currently, over 200 biotech companies are pursuing clinical mAb projects through R&D investment, corporate acquisitions, and licensing transactions ***(1)***. The same trend, albeit on a smaller scale, can be seen in the research and diagnostics arenas, where mAbs are widely used as irreplaceable tools for targeted detection, quantification, and imaging ***(2)***.

These significant achievements, combined with the relative ease of use of the currently well developed mAb technologies, attract a large number of new researchers from academia and industry. Increasing amounts of information are being generated, and the quality of research sometimes does not match the high standards of the field. This predicament is confounded by some bioreagent companies trying to cut corners to improve their profit margins in this very lucrative marketplace. Therefore, one of the major challenges for the newcomers is clear understanding of potential pitfalls and mistakes to avoid when developing and using mAbs tailored to specific end-use applications.

This chapter briefly describes the most common obstacles, and some solutions to them, in the design, development, and applications of mAbs. As shown in **Table 1**, these problems arise at each step of the mAb development process and should be understood and addressed promptly in order to maintain the project's momentum. Our goal is not to describe every possible experimental scenario, but to show the logic of the process and call for constant vigilance to successfully meet new and on-going challenges.

Table 1
Potential Pitfalls and Their Origin in the mAb Development Process

Problem Area	Specific Problem	Problem Origin	Cross-References in the Text
primary mAb characteristics	undesired specificity	inadequate immunization and clone selection protocols, resulting in mAbs with superfluous specificities and broad cross-reactivity	3.1. Development of the UIC2 Hybridoma; 3.2. UIC2 mAb Selection; 3.3. UIC2 mAb Characterization (*see* **Notes 1– 9, 14**)
	low sensitivity	low affinity mAbs due to insufficient selection between mAbs with the desired end-use specificity	
	cross-reactivity	inadequate or insufficient characterization of the pre-selected mAbs, resulting in mAbs directed against epitopes shared with other targets	
	target epitope limitations	suboptimal binding to epitopes of the antigen of choice due to flawed design of mAb selection and characterization protocols (e.g., ELISA vs IHC)	
mAb production and handling	cross-reactivity when using mAbs purified animal sources	in vivo contamination by animal immunoglobulins (e.g., from ascites or serum) and other reactive proteins	3.4. UIC2 Production and Handling (*see* **Notes 10, 11**)
	cross-reactivity when using mAbs derived from tissue culture supernatants	in vivo contamination by immunoglobulins from tissue culture media supplemented with animal sera	
	lack of reactivity in mAb preparations	loss of mAb secretion or overgrowth by non-producers due to insufficient re-cloning or passaging hybridoma cultures for extended periods of time	
	cross-reactivity with unrelated antigens	cross-contamination by unrelated mAb producing cells	
	low sensitivity after mAb purification	reduced mAb reactivity resulting from inadequate purification protocols (e.g., very low pH)	
	decrease or loss of activity during storage and transportation	loss of mAb reactivity due to flawed storage or transportation procedures	

mAb logistics	desired mAb is unavailable	restricted access to intellectual property or proprietary ownership limitations	3.5. UIC2 Commercialization and Logistics (*see* **Notes 12–14, 16**)
	poor performance by mAbs provided by commercial suppliers	multiple reasons, stemming mostly from low internal validation and insufficient QA/QC standards	
	mAb performance inconsistent with its specifications or associate protocols	incorrect information provided by the mAb source or related scientific literature	
	prohibitedly high cost of the desired mAb	mAb price limitations due to excessive monopoly in the marketplace, patent fees, high production expenses, or other commercial considerations	
mAb end-use applications	inconsistent or poor performance of the mAb of choice	wrong choice of the mAb, or flawed mAb information, or insufficient internal validation	3.6. UIC2 end-use applications: the UIC2 Shift Assay (*see* **Notes 8, 14–16**)
	poor performance of the chosen protocol	suboptimal choice of experimental modalities, or flawed mAb protocol information	
	poor performance of the chosen detection system	incorrect choice of the detection system or antigen treatment/ retrieval methodology	

Throughout the chapter, we discuss our studies on human multidrug resistance protein pump, P-glycoprotein (Pgp), encoded by the MDR1 gene. Since only 7% of the protein is exposed on the membrane, it had been proven notoriously difficult to generate mAbs against external epitopes of human Pgp ***(3)***. Despite multiple efforts, only a handful of mAbs reactive with extracellular epitopes had been developed, and none of these mAbs exhibited functional activity. In 1992, we described a mouse mAb, UIC2, that recognized extracellular conformational epitopes of human Pgp, inhibited the efflux of compounds transported by Pgp from MDR1 cells, and reversed the in vitro resistance to MDR1 chemotherapy drugs ***(4–7)***. These studies are discussed in the context of the mAb development process.

2. Materials

Standard reagents, cell culture maintenance and fusion media, as well as buffers used for the development and characterization of the UIC2 mAb, are described in detail in this book in the chapter "Mouse Hybridomas as an Entry-way to Monoclonal Antibody Design and Production."

2.1. Reagents

1. 25 µM vinblastine (Sigma, St. Louis, MO) solution was prepared in tissue-culture grade water, filtered through a 0.22 µ cellulose acetate unit (Corning, NY), and stored at 20°C.
2. Control chemotherapeutic compounds for vinblastine in the UIC2 shift assay: depending on solubility, stock solutions were prepared in water, DMSO, or RPMI-1640.
3. Control diluents for the UIC2 shift assay were added at the same final concentrations.
4. Fluorescent probes: 3,3-diethyloxacarbocyanine iodide, $DiOC_2$ and rhodamine 123 were purchased from Molecular Probes (Eugene, OR); Propidium Iodide (PI; Molecular Probes, Eugene, OR); all probes were diluted in 96% ethanol and stored at −70°C until use.
5. Radioimmunoprecipitation reagents: deoxycholic acid and phenylmethylsulfonyl fluoride (both from Sigma); ^{35}S-methionine (ICN, Costa Mesa, CA); immobilized protein A beads (Repligen, Cambridge, MA).
6. Sepharose-Protein A (Bio-Rad, Richmond, CA) was used for affinity chromatography.

2.2. Buffers

1. UIC2 shift Assay Buffer (AB): PBS supplemented with 2% fetal calf serum, FCS);
2. UIC2 shift assay Stop Buffer (SSB): PCS supplemented with 2% FCS and 0.01% sodium azide.

2.3. Cell Lines and Primary Cells

1. Mouse BALB/c 3T3-1000 cell line expressing human Pgp was derived by transfecting BALB/c 3T3 fibroblasts with human MDR1 cDNA in a mammalian expression vector pUCFVXMDR1, followed by a multistep selection of transfected cells for resistance to 1 µg/ml vinblastine ***(4)***.
2. Human K562/i cell line expressing human Pgp was developed using infection of human K562 leukemia cells with a recombinant retrovirus pLMDR1L6 carrying human MDR1 cDNA followed by subcloning, without cytotoxic selection, of high Pgp expressors, as determined by flow cytometry using functional MDR1 efflux assays ***(8)***.
3. Calibrating cell lines expressing pre-determined levels of Pgp (KB-8, KB-8-5, KB-8-5-11, and KB-V1) were selected from parental human KB-3-1 carcinoma by multistep selection with colchicine or vinblastine ***(1)*** (*see* **Note 1**).
4. Other cell lines utilized for the characterization of the UIC2 mAb were described in detail in (***refs. 4–8***).
5. UIC2 and UIC2/A hybridoma cell lines secreting the UIC2 mAb in complete or protein-free medium, respectively, can be purchased from ATCC (Accession No. HB11207 and HB11287) (*see* **Note 2**).
6. Peripheral blood lymphocytes (PBL) were isolated from buffy coats obtained from healthy volunteers by density gradient separation using Histopaque-1083 (Sigma, St. Louis, MO). PBL's were washed twice in RPMI-1640 and adjusted to10^6 cells/ml in RPMI-1640 for functional assays and flow cytometry analysis.

2.4. Antibodies

1. The following anti-Pgp mAbs were utilized to characterize the UIC2 mAb: MRK16 (IgG2a; kindly provided Dr. T. Tsuruo, University of Tokyo) directed against a human Pgp conformational epitope; HYB-241 and HYB-612 (both IgGl; a gift from L. Rittmann-Grauer, Hybritech), and mAb C219 (IgG2a; purchased from Centocor, Malvern, PA).
2. Affinity purified preparations of mouse myeloma protein UPC10 (IgG2a) were obtained from Sigma. All mAb samples were at least 95% pure IgG, as determined by SDS/PAGE. When necessary, mAbs were extensively dialyzed against phosphate-buffer saline (PBS) or Dulbecco's modified Eagle's medium (DMEM).
3. Unlabeled azide-free UIC2 mAb (mouse IgG2a) for Pgp functional assays can be purchased from Chemicon (MAB4334Z; Chemicon International, Temecula, CA) or purified using Protein A affinity chromatography from protein-free hybridoma supernatants (4). Phycoerythrin (PE) conjugated UIC2 can be also obtained from Chemicon (MAB4334PE) (*see* **Note 3**).
4. Control mAbs for flow cytometry were as follows: IgG2a-PE (negative mAb control to UIC2-PE)-from Sigma; IgG1-FITC and –PE, CD3-APC, CD4-FITC, CD8-FITC, CD14-FITC, CD15-FITC, CD19-FITC, CD45-FITC, CD14-PE, and CD54-PE-from Becton Dickinson Immunocytometry Systems (BDIS, San Jose, CA); IgG1-APC, IgG2a-APC and CD56-FITC-from ExAlpha (Boston, MA); unconjugated purified IgG1, IgG2a, and IgG2b (negative controls to primary mAbs

used at matching concentrations in indirect immunostaining); PE-conjugated goat anti-mouse IgG2a (for secondary detection) from Caltag (Burlingame, CA).

3. Methods

The UIC2 mouse-mouse hybridoma was developed using standard protocols described in detail in this book in the chapter "Mouse Hybridomas as an Entry-way to Monoclonal Antibody Design and Production," with some modifications introduced to address the specifics of the experimental system and match the properties of a desired anti-Pgp mAb to its intended end-use applications.

3.1. Development of the UIC2 Hybridoma

1. In order to optimize immunization and mAb selection protocols, we developed a mouse syngeneic cell line expressing high levels of human Pgp. Mouse BALB/c 3T3 fibroblasts (which were derived from and immunologically compatible with BALB/C mice used for hybridoma production) were transfected with human MDR1 cDNA using a mammalian expression vector (the pUCFVXMDR1 plasmid). The transfected cells were then additionally selected in growth media containing increased concentrations of vinblastine (up to 1 mg/ml). The resulting mouse cell line, BALB/c 3T3-1000, expressed high levels of human Pgp, and served as a well-matched (i.e. immunologically compatible with BALB/c mice, with the exception of human Pgp and. possibly, some other MDR related proteins) (*see* **Note 4**).
2. Syngeneic BALB/c mice were injected subcutaneously and intraperitoneally (i.p.) six times at two-week intervals with 10^7– 2×10^7 living and carefully washed BALB/C 3T3-1000 cells. The final boosting was done with 2×10^7 cells i.p., followed by slow injection of 5×10^6 10 cells intravenously to avoid anaphylactic shock. Four days after the last administration of BALB/c 3T3-1000, the spleen from one animal was removed and resulting splenocytes were fused with P3-X63-Ag8.653 partner myeloma cells.

3.2. UIC2 mAb Selection

1. Because our goal was to develop a functional mAb recognizing functional Pgp expressed on the outer cell membrane, we chose indirect immunofluorescence microscopy as the ultimate selection methodology for primary clones. Although more technically challenging than other high throughput techniques (e.g., ELISA), this methodology gave a direct answer to the experimental question at hand. Hybridoma supernatants were screened by indirect immunofluorescence microscopy, in parallel, on 12-well multitest slides (ICN) with living BALB/c 3T3 or BALB/c 3T3-1000 cells. One hybridoma clone of 556 clones tested produced a mAb, termed UIC2, which was reactive with Pgp expressing BALB/c 3T3-1000 but not with the parental BALB/c 3T3 cells (*see* **Note 5**).
2. A stable hybridoma line secreting the UIC2 mAb (IgG2aκ) was established through three additional rounds of subcloning by end-point dilution and screening of the

supernatant fluids. At each point in time, the fastest growing clones that produced the highest levels of UIC were selected in indirect immunofluorescence.

3.3. UIC2 mAb Characterization

1. UIC2 was purified from tissue culture supernatants and ascitic fluid by Sepharose-Protein A affinity chromatography. UIC2 mAb, tested by SDS-PAGE, was at least 95% pure IgG and did not fix rabbit complement in complement-mediated cytotoxicity tests.
2. To avoid nonspecific cross-reactivity from irrelevant mouse immunoglobulins, UIC2 purified from protein-free tissue culture supernatants was used for further mAb characterization (*see* **Note 6**).
3. As shown in **Table 2**, the UIC2 mAb reacted exclusively with human Pgp expressed on human and mouse cells and did not recognize mouse Pgp. UIC2 reactivity with Pgp from primate cells (including African green monkey) was later confirmed by immunofluorescence and IHC. Characteristically, UIC2 bound to human Pgp expressors in a dose-dependent fashion.
4. After UIC2 was characterized in morphological tests, a definitive proof of UIC2 specificity for human Pgp was provided by radioimmunoprecipitation (**Fig. 1A**). 5–10 × 10^6 BALB/c 3T3-1000 cells were metabolically labeled with 50 µCi/ml

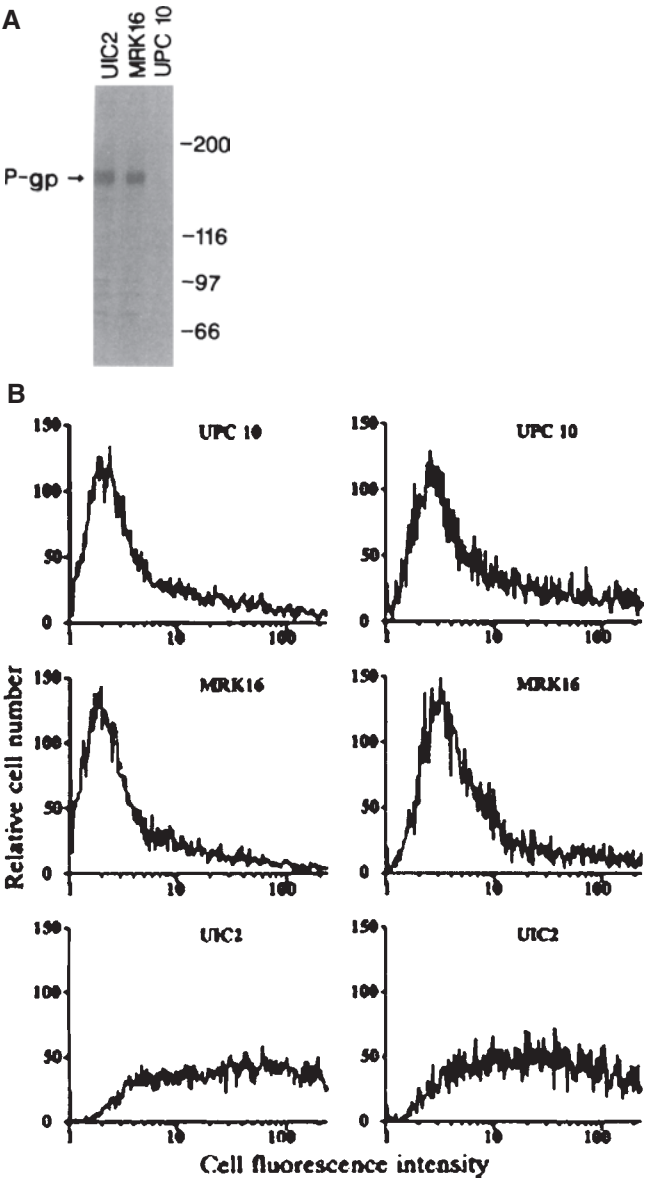

Fig. 1. Characterization of the UIC2 mAb in radioimmunoprecipitation (**A**) and flow cytometry (**B**) (from reference 4).

of ^{35}S-methionine in methionine-free DMEM supplemented with 10% FCS for 10–18 h. The cells were rinsed with PBS, and purified UIC2 was added in 2.6 ml of PBS to a final concentration of 20 μg/ml. After a one-hour incubation at room temperature, the cells were rinsed with PBS and then lysed with a detergent solution

containing 0.2% deoxycholic acid and 0.2 µM phenylmethylsulfonyl fluoride in PBS for 2–4 min. The lysates were pre-cleared by microcentrifugation for 15 min at 4°C and incubated with immobilized protein A beads for one hour at 4°C. After five washes with the lysis solution, the precipitated protein was analyzed by SDS/PAGE in 7.5% gels.

5. The UIC2 mAb recognized a protein of 170–180 kDa expressed in MDR1 cells. This protein co-migrated in the gel with a band immunoprecipitated by another Pgp-specific mAb (MRK16) under the same conditions, thereby directly confirming that the antigen recognized by UIC2 mAb was human Pgp ***(4)***.
6. Solubilization with deoxycholate was critical for UIC2 immunoprecipitation. Solubilization with a more common detergent, CHAPS, allowed for efficient immunosedimentation of Pgp by MRK16 but effectively abolished the reactivity of Pgp with the UIC2 mAb. This result suggested (and later proved directly by epitope mapping) that UIC2 mAb and MRK16 mAb recognized different Pgp epitopes exhibiting different sensitivity to detergents (*see* **Note 7**).
7. Similarly to the MRK16 mAb, UIC2 did not react with denatured Pgp on Western blots, including conditions where human Pgp was detectable by the C219 mAb which recognizes an intracellular epitope of this protein ***(9)***. The choice of UIC2 characterization technique and the revealed target epitope restrictions were vital for decisive characterization of this mAb and its end-use applications (*see* **Note 8**).
8. The only remaining piece of evidence proving the functional nature of the UIC2 mAb was obtained in flow cytometry experiments on living multidrug resistant cells (**Fig. 1B**). 10^6 cells (K562/i or CEM-VLB100) expressing human Pgp were incubated with different anti-Pgp mAbs at 20 µg/ml in 3–5 ml of serum-free medium for 30 min at 0°C, washed twice, and loaded while with 0.5–1.0 µg/ml of Rh123 for 10 min for one hour. Rhodamine 123 (Rh123) is a mitochondrial fluorescent dye that is extruded from living cells by the Pgp membrane pump. 20 µg/ml of UIC2 was also added to the dye-free medium during the efflux period at 37°C. Dye retention after efflux was measured by fluorescence flow cytometry vs MRK16, or control IgG2a (mAb UPC10), or UIC2 pre-absorbed with anti-mouse IgG or anti-mouse IgM (negative isotype control) adsorbents.
9. UIC2 mAb did not alter the accumulation of a Rhodamine 123 at 0°C. However, UIC2 significantly inhibited subsequent efflux of Rh123 at 37°C. In sharp contrast, under the same conditions, MRK16 and two other anti-Pgp mAbs did not inhibit the efflux of Rhodamine 123 although the intensity of immunofluorescent staining of all tested cell lines by these mAbs was essentially the same. The inhibitory effect of UIC2 were abrogated by pre-absorption with the anti-mouse IgG (but not with control anti-mouse IgM) sorbent. These studies ***(4,7)*** directly demonstrated that the material responsible for inhibition of Rhodamine 123 efflux was the UIC2 mAb (*see* **Note 9**).

3.4. UIC2 Production and Handling

1. For clinical and commercial applications, we developed a UIC2 subclone, UIC2/A, capable of secreting high mAb concentrations in serum-free, protein-free culture media.

2. UIC2/A (ATCC accessioning number HB11287), was selected by gradually replacing the original growth medium with PFHM II Protein-Free Hybridoma Medium after the fourth round of recloning.
3. After one month of cultivation in the protein-free medium, UIC2 hybridoma cells had lost their ability to grow while attached to the flask surface. At that point, hybridoma cells were cloned by serial dilution in unmodified PFHM II in 96-well plates and supernatants from the best wells were tested for antibody production by indirect immunofluorescence. A clone that gave the strongest immunofluorescence signal was selected, transferred to a 25-ml flask, and the cell line was passaged as a suspension culture in PFHM II medium in 25-ml, to 75-ml, and finally to 175-ml flasks. When supplemented with 25 mM HEPES, UIC2/A could be cultivated in roller bottles, producing large volumes of medium with high UIC2 titers (0.2–0.4 mg/ml).
4. Indirect immunofluorescence was used to verify that UIC2/A hybridoma was secreting the mAb with the specificity and isotype (IgG2a) identical to those produced by parental UIC2 (*see* **Note 10**).
5. As shown in **Fig. 2**, the UIC2 mAb from UIC2/A supernatants was >80% pure without any purification (lanes 6–9). After a single-step purification on a Protein-A affinity column, the purity of the UIC2/A mAb was close to 100% (lanes 3 and 4), similar to that of the Protein A-purified mAb from ascitic fluids produced by parental UIC2 hybridoma (lanes 1 and 2).
6. UIC2 was stored in aliquots of 1–5 mg per vial at −20°C. Conveniently, this mAb is stable for months when stored under sterile conditions at 4°C, in PBS or culture medium at neutral pH at 0.5 mg/ml–10 mg/ml concentrations. In this form, UIC2 can be used for functional in vitro experiments.
7. The UIC2 mAb can be safely shipped in plastic vials at ambient temperature using overnight postal delivery or on dry ice for longer periods of time (*see* **Note 11**).

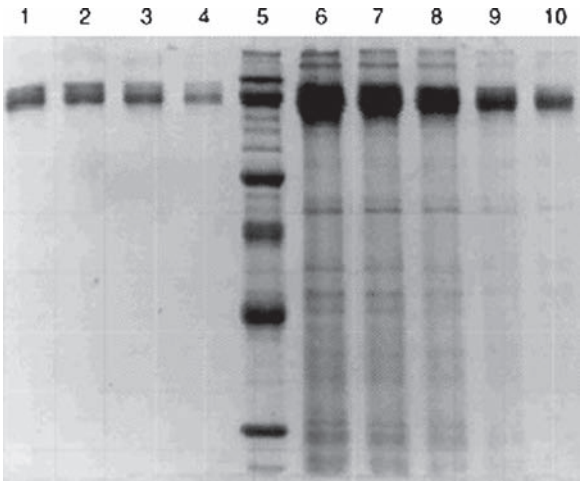

Fig. 2. Electrophoresis separation, under non-reducing conditions, of UIC2 and UIC2/A mAb preparations.

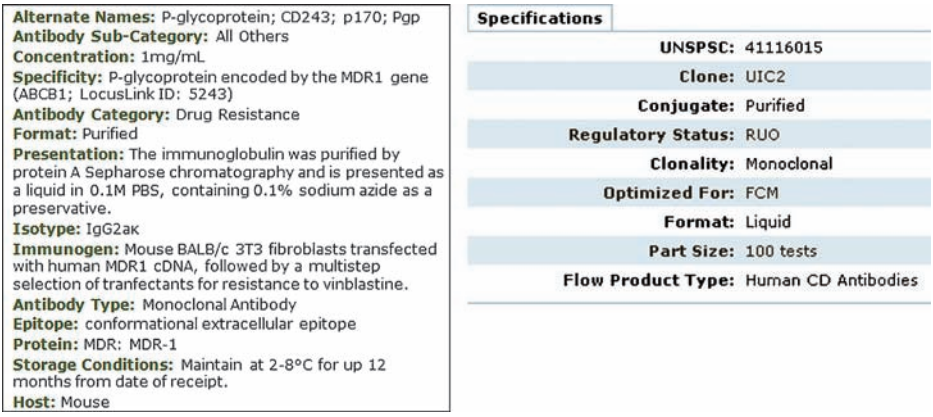
3.5. UIC2 Commercialization and Logistics

1. The ability of the UIC2/A cell line to produce high titers of the UIC2 mAb in protein-free media makes this cell line particularly useful for industrial-scale production.
2. When manufactured as a commercial research reagent by Chemicon International, gram amounts of the UIC2 antibody were readily produced from UIC2/A using the INTEGRA (Chur, Switzerland) cell line perfusion system and the Cellex (Minneapolis, MN) ACUSYST-miniMAX bioreactor (*see* **Note 12**).
3. In many applications (e.g., immunofluorescence and IHC staining, cell separation, immunoprecipitation) UIC2/A supernatants can be used without additional purification or concentration, resulting in major cost reductions without compromising the quality of mAb preparations.
4. The UIC2A mAb is currently available as a research reagent from Chemicon International (a division of Millipore Corporation), Beckman Coulter Inc., and Meridian Life Sciences, Inc., in the form of unconjugated and Phycoerythrin-conjugated preparations. Additionally, sterile and preservative-free UIC2 formulation and biotin labeled UIC2 are available from Chemicon (*see* **Note 13**).
5. One of the most convenient search engines to identify mAbs and find associated information and protocols is hosted by Biocompare, a free Web site at http://www.biocompare.com/jump/2045/Antibodies.html. A keyword search for "UIC2" would yield all commercial sources of the mAb and provide links to UIC2 product information (including pricing) and company product pages.
6. **Fig. 3** presents two examples of UIC2 product information and specifications from Chemicon and Beckman Coulter. Note detailed description of mAb presentation, concentration, immunogen, and storage conditions in Chemicon's specifications.



Alternate Names: P-glycoprotein; CD243; p170; Pgp
Antibody Sub-Category: All Others
Concentration: 1mg/mL
Specificity: P-glycoprotein encoded by the MDR1 gene (ABCB1; LocusLink ID: 5243)
Antibody Category: Drug Resistance
Format: Purified
Presentation: The immunoglobulin was purified by protein A Sepharose chromatography and is presented as a liquid in 0.1M PBS, containing 0.1% sodium azide as a preservative.
Isotype: IgG2aκ
Immunogen: Mouse BALB/c 3T3 fibroblasts transfected with human MDR1 cDNA, followed by a multistep selection of tranfectants for resistance to vinblastine.
Antibody Type: Monoclonal Antibody
Epitope: conformational extracellular epitope
Protein: MDR: MDR-1
Storage Conditions: Maintain at 2-8°C for up 12 months from date of receipt.
Host: Mouse

Specifications

UNSPSC:	41116015
Clone:	UIC2
Conjugate:	Purified
Regulatory Status:	RUO
Clonality:	Monoclonal
Optimized For:	FCM
Format:	Liquid
Part Size:	100 tests
Flow Product Type:	Human CD Antibodies

Fig. 3. Specifications for unconjugated UIC2 mAb preparations provided by Chemicon International (left panel) and Beckman Coulter, Inc. (right panel).

In contrast, Beckman Coulter's specifications lack most of the mAb specific description, including such essential information as UIC2 presentation and concentration. This information, or lack thereof, is critical for a researcher to identify the best source of the desired mAb and the most appropriate experimental and detection systems related to this mAb (*see* **Note 14**).

7. Similar Internet based information based approaches can be used to reduce costs associated with the mAb of choice. For example, list prices for 100 tests of unconjugated UIC2 are $410, $430 and $597 from Chemicon, Beckman Coulter, and Meridian Life Sciences, respectively. Combined with other factors (such as product specifications, company's reputation, time of delivery, history of backorders, shipping costs, etc.), this information can be utilized by mAb users to optimize the quality and costs of their studies.

3.6. UIC2 End-Use Applications: The UIC2 Shift Assay

1. The UIC2 mAb is currently widely used by academic and industry researchers to detect human Pgp using flow cytometry, IHC, immunoimaging, and a variety of mAb based biochemical and cell based assays. Another important area of UIC2 uses is functional studies of Pgp in normal and transformed human cells.
2. Because UIC2 does not recognize mouse and rat Pgp's, this mAb can be successfully used to detect human Pgp in human xenotransplants without worrying about non-specific cross-reactivity from rodent tissue background (*see* **Note 15**).
3. Yet another advantage of using UIC2 in functional studies is its ability to enhance specific Pgp staining in the presence of Pgp-transported drugs at physiologic conditions. We found that the UIC2 mAb inhibited efflux of Rhodamine 123, $DiOC_2$, and many other fluorescent dyes and drugs transported by Pgp from MDR1 cells. Additionally, UIC2 reversed the in vitro resistance of MDR1 cells to Pgp-transported drugs in a dose-dependent fashion. Schinkel et al. demonstrated that observed variations in binding specificity between UIC2 vs other anti-Pgp mAbs correlated with functional differences in their ability to inhibit Pgp-mediated drug efflux ***(4–8)***.
4. Based on these phenomenona, we developed and validated a new flow cytometry test, the UIC2 Shift assay, which provides enhanced quantitative detection of Pgp expression and function in human MDR1 cells. The UIC2 shift assay will be described below as an example of valuable end-user application based on unique properties of the UIC2 mAb and potential pitfalls associated with this test.
5. UIC2 shift assay: load target cells (in this case, human PBL) with $DiOC_2$ at a final concentration of 1 µg/ml in RPMI-1640 on ice for 15 min in the dark. Immediately after loading, wash the cells twice in ice cold SSB, resuspend at 37°C in SSB, transfer to tissue culture flasks (10^6 cells in 10 ml), and allowed to efflux at 37°C in 5% CO_2 for 3–5 hr (typically, 15 min to one hour for high Pgp expressors and two to five hours for low Pgp expressors). Incubations at 4°C or with known Pgp substrates (e.g., vinblastine or verapamil) are to be included in the test as efflux background controls. After efflux, wash the cells twice with ice-cold SSB, and analyze by flow cytometry at 4°C in SB in the presence of 1 µg/ml PI.

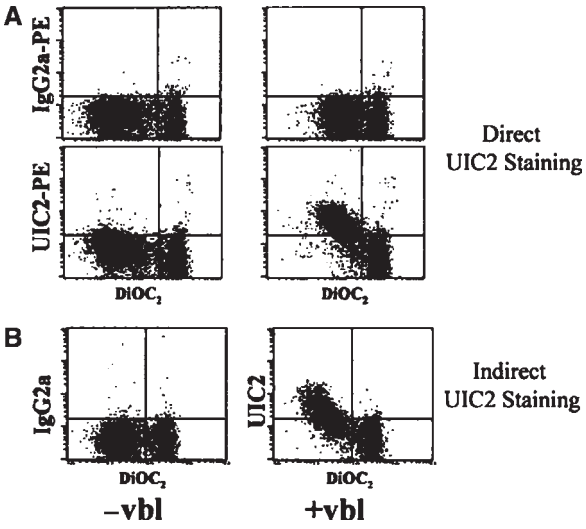


Fig. 4. Direct (**A**) and indirect (**B**) flow cytometry analysis of human PBL with the UIC2 mAb (from reference 7).

6. As demonstrated in **Fig. 4**, UIC2 shift (i.e., enhanced Pgp staining in the presence of vinblastine) was observed mostly in $DiOC_2$-dim PBL in the direct and indirect versions of the assay. Pgp staining intensity was directly proportional to the degree of $DiOC_2$ efflux. No enhancement was observed in PBLs incubated with control IgG2a-PE in the presence of vinblastine at 37°C.
7. The intensity of indirect conventional UIC2 immunostaining (**Fig. 4B**, right graph) was, as expected, significantly higher than that of direct immunostaining with UIC2-PE (**Fig. 4A**, lower left graph). However, the UIC2 shift assay with directly labeled UIC2-PE only (**Fig. 4A**, lower right graph) produced Pgp immunostaining which was as sensitive as conventional indirect immunostaining. The latter observation exemplifies the ultimate end-use application of UIC2 to enhance the detection of human Pgp in living cells.
8. At all stages of the UIC2 shift development process and during its use in clinical diagnostics, all experimental protocols and reagents were internally validated and monitored for consistent performance (*see* **Note 16**).

4. Notes

1. The use of calibrating cell lines, i.e. a series of cell lines derived from one parental antigen-negative cell line and expressing different levels of the target antigen, is highly recommended at all stages of mAb development and characterization. Some examples of utilizing Pgp calibrating cell lines to validate UIC2 were presented in references 4 and 6.
2. ATCC (www.atcc.org) and other noncommercial institutions, such as the Developmental Studies Hybridoma Bank at the University of Iowa (DHSB,

http://dshb.biology.uiowa.edu/), can be extremely useful in all aspects of mAb research and applications. Not only these sources are publicly accessible internationally, but they also provide a wide variety of hybridoma cell lines at low prices that fit even the toughest research budget. In addition, consider requesting hybridoma cells or antibody preparations directly from the research group who developed and reported the mAb.

3. Azide-free mAbs, and preservative-free mAb preparations in general, are used mostly for functional studies and imaging in various in vitro models. These preparations are usually dialyzed against cell growth media, sterilized via filtration, kept sterile at 4°C for weeks and even months, and can be added to cell cultures directly from the mAb storage vial. Total protein concentrations should be maintained in the 0.5–10 mg/ml range using concentrated mAbs or inert carrier proteins (e.g., culture-grade bovine serum albumin).
4. Syngeneic mouse cells of BALB/c origin expressing the antigen(s) of choice are highly recommended for immunization and primary clone selection to generate mAbs against non-mouse functional epitopes. Some significant advantages of this approach include relatively safe and efficient immunization schemes, low numbers of irrelevant primary clones, and further uses of these cells for characterization and internal validation purposes.
5. Accurate choice of primary clone selection techniques is one of the most critical components of mAb development process. Some researchers and mAb companies attempt to cut corners and use deceptively simple and inexpensive clone selection techniques (i.e., ELISA when developing mAbs for IHC or flow cytometry protocols) that are incompatible with the end-use application. Such efforts usually result in the production of inadequate mAbs and, in general, waste of precious time and resources. The general rule of thumb is that your procedure for primary clone selection should be identical or very similar to your end-use application. In other words, if your objective is to generate a mAb that will work well in flow cytometry on live cells, choose the resolving flow cytometry or immunofluorescent techniques and avoid more simple, but not resolving ELISA.
6. Polyclonal immunoglobulins from blood and interstitial fluids, which are present throughout the body including ascitic fluids, as well as non-immune carrier proteins that bind non-specifically and unpredictably to a variety of antigens, are arguably the most common origin of cross-reactivity in research and, especially, commercial mAbs purified from mouse, rat, hamster and rabbit ascitic fluids. Another potential source of cross-reactivity is serum immunoglobulins from tissue culture supernatants when using adult bovine serum as a supplement. These contaminants essentially defeat the purpose of mAbs and should be avoided at all costs. Therefore, mAb

selection and production in serum-free, protein-free media are strongly recommended.

7. It is not unusual for mAbs directed against complex conformational epitopes to be completely inactive in Western blotting and other biochemical techniques resulting in "unphysiological" modifications of the target antigen. Choosing the right mAb characterization methodology (e.g., radioimmunoprecipitation vs Western blotting) and resolving experimental conditions (e.g., using the right mix of detergents in the case of UIC2) will, more often than not, overcome this obstacle.
8. Characteristically, several commercially available anti-Pgp mAbs, including mAb C219 and the widely used mAb JSB-1, have proven to exhibit cross-reactivity with c-ERB2 ***(10, 11)*** and pyruvate carboxylase ***(12)***, respectively. To avoid this pitfall, UIC2 epitope specificity was extensively characterized and subsequently internally validated for each intended application.
9. It was the multifaceted UIC2 characterization, using methodologies and detection systems providing direct answers to experimental questions at hand, that allowed for successful commercialization of the UIC2 mAb and its high efficiency in end-use applications. Same logic applies to the development of therapeutic mAbs.
10. Continuous monitoring of mAb-producing cultures and, if needed, recloning are required to maintain stable high levels of mAb production and avert cross-contaminations by extraneous hybridomas. Long-term passaging of initial hybridoma cultures should be avoided to prevent overgrowth by non-producing clones. Frequent freezing and short (weeks at a time) manufacturing cycles will help to obviate these problems.
11. Loss of mAb activity sometimes occurs as a result of mAb storage and transportation, especially during summer time when packages are exposed to higher temperatures both in the plane and on the ground.
12. The described low-cost procedures can be used to produce large amounts of mAbs at practically any academic lab or core facility. The key to large-scale, low-cost manufacturing is having a hybridoma that had been selected for growth in serum-free, protein-free media and for efficient production of the mAb. In the case of UIC2, 10 mg of the mAb could be readily harvested from tissue culture supernatants from just one 24-well plate. Scaling up to gram levels was also achievable using relatively inexpensive plastic cell factories or roller bottles.
13. The right choice of mAb presentation and, in particular, labeling for subsequent secondary detection are critical for efficient end-use applications. For example, labeling UIC2 with FITC produced weak and practically useless fluorescent conjugates for flow cytometry studies, while labeling

with Phycoerythrin resulted in reliable and consistent direct and indirect secondary detection. As discussed above, azide-free presentation of UIC2 was necessary for functional studies. Consequently, only commercial UIC2 preparations suitable for its end-use applications were prepared and marketed by UIC2 mAb suppliers.

14. Examples of inaccurate and simply incorrect information provided by commercial mAb sources are many and diverse, and can be a challenging subject for a separate paper. In general, the researcher should be always vigilant and must always cross-reference mAb information provided by the company with the original publications, subsequent studies, and other publicly available sources (e.g., vast NIH resources; www.pubmed.gov). Extensive internal validation of mAbs provided by different companies is also a must.
15. The ability to use mAb against human antigens in the rodent tissue environment is yet another advantage of utilizing transduced syngeneic mouse cells for immunization and selection. Equally importantly, resulting mAbs can be readily utilized in animal research and pre-clinical studies using mAbs with potential for use in therapeutic applications.
16. As discussed above, extensive internal validation of the mAb and related protocols is essential for its efficient utilization in end-use applications. For example, information for "prediluted" mAb preparations provided by some commercial sources is often incomplete and deceptive in that the mAb arrives in its final form and no internal validation is suggested. In this context, each and every new mAb preparation or protocol should be internally validated and cross-verified against previous mAb batches using the same detection technique.

Recombinant Antibody Expression and Purification

Achim Knappik and Ralf Brundiers

1. Introduction

1.1. Recombinant Antibodies

Developments in the fields of bacterial expression of functional antibodies and methods to select genes from a library by using the phenotype of the encoded polypeptide have been a breakthrough in antibody technology. Today, phage display in combination with antibody gene libraries is widely used to select *E. coli* host cells that express desired antibody fragments. Such gene libraries are typically produced either from natural sources (e.g., from the spleen of an immunized animal or from plasma cells of human donors) or generated by genetic engineering. The latter has been used to create naïve libraries based on one or more antibody VH and VL gene segments that are diversified by cassette mutagenesis or similar approaches. Such libraries are typically unbiased and can be used for any given antigen ***(1–3)***. Modern naïve libraries are generally large (more than 10^{10} members), contain only few non-functional members, yield antibodies that are well expressed in *E. coli* (more than 1 mg of purified material per liter of culture) and are designed to allow further affinity maturation, if needed. Phage display is then most often used to select desired antibodies from such libraries (*see* ***refs. 4*** and ***5*** for reviews).

Recombinant antibodies offer many advantages over traditionally generated monoclonal antibodies that are only beginning to be explored. These advantages stem from two properties: the ability to assess the antibody DNA within an *E. coli* environment that allows the use of well-known genetic engineering methodologies, and the use of antibody fragments rather than intact IgG molecules, because of their smaller size and because of the absence of the Fc domain. The latter eliminates nonspecific binding to cellular Fc receptors and avoids other, sometimes unwanted, effects caused by the Fc part of intact IgG.

1.2. E. coli Expression of Recombinant Antibodies

Since antibodies contain disulfide bonds that are necessary for maintaining their overall structure and binding activity, the folding of the molecule has to take place under oxidizing conditions. Gram-negative *E. coli* provides an oxidizing compartment between the cytoplasmic and outer membrane, the so-called periplasmic space. Hence, the attachment of bacterial leader sequences to the N-terminus of an antibody fragment directs the translated antibody chain(s) into the periplasmic space by the bacterial transport apparatus, where folding can take place under oxidizing conditions. To achieve secretion of antibody Fab fragments, both chains must be equipped with signal sequences. In order to cosecrete both chains to the bacterial periplasm, they are best arranged in an artificial operon, thereby being coordinately regulated by one promoter (**Fig. 1**). In most current systems, the antibody light chain genes precedes the heavy chain gene segment in the two-cistron system, leading to higher expression levels of the light chain. This ensures that the amount of heavy chain without light chain partner is minimized, since unpartnered heavy chain is mostly insoluble, which

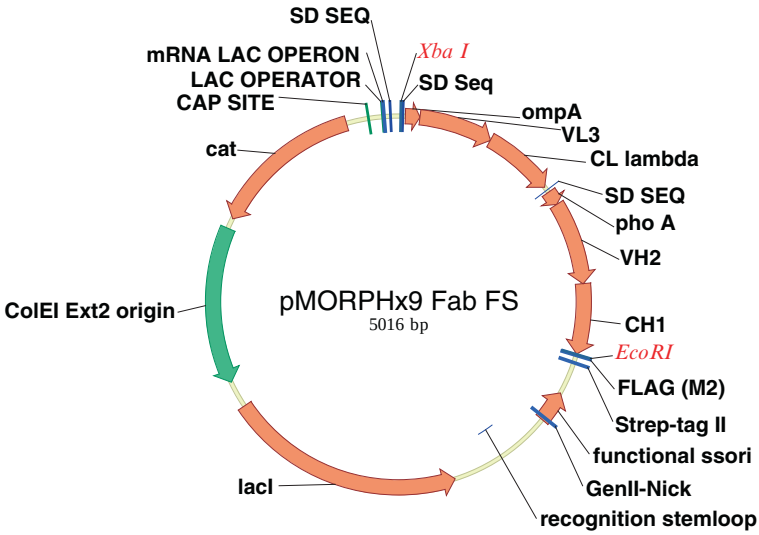

Fig. 1. Schematic view of an antibody Fab expression vector. Features are: a high-copy ColEI origin of replication, a chloramphenicol resistance gene (cat), a lac-promotor/operator region that is inducible by IPTG, and a lacI gene for repression of transcription when the inducer is absent. The Fab gene is arranged as bicistronic unit, flanked by the unique restriction sites XbaI and EcoRI. Each chain is equipped with signal sequences (ompA for the light chain and phoA for the heavy chain). Tags and other functional elements are encoded in frame after the EcoRI site, leading to fusions at the C-terminus of the CH1 domain. In the example shown here, the Fab is fused to a FLAG and and a StrepII tag.

induces a stress to the cell. Since purification tags are fused to the heavy chain (see below), excess light chain will not be purified.

The folding of periplasmic antibody protein does not proceed quantitatively for many antibody fragments. The yield of this process depends on external factors such as temperature, but also on the type of fragment and antibody primary sequence. Modern synthetic antibody libraries use stable and well-expressed antibody frameworks built form codon-optimized sequences, leading to yields of purified active material well above 1 mg per L of standard shaking flask culture (**Fig. 2**). Such expression yields are sufficient to allow screening of antibody expressing clones after library selection by cultivation in 384 well microtiter plates. After induction of antibody expression, E. coli cells are subsequently lysed (either gently by an osmotic shock procedure to release the periplasmic content, or simply by adding lysozyme). The antibody containing lysates can then be tested by ELISA or other methods for the presence of antigen-specific antibody material. Screening by ELISA is one of the most used and well-established methods to screen antibody expressing clones. Target molecules can be directly coated onto 384-well microtiter plates, or biotinylated target antigens can be captured onto streptavidin plates. Bacterial extracts are added to the micro titer plates and bound antibody fragments are detected with enzyme-conjugated polyclonal antiserum or with antibodies directed against

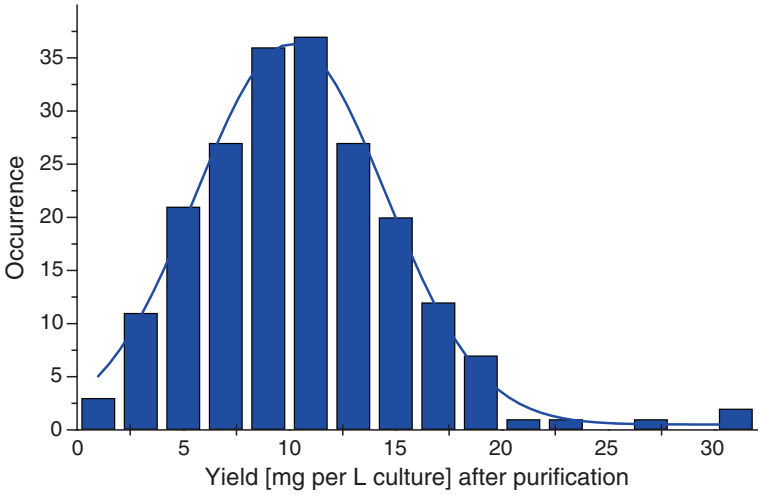

Fig. 2. Histogramm of expression yields after purification from 206 independent clones obtained from the HuCAL® library after phage display selections. Antibodies have been expressed either in monovalent or bivalent Fab format and purified using one-step NiNTA affinity chromatography. Expression yields follow an approximate Gaussian distribution with a center at 10 mg per liter culture volume.

the C-terminal tags provided by the vector (see **Fig. 1**). Often positive hits are sequenced to determine the number of unique antibodies from a selection. The process described above can be automated to a large extent using standard pipetting robots, thereby enabling a massive increase in throughput ***(6)***, one of the advantages over animal-based methodologies. Screening of recombinant antibody fragments on whole cells ***(7)*** and tissues ***(8)*** have also been reported.

After screening, the antibodies can be individually expressed and purified in larger scale. Soluble antibody fragments produced by bacterial colonies isolated as explained above are typically purified by one-step affinity chromatography using peptide tags that have been fused to the C-terminus of the antibody fragment. After purification, the material can be mostly aliquoted and stored frozen, similar to traditional monoclonal antibodies.

1.3. Antibody Formats

The two major types of recombinant antibody fragments that are usually expressed in *E. coli* are named single-chain Fv (scFv) and Fab.

By introducing a short sequence encoding a peptide linker between the VH and the VL gene segments a single polypeptide chain is created that folds into the so-called scFv antibody fragment ***(9)***. A variety of linkers has been tested, and the most frequently used one is a repetition of the sequence Gly_4Ser with 3 or 4 units. It has been shown that shortening the linker between the two variable domains leads to so-called diabodies ***(10)***, which pair with the complementary domains of another scFv and thereby promote the assembly of dimeric or bispecific molecules with two functional antigen binding sites. Since scFv is encoded by a single gene, expression systems do not need coordinated expression of two chains as with the heterodimeric Fab molecule. In addition, in vitro display systems, such as ribosome display ***(11)*** need single polypeptide chains as library members, in order to avoid swapping of chains and thereby loss of the phenotype – genotype linkage.

Another commonly used recombinant antibody fragment is the Fab fragment (**Fig. 3**), which is composed of the truncated heavy chain containing the variable and the first constant region (the so-called Fd fragment), and the entire light chain composed of the variable and constant domain. These two polypeptides are either covalently linked by disulfide bridges at the C-terminus, or are produced in higher yields without those, which nevertheless lead to highly stable H/L heterodimers ***(7)***. Advantages of the Fab fragment are (i), the similarity with the full-length Ig molecule, since it does not contain an artificial linker sequence which might interfere with the antigen binding site, (ii), the fact that well-established anti-Fab detection antibodies can be used and (iii), the fact that it is truly monovalent (which is not always the case with scFv fragments). The latter property is important for example when avidity effects should be avoided, e.g. when the intrinsic binding affinity needs to be determined.

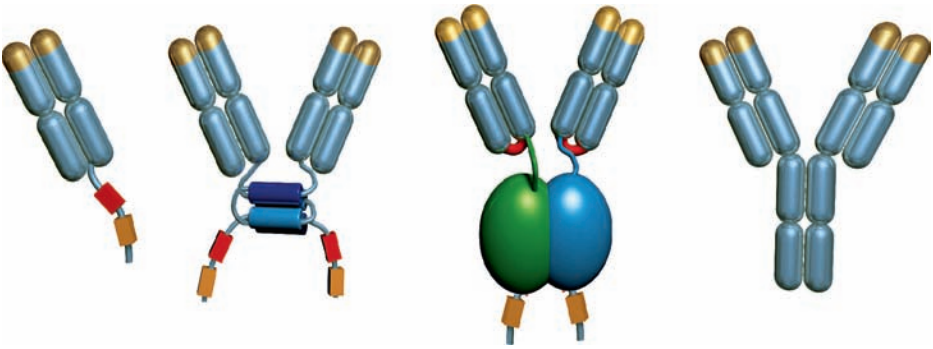

Fig. 3. Comparative schematic view of monovalent Fab with two peptide tags, bivalent Fab (dimerized by a helix-turn-helix motif) with two peptide tags, Fab fused to bacterial alkaline phosphatase (BAP) with one peptide tag, and IgG1. The region involved in antigen binding is shown in golden color. Note that the BAP fusion leads to bivalent Fab molecules, since BAP is a homodimer.

Antibody fragments usually have the same antigen-binding specificity as the corresponding intact antibody, since the complete antigen binding site is present. However, multivalency, which is a very effective means of increasing the functional affinity (avidity) to a surface-bound or polymeric antigen, is a very general property of antibodies. IgG contain two binding sites per molecule, which increases the apparent affinity (avidity) compared to a Fab or monomeric scFv antibody fragment. The most noticeably example is IgM, which carries 10 recognition binding sites. For particular applications, multivalency might be advantageous or even required. Thus, bivalency and further multivalency have been also engineering for recombinant antibody fragments. ScFv or Fab fragments can be dimerized by linking them to a small modular dimerization domain in the form of one or two amphipatic helices ***(12)***. For example, the leucine zipper from the yeast transcription factor GCN4 has been shown to be suitable as a dimerization device. These "miniantibodies" assemble in dimeric form in E. coli with typically no loss in final yield, and the binding performance in assays like IHC or Western blot is mostly indistinguishable from a whole antibody in avidity. Antibody fragments fused to the small tetramerization domain of p53 can form tetrameric molecules ***(13)***.

Genetic fusions to enzymes like bacterial alkaline phosphatase (BAP) connect the binding and detection capability into one molecule (*see* **Fig. 3**). Even such fusions, which lead to molecules of the size of full-length IgG antibodies (about 150 kDa) can be expressed in *E. coli* with almost the same yields as smaller antibody fragments. Since the BAP is a homo-dimer, the resulting molecules are bivalent. Many other antibody fusions for various applications have been described in the literature, such as core streptavidin for avidity increase,

beta-lactamase for prodrug activation or interleukin-8 fusion for neutrophil activation, to name a few. Clearly this field is still in its infancy.

1.4. Peptide Tags for Purification and Detection

Purification of whole antibodies has mostly relied on antigen-affinity chromatography or affinity chromatography using bacterial immunoglobulin-binding proteins such as proteins A and G. However, the usefulness of this strategy for antibody fragments is limited, as these bacterial proteins bind mostly to the constant domains. However, the generation of antibodies *in vitro* enables manipulation of their sequences, for instance by linking desired sequences such as affinity tails to the antibody framework regions. Such affinity tails are often short peptide tags, which are used for purification, but also for antibody immobilization and detection. Typically, such fusions are cloned in-frame at the 3′-end of the antibody gene, leading to a maximum distance in the native fusion protein between the antigen-binding site and the additional functionality. A few such peptide fusions will be highlighted here:

Peptide tags are mostly used for affinity purification purposes. Most tags that have been generally developed for recombinant protein purification will

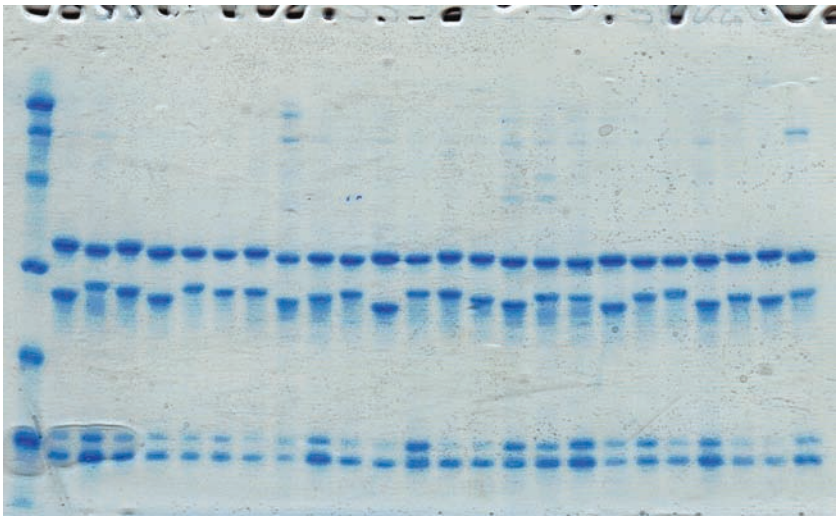

Fig. 4. Coomassie-stained SDS gel (15%, Criterion gel, Bio-Rad, low range marker, Bio-Rad) of 24 different His-tagged Fab antibodies after NiNTA purification, all in the bivalent format. The amount of 1.5 µg total protein was loaded on each lane. The heavy chain (equipped with a helix-turn-helix motif and the myc- and his_6-peptide tags) runs at about 35 kDa, whereas the light chain typically runs below 30 kDa. The impurities at about 15 kDa are C-terminal CH1 fragments that contain the His_6-tag and therefore co-purifiy. They do not contain any aromatic amino acids and therefore do not interfere with A280nm measurements.

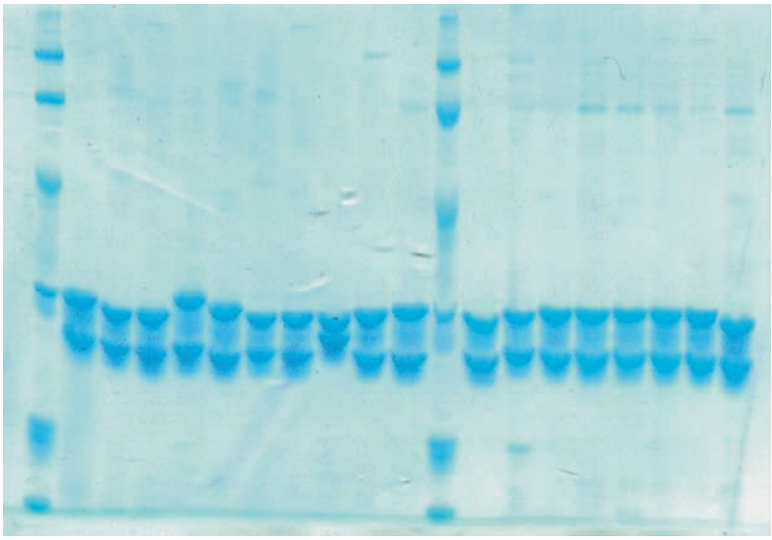

Fig. 5. Coomassie-stained SDS gel (15%, Criterion gel, Bio-Rad, low range marker, Bio-Rad) of 18 different Strep-tagged Fab antibodies after Strep-tag purification. The amount of 3 µg total protein was loaded on each lane. The heavy chain runs at about 31 kDa, whereas the light chain typically runs below 30 kDa. In comparison to the NiNTA purification, the Strep-tag purification combined with the periplasmic preparation will result in significant higher purities (usually >90%).

also work for antibodies. The most convenient strategy is probably the use of a stretch of histidines, the so-called his-tag, a series of 5 to 6 histidines that bind to affinity media such as NTA-agarose or Talon resin, when metal ions (nickel or cobalt) are bound. His-tagged proteins bind with milli-molar affinity to the column and are gently eluted with 150–300 mM imidazole (**Fig. 4**). Another such tag is the StrepII-tag ***(14)***, which shows affinity to streptavidin- or streptactin-sepharose (streptactin is a genetically engineered streptavidin with higher affinity to the Strep-tag) (**Fig. 5**). Commercial antibodies to both tags are available, so the tags can be used for detection purposes as well. Other detection tags like the V5-tag (GKPIPNPLLGLDST), which is derived from a small epitope present on the P/V proteins of the paramyxovirus, SV5, or the myc-tag (EQKLISEEDL), which correspond to residues 408–439 of the human p62 c-myc protein are also frequently used, because specific high-affinity monoclonal antibodies are commercially available. The FLAG-tag (DYKDDDDK) is of special interest since a monoclonal antibody (termed M1) exists that only binds to the tag when the N-terminus is free and not involved in a peptide bond. This has been used to monitor cleavage of signal sequences during *E. coli* antibody expression ***(15)***.

2. Materials

2.1. Bacterial Cell Culture

1. 2xYT Medium:
   - 2xYT (Yeast Extract Tryptone) Media; Difco.
   - Dissolve 155 g 2xYT powder in 5 L deionized water.
   - After total dissolution, autoclave at 121°C for 20 min.
   - Store at room temperature.
2. Glucose stock (40%):
   - D(+)-glucose monohydrate, (MW = 198 g/mol).
   - Dissolve 44 g glucose in 100 mL deionized water.
   - After total dissolution, sterile filtration using 0.2 µm filter.
   - Store at room temperature.
3. CAM (Chloramphenicol) stock (34 mg/ml in ethanol):
   - Dissolve 3.4 g chloramphenicol in 100 mL ethanol (p.a.).
   - After total dissolution, sterile filtration using 0.2 µm filter.
   - Store at −20°C.
4. IPTG stock (1M in ddH_2O):
   - Dissolve 4.2 g IPTG in 100 ml deionized water.
   - After total dissolution, sterile filtration using 0.2 µm filter.
   - Store at −20°C.
5. Preculture medium: mix 974 ml 2xYT medium with 25 ml glucose stock solution and 1 ml CAM-stock solution.
6. Expression-culture medium: mix 974 ml 2x YT-medium with 2.5 ml glucose stock solution and 1 ml CAM-stock solution.
7. Sterile filter: Acrodisc 13 mm syringe filters, 0.2 µm (Pall).

2.2. Cell Lysis

1. Cell Lysis Buffer: Take 120 ml BugBuster (Merck), add 240 mg Lysozyme (Roche), 1250 U Benzonase (Merck; 250 U/µl = 5 A/µl), and 5 PIT (Complete Protease Inhibitor) tablets, EDTA free (Roche #1873580) (see **Note 1**).
   Always prepare fresh solution.
2. BSS buffer: 200 mM boric acide, 160 mM NaCl, pH 8.0. Dissolve 12.37 g boric acid add 9.35g NaCl in 1000ml deionized water. Adjust to pH to 8.0 with NaOH. After total dissolution, sterile filtration using 0.2 µm filter. Store at room temperature.
3. PeriPrep lysis buffer: 200 mM boric acide, 160 mM NaCl, 2 mM EDTA, protease Inhibitor, pH 8.0. Dissolve 0.75g EDTA: Titriplex®III, (VWR, #108421) and 40 PIT (Complete Protease Inhibitor) tablets, EDTA free, (Roche), in 1000 ml BSS buffer (*see* **Note 1**). Adjust to pH to 8.0 with NaOH.
   Always prepare fresh solution.
4. Avidin stock solution 10mg/ml (for Strep-Tag purifications) (*see* **Note 2**). Dissolve 10 mg avidin in 10ml deionized water. Store at −20°C.
5. Seriflip filter device (STERIFLIP, Milipore).

2.3. Affinity Chromatography

2.3.1. IMAC Affinity Chromatography

1. IMAC-RB (running buffer): 20 mM NaH_2PO_4, 500 mM NaCl, 10 mM imidazol, pH 7.4. Dissolve 2.4 g NaH_2PO_4, 29.2 g NaCl, 0.68g imidazole in 1000ml deionized water. Adjust to pH to 7.4. After total dissolution, sterile filtration using 0.2 µm filter. Store at room temperature.
2. IMAC-WB (washing buffer): 20 mM NaH_2PO_4, 500 mM NaCl, 20 mM imidazol, pH 7.4. Dissolve 2.4 g NaH_2PO_4, 29.2 g NaCl, 1.36 g imidazol in 1000 ml deionized water. Adjust to pH to 7.4. After total dissolution, sterile filtration using 0.2 µm filter. Store at room temperature.
3. IMAC-EB (elution buffer): 20 mM NaH_2PO_4, 500 mM NaCl, 250 mM Imidazole, pH 7.4. Dissolve 2.4 g NaH_2PO_4, 29.2 g NaCl, 17 g imidazole in 1000 ml deionized water. Adjust to pH to 7.4. After total dissolution, sterile filtration using 0.2 µm filter. Store at room temperature (*see* **Note 3**).
5. Ni-NTA agarose (Qiagen) (*see* **Note 4**).
4. Gravity flow plastic columns: Poly Prep (BioRad).

2.3.2. Strep Tag Affinity Chromatography

1. Strep-RB (running buffer): 100 mM Tris-HCl, 750 mM NaCl, 1 mM EDTA, pH 8.0. Dissolve 12.1 g Tris, 43.8 NaCl, 0.37g EDTA in 1000 ml deionized water. Adjust to pH to 8.0. After total dissolution, sterile filtration using 0.2 µm filter. Store at room temperature.
2. Strep-EB (elution buffer): Strep-RB + 5 mM D-Desthiobiotin. 100 mM Tris-HCl, 750 mM NaCl, 1 mM EDTA, 5 mM D-desthiobiotin, pH 8.0. Dissolve 12.1 g Tris, 43.8g NaCl, 0.37 g EDTA, 1.1 g D-D-desthiobiotin in 1000 ml deionized water. Adjust to pH to 8.0. After total dissolution, sterile filtration using 0.2 µm filter. Store at 4°C and not longer than 1 week (*see* **Note 5**).
3. Strep-RegB (regeneration buffer): 5 mM HABA, 100 mM Tris-HCl, pH 8.0. Dissolve 1.21 g HABA (HABA-ImmunoPure Pierce/Perbio) and 12.1 g Tris in 1000ml deionized water. Adjust to pH to 8.0 with HCl. After total dissolution, sterile filtration using 0.2 µm filter. Store at 4°C.
4. Streptactin sepharose (IBA-GMBH).
5. Gravity flow plastic columns: Poly prep (BioRad).

2.3.3. Size Exclusion Chromatography

1. PBS: 0.136 M NaCl, 2.68 mM KCl, 8.1 mM Na_2HPO_4, 1.46 mM KH_2PO_4, pH 7.4. Dissolve 0.2g KCl, 8g NaCl, 1.44g Na_2HPO_4 and 0.24g KH_2PO_4 in 1000ml deionized water. Adjust to pH to 7.4. After total dissolution, sterile filtration using 0.2 µm filter. Store at room temperature.
2. 3xPBS: 0.401 M NaCl, 8.04 mM KCl, 24.3 mM Na_2HPO_4, 4.38 mM KH_2PO_4, pH 7.4. Dissolve 0.6 g KCl, 24 g NaCl, 4.32 g Na_2HPO_4, and 0.72g KH_2PO_4 in 1000 ml deionized water. Adjust to pH to 7.4. After total dissolution, sterile filtration using 0.2 µm filter. Store at room temperature.

3. PD10 columns: GE (Amersham Pharmacia Biotech).

2.3.4. Sterile Filtration, Concentration Determination, SDS-PAGE

1. Sterile filter: Acrodisc 13mm syringe filters, 0.2 µm (Pall).
2. UV-compatible cuvette: UVette (VWR international).
3. SDS-sample buffer 5 x concentrated:
   125 mM Tris-HCl pH6,8 10% glycerol, 0,5% SDS, 0,05% (w/v) bromophenol blue, 5% beta-mercaptoethanol.
4. SDS running buffer: 25 mM Tris, 192 mM glycine, 0,1% SDS.
5. SDS-PAGE system: Criterion 15% Tris. 26W (Bio-Rad).
6. Gel staining solution: Gelcode Blue stain reagent (Pierce).

3. Methods

3.1. Strep-Tag Expression and Purification

3.1.1. Preculture

1. Fill 20 ml medium 1 (2xYT + 1% glucose + CAM) into a 100 ml Erlenmeyer flask.
2. Inoculate culture with a single colony with a sterile inoculating loop. Freshly transformed TG1F$^-$ cells are recommended (*see* **Note 6**).
3. Incubate at 30°C, O/N (18 h +/– 2h), 250 rpm.

3.1.2. Expression Culture

1. Fill 750 ml medium 2 (2xYT + 0.1% glucose + CAM) into a 2 L baffled Erlenmeyer flask.
2. Inoculate with 1/300 volume (2.5 ml) of preculture.
3. Incubate at 30°C, 3 h, 180 rpm.
4. Induce with 560 µL IPTG (1M) stock solution (0.75 mM final concentration).
5. Express Fab at 30°C, 160 rpm, O/N (20 h +/–2 h post induction time) (*see* **Note 7**).

3.1.3. Cell Harvest and Periplasmic Prep (PP)

1. Harvest cells by centrifugation at 5000 g, 30 min, 4°C.
2. Decant supernatant and discard after autoclaving (*see* **Note 8**).
3. Resuspend the bacterial pellet with 30–35 ml cold (<10°C) PeriPrep lysis buffer by pipetting carefully up and down or by shaking at 250 rpm.
4. Transfer suspension into 50 ml Falcon tube and adjust volume to 40 ml.
5. Mix suspension carefully by inverting the tube several times.
6. Incubate O/N, 4°C.

3.1.4. Purification

1. Centrifuge suspension at 16000 g, 4°C, 30 min.
2. Transfer supernatant into a fresh 50 ml Falcon tube by decanting.

3. Add 50 µL avidin stock per sample.
4. Incubate 30 min, 4°C.
5. Filter supernatant with Steriflip filtration device (0.22µm) (*see* **Note 9**).
6. Load a Poly-Prep column with 2 ml Streptactin sepharose (50%; 1 ml bed volume).
7. Equilibrate column with 30 ml Strep-RB by filling once the funnel (~30ml).
8. Load sample to the column and collect the flow through in the respective Falcon tube.
9. Remove funnel and wash twice with 5 ml Strep-RB.
10. Add 0.5 ml Strep-EB and discard flow through.
11. Place column on 2 ml Eppendorf cup.
12. Elute Fab with 2 ml Strep-EB and collect eluate; continue with step buffer exchange.

3.1.5. Regeneration of Strep-Tactin Columns (Optional)

1. After elution regenerate column two times with 5 ml Strep-RegB.
2. Place a funnel onto the column and re-equilibrate the column with 30 ml Strep-RB.
3. Store columns in approx. 2 ml Strep-RB at 4°C (*see* **Note 10**).

3.2. His-Tag Expression and Purification

3.2.1. Preculture

1. Fill 20 ml medium 1 (2×YT + 1% glucose + CAM) into a 100 ml Erlenmeyer flask.
2. Inoculate culture with a single colony with a sterile inoculating loop. Freshly transformed TG1F$^-$ cells are recommended (*see* **Note 6**).
3. Incubate at 30°C, O/N (18 h +/−2 h), 250 rpm.

3.2.2. Expression Culture

1. Fill 750 ml Medium 2 (2 × YT + 0.1% glucose + CAM) into a 2 L baffled Erlenmeyer flask.
2. Inoculate with 1/300 volume (2.5 ml) of preculture.
3. Incubate at 30°C, 3 h, 180 rpm.
4. Induce with 560 µL IPTG (1M) stock solution (0.75 mM final concentration).
5. Express Fab at 30°C, 160 rpm, O/N (20 h +/− 2 h post induction time) (*see* **Note 7**).

3.2.3. Cell Harvest and Whole Cell Lysis (*see* **Note 11**)

1. Harvest cells by centrifugation at 5000 g, 30 min, 4°C.
2. Decant supernatant and discard after autoclaving (*see* **Note 8**).
3. Resuspend the bacterial pellet with 10 ml cold whole-cell lysis buffer by pipetting carefully up and down or by shaking at 250 rpm.
4. Transfer suspension into 50 ml Falcon tube and mix suspension carefully by inverting the tube several times.
5. Incubate for 30 min, at room temperature.
6. Centrifuge suspension at 16000 g, 4°C, 30 min.

7. Transfer the cleared supernatant in a new Falcon tube.
8. Filter supernatant with Steriflip filtration device (0.22 µm) (*see* **Note 9**).

3.2.4. Purification

1. Load a Poly-Prep column with 2 ml Ni-NTA-Sepharose (50%; 1 ml bed volume).
2. Equilibrate column with IMAC-RB by filling once the funnel (~30 ml).
3. Load sample to the column and collect the flow through in the respective Falcon tube.
4. Remove funnel and wash three times with 5 ml IMAC-WB.
5. Add 0.5 ml IMAC-EB and discard flow through (*see* **Note 4**).
6. Place column on 2 ml Eppendorf cup.
7. Elute Fab with 2 ml IMAC-EB and collect eluate; continue with step buffer exchange.

3.3. SEC for Buffer Exchange

3.3.1. Buffer Exchange with PD10 Desalting Column

1. Place column in a rack (e.g. Biorad polycolumn rack) and equilibrate the column with 20 ml PBS (for Fab) or 3xPBS (for bivalent Fab constructs) (*see* **Note 12**).
2. After running buffer through the column, add a total volume of 2 ml of the purified Fab solution.
3. Discard the eluent.
4. When the sample has run into the column, add additional 1 ml of PBS (or 3xPBS).
5. Discard the eluent.
6. When the buffer has run into the column, place a 15 ml Falcon tube under the column and elute the purified Fab with 2.5 ml PBS (or 3xPBS).
7. Wash the column with 20 ml PBS (or 3xPBS).
8. Store columns in approx. 2 ml PBS (or 3xPBS).
   Columns can be reused several times.

3.3.2. Sterile Filtration and Concentration Determination

1. Filter eluate with 0.2 µm filter (Pall; 13 mm) fixed to 2 ml syringe into fresh 15 ml Falcon tube.
2. Take an aliquot of 200 µL for **step 3.3.3**.
3. Fab samples can be stored under sterile condition for several weeks. For long term storage, freezing at −20°C or −80°C is recommended (*see* **Note 13**).

3.3.3. Determination of Concentration and Purity

1. Determine the protein concentration by measuring the absorption at 280 nm (*see* **Note 5**).
   A_{280}nm × 0.65 = concentration in mg/ml (for monovalent Fab constructs).
   A_{280}nm × 0.7 = concentration in mg/ml (for bivalent Fab constructs).
   (dilute sample 1:4 or 1:10 with PBS or (3xPBS) to get values in the linear range between (0.1 and 1AUF).
2. Take up to 5 µg of you protein sample and add with SDS-sample buffer and water to a final volume of 25 µl.

3. Heat sample for 5 min to 95°C for total denaturation.
4. Load protein-sample on 15% Tris-HCl SDS-PAGE (e.g., Biorad Criterion System). Protein amounts between 1.5 and 3 µg are recommended for optimal visual inspection of Fab-bands and impurities.
   Run SDS-PAGE according to manufacture instructions.

4. Notes

1. Use of protease inhibitor mix is not needed in general but recommended to avoid possible degradation of some Fab fragments. The by-products in the purification of bivalent Fab including the BAP fusion construct are not effected by the addition of the protease inhibitor. Be aware that some protease inhibitor mixes contain EDTA or EGTA. Don't use these ingredients in IMAC purification, the metal ion will be chelated and the material will loose binding-activity.
2. Avidin will bind traces of biotin produced by E. coli. In particular, if a Strep-tag column is used several times the biotin will poison the column because it has a much higher affinity to Streptactin as the Strep-tag. At this point washing with Strep-RegB is not sufficient to regenerate the column.
3. Elution of Fab fragments will start at imidazol concentrations of ~50 m*M*, the bivalent construct with two tags will elute at higher concentrations (>75 m*M*).
4. Ni-NTA shows good results in our hands, but some authors prefer other IMAC resins (e.g., Talon-resin or Zn/Cu ions).
5. Desthiobiotin takes a long time to dissolve (gentle warming helps). Low concentrations of desthiobiotin will not interfere with many assays. It also shows no significant UV-absorption or interference in protein concentration assays. The final product is often also very pure (>90% judged on SDS-page). So it is often possible omit buffer exchange and use the eluted product directly in many applications.
6. For optimal expression performance it could be helpful to screen several clones. About 80% of all clones from the HuCAL® library will express in a range of +/−20%. In some case it is possible to find clones which show much higher expression rates (*see* **Fig. 2**).
7. These conditions show the best results for most Fab fragments. Nevertheless it could be helpful to optimise the expression conditions for optimal results. In some cases, lower temperatures (25°C) and lower IPTG concentrations (0.2 mM) will give better results.
8. In some cases (depending on the individual antibody and on the expression conditions, e.g. long expression times, or media that contains glycerol), significant amounts of the Fab can be found in the expression media. This can be checked with an anti-Fab-ELISA.

9. Filtration can be omitted but this may cause clogging or contamination of the columns, in particular if the columns are used several times.
10. Streptactin columns can be used more than 10 times over more than 6 month without significant loss of binding activity.
11. For purification of bivalent Fab or large Fab-fusions it is not recommended to use a periplasmic preparation, because the release in the lysis buffer is often limited and the purification yields drop down.
12. The use of 3xPBS is recommended in purifications of bivalent Fab fragments, because these constructs sometimes tend to aggregate in PBS (depending on the individual antibody and the final concentration). This aggregation can be avoided by using a buffer with higher ionic strength like 3xPBS.
13. After thawing 3xPBS samples, a precipitate can often been seen at the bottom of the well or tube. This is salt from the PBS. It will disappear after thawing and gentle shaking.

Screening Hybridoma Culture Supernatants Using Solid-Phase Radiobinding Assay

Mark Page and Robin Thorpe

1. Introduction

A large number of hybridoma culture supernatants (up to 200) need to be screened for antibodies at one time. The assay must be reliable so that it can accurately identify positive lines, and it must be relatively quick so that the positive lines, which are 75–100% confluent, can be fed and expanded as soon as possible after the assay results are known. Solid-phase binding assays are appropriate for this purpose and are commonly used for detection of antibodies directed against soluble antigens ***(1)***. The method involves immobilizing the antigen of choice onto a solid phase by electrostatic interaction between the protein and plastic support. Hybridoma supernatants are added to the solid phase (usually a 96-well format) in which positive antibodies bind to the antigen. Detection of the bound antibodies is then achieved by addition of an antimouse immunoglobulin labeled with radioactivity (usually ^{125}I) and the radioactivity counted in a γ counter.

2. Materials

1. Antigen: 0.5–5 µg/mL in phosphate-buffered saline (PBS) with 0.02% sodium azide.
2. PBS: 0.14 *M* NaCl, 2.7 m*M* KCl, 1.50 m*M* KH_2PO_4, 8.1 m*M* Na_2HPO_4.
3. Blocking buffer: PBS containing either 5% v/v pig serum, 5% w/v dried milk powder, or 3% w/v hemoglobin (*see* **Note 1**).
4. Hybridoma culture supernatants.
5. Negative control: irrelevant supernatant or culture medium.
6. Positive control: serum from immunized mouse from which spleen for hybridoma production was derived.
7. Antimouse/rat immunoglobulin, ^{125}I-labeled (100 µCi/5 µg protein).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Method

1. Pipet 50 µL of antigen solution into each well of a 96-well microtiter plate and incubate at 4°C overnight. Such plates can be stored at 4°C for several weeks. Seal plates with cling film to prevent the plates from drying out (*see* **Note 2**).
2. Remove antigen solution from wells by either a Pasteur pipet (cover the tip with a small piece of plastic tubing to prevent scratching the antigen-coated wells) or by shaking the contents from the plate in one quick movement (*see* **Note 3**).
3. Wash the plate by filling the wells with PBS and rapidly discarding the contents. Repeat this twice more, tap the plate dry, then fill the wells with blocking buffer, and incubate at room temperature for 30 min to 1 h. Wash three more times with PBS.
4. Pipet 100 µL of neat hybridoma supernatant into the wells, and incubate for approx 3 h at room temperature. Include the negative and positive controls.
5. Wash with blocking buffer three times.
6. Dilute the ^{125}I-labeled antimouse immunoglobulin in blocking buffer to give 1×10^6 cpm/mL. Add 100% µL to each well, and incubate for 1 h at room temperature.
7. Wash with blocking buffer.
8. Cut out individual wells using scissors or a hot nichrome wire plate cutter, and determine the radioactivity bound using a γ counter. A positive result would have counts that are four to five times greater than the background. Normally, the background counts would be around 100–200 cpm with a positive value of at least 1000 cpm (*see* **Note 4**).

4. Notes

1. Filter the milk and hemoglobin solutions coarsely through an absorbent cloth (e.g., Kimnet, Kimberley Clark) to remove lumps of undissolved powder.
2. Antigens (diluted in distilled water) can be dried onto the plates by incubation in a warm room (37°C) without sealing. This method is usually preferred if the antigen is a peptide improving binding to the plastic; however, the background signal may be increased.
3. The antigen solution may be reused several times to coat additional plates, since only a small proportion of the protein adheres to the plastic.
4. Counting radioactivity in a 96-well format can also be performed by using plates designed for use in scintillation counters. The assay is performed as described, except that in the final step, a scintillation fluid (designed to scintillate with ^{125}I, such as Microscint 20, Packard Instrument Co.) is added to each well, and the scintillation counted in a purpose-built machine (e.g., Topcount, Packard Instrument Co.).

Screening Hybridoma Culture Supernatants Using ELISA

Mark Page and Robin Thorpe

1. Introduction

Enzyme-linked immunosorbent assay (ELISA) is a widely used method for the detection of antibody and is appropriate for use for screening hybridoma supernatants ***(1)***. As with radiobinding assays, it is a solid-phase binding assay that is quick, reliable, and accurate. The method is often preferred to radioactive assays, since the handling and disposal of radioisotopes is avoided and the enzyme conjugates are more stable than radioiodinated proteins. However, most of the substrates for the enzyme reactions are carcinogenic or toxic and, hence, require handling with care.

Enzymes are selected that show simple kinetics, and can be assayed by a simple procedure (normally spectrophotometric). Cheapness, availability, and stability of substrate are also important considerations. For these reasons, the most commonly used enzymes are alkaline phosphatase, β-D-galactosidase, and horseradish peroxidase.

2. Materials

1. PBS-Tween: Phosphate-buffered saline (PBS) (0.14 *M* NaCl, 2.7 m*M* KCl, 1.5 m*M* KH_2PO_4, 8.1 m*M* Na_2HPO_4) containing 0.05% Tween-20.
2. Antigen: 1–5 µg/mL in PBS.
3. Blocking buffers: PBS-Tween containing either 5% v/v pig serum or 5% w/v dried milk powder (*see* **Note 1**).
4. Hybridoma culture supernatants.
5. Alkaline phosphatase conjugated antimouse immunoglobulin.
6. Carbonate buffer: 0.05 *M* sodium carbonate, pH 9.6.
7. *p*-Nitrophenyl phosphate, disodium hexahydrate: 1 mg/mL in carbonate buffer containing 0.5 m*M* magnesium chloride.
8. 1 *M* sodium hydroxide.

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Method

1. Pipet 50 µL of antigen solution into each well of a 96-well plate, and incubate overnight at 4°C. Such plates can be stored for 4°C for several weeks. Seal plates with cling film to prevent the plates from drying out (*see* **Note 2**).
2. Remove antigen solution from wells by either a Pasteur pipet (cover the tip with a small piece of plastic tubing to prevent scratching the antigen-coated wells) or by shaking the contents from the plate in one quick movement (*see* **Note 3**).
3. Wash the plate by filling the wells with PBS and rapidly discarding the contents. Repeat this twice more, then fill the wells with blocking buffer, and incubate at room temperature for 30 min to 1 h. Wash three more times with PBS.
4. Pipet 100 µL of neat hybridoma supernatant into the wells, and incubate for approx 3 h at room temperature. Include the negative and positive controls (*see* **Note 4**).
5. Wash with blocking buffer three times.
6. Prepare 1:1000 dilution of alkaline phosphatase-conjugated antimouse immunoglobulin in PBS-Tween, and add 200 µL of this to each well. Cover, and incubate at room temperature for 2 h.
7. Shake-off conjugate into sink and wash three times with PBS.
8. Add 200 µL *p*-nitrophenyl phosphate solution to each well, and incubate at room temperature for 20–30 min.
9. Add 50 µL sodium hydroxide to each well, mix, and read the absorbance of each well at 405 nm (*see* **Note 5**). Typical background readings for absorbance should be less than 0.2 with positive readings usually three or more standard deviations above the average background value.

4. Notes

1. Filter the milk solution coarsely through an absorbent cloth (e.g., Kimnet, Kimberley Clark) to remove lumps of undissolved powder.
2. Antigens (diluted in distilled water) can be dried onto the plates by incubation in a warm room (37°C) without sealing. This method is usually preferred if the antigen is a peptide improving binding to the plastic; however, the background signal may be increased.
3. The antigen solution may be reused several times to coat additional plates, since only a small proportion of the protein adheres to the plastic.
4. All assays should be carried out in duplicate or triplicate.
5. Purpose-built plate readers provide a very rapid and convenient means of determining the absorbance.

Growth and Purification of Murine Monoclonal Antibodies

Mark Page and Robin Thorpe

1. Introduction

Once a hybridoma line has been selected and cloned, it can be expanded and seed stocks cryopreserved for future use. Relatively large amounts of purified MAb may also be required. There are a variety of procedures for this that ensure the establishment of a stable cell line secreting high levels of specific immunoglobulin. High concentrations of antibody can be generated by growing the line in the peritoneal cavity of mice/rats of the same strain as the tumor cell line donor and spleen cell donor. Antibody is secreted into the ascitic fluid formed within the cavity at a concentration up to 10 mg/mL. However, the ascites will contain immunoglobulins derived from the recipient animal that can be removed by affinity chromatography if desired. Several in vitro culture methods using hollow fibres or dialysis tubing ***(1)*** have been developed and are commercially available; this avoids the use of recipient mice/rats and contamination by host immunoglobulins, although contamination with culture medium-derived proteins may be a problem.

2. Materials

1. RPMI-1640/DMEM medium.
2. Fetal bovine serum (FBS).
3. Phosphate-buffered saline (PBS): 0.14 *M* NaCl, 2.7 m*M* KCl, 1.50 m*M* KH_2PO_4, 8.1 m*M* Na_2HPO_4.
4. HT medium: 1 mL 50X HT supplement in 50 mL 10% FBS/RPMI.
5. HT supplement (Gibco, Paisley, UK).

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

3. Method

3.1. Growth of Hybridomas

1. After cloning, grow hybridomas in 1 mL HT medium in separate wells of a 24-well plate. Check growth every day and feed with 0.5–1 mL HT medium if supernatant turns yellow (*see* **Note 1**).
2. When cells are 75–100% confluent (*see* **Note 2**), expand into two further wells with fresh HT medium. When these are confluent, transfer into a 25-cm^3 flask and feed with approx 10 mL medium (*see* **Note 3**). Subsequently, cell lines should be weaned off HT medium by increasing the dilution of HT medium stepwise with normal medium lacking the HT supplement, eventually culturing the cells in normal medium. Do this by reducing the amount of HT medium by 25–50% at each feed for expansion of the hybridomas. For example, reduce the amount of HT from 100 to 75 to 50 to 25 to 0% replacing with normal medium.
3. The FBS may be reduced to 5% or lower if hybridoma growth is strong.

3.2. Purification of MAb

MAb purification can be carried out by a number of methods as described in Chapters 179–190 and 207.

4. Notes

1. Phenol red is included in the medium as a visual indicator of pH. A yellow supernatant indicates acid conditions as a result of dissolved CO_2 (carbonic acid) derived from active cell growth (respiration). Normally, a yellow supernatant will indicate that the cells should be split (passaged) because the active cell growth will have exhausted the medium of nutrients and hence will not sustain cell viability.
2. Cells are confluent when the bottom of the flask/well is completely covered. Usually, the cells will require feeding or expanding at this stage (*see* **Note 1**).
3. To prevent inadvertant loss of precious cell lines, it may be prudent to freeze cloned lines before expansion into flasks.

Affinity Purification Techniques for Monoclonal Antibodies

Alexander Schwarz

1. Introduction

Monoclonal antibodies have many applications in biotechnology such as immuno-affinity chromatography, immunodiagnostics, immunotherapy, drug targeting, biosensors, and many others. For all these purposes homogeneous antibody preparation are needed. Affinity chromatography, which relies on the specific interaction between an immobilized ligand and a particular molecule sought to be purified, is a well-known technique to purify proteins from solution. Three different affinity techniques for the one-step purification of antibodies—protein A, thiophilic adsorption, and immobilized metal affinity chromatography—are described in this chapter.

1.1. Protein A Chromatography

Protein A is a cell wall component of *Staphylococcus aureas*. Protein A consists of a single polypeptide chain in the form of a cylinder, which contains five highly homologous antibody binding domains. The binding site for protein A is located on the Fc portion of antibodies of the immunoglobulin G (IgG) class ***(1)***. Binding occurs through an induced hydrophobic fit and is promoted by addition of salts such as sodium citrate or sodium sulfate. At the center of the Fc binding site as well as on protein A reside histidine residues. At alkaline pH, these residues are uncharged and hydrophobic, strengthening the interaction between protein A and the antibody. As the pH is shifted to acidic values, these residues become charged and repel each other. Differences in the pH-dependent elution properties **(Table 1)** are seen between antibodies from different classes as well as different species due to minor differences in the binding sites. These

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

Table 1
Affinity of Protein A for IgG for Different Species and Subclasses

IgG species/subclass	Affinity	Binding pH	Elution pH
Human IgG1	High	7.5	3
Human IgG2	High	7.5	3
Human IgG3	Moderate	8	4–5
Human IgG4	High	7.5	3
Mouse IgG1	Low	8.5	5–6
Mouse IgG2a	Moderate	8	4–5
Mouse IgG2b	High	7.5	3
Mouse IgG3	Moderate	8	4–5
Rat IgG1	Low	8.5	5–6
Rat IgG2a	None–low		
Rat IgG2b	Low	8.5	5–6

differences can be successfully exploited in the separation of contaminating bovine IgG from mouse IgG, as shown in **Subheading 1.3**.

The major attraction in using protein A is its simplicity. The supernatant is adsorbed onto a protein A gel, the gel is washed, and the antibody is eluted at an acidic pH. The antibody recovered has a purity of >90%, often with full recovery of biological activity. The method described in **Subheading 3.1**. provides a more detailed description of the purification for high-affinity antibodies.

The affinity between protein A and the antibody is due mainly to hydrophobic interactions at the binding sites ***(1)***. The interaction can be strengthened by the inclusion of higher concentrations of chaotropic salts such as sodium citrate or sodium sulfate. Although the addition of chaotropic salts is unnecessary in the case of high-affinity antibodies, it allows weakly binding antibodies such as mouse IgG1 to strongly interact with protein A. This purification scheme is outlined in **Subheading 3.2**. The different affinities resulting from minor differences in the Fc region can also be utilized for the separation of subclasses or the separation of different species in hybridoma supernatant using a pH gradient. However, this is possible only if the difference in affinity is large enough like in the case of the separation of mouse IgG2b from bovine IgG. If fetal calf serum supplemented growth media is used, bovine IgG will contaminate the monoclonal antibody if the method described in **Subheading 3.1**. or **3.2**. is used. An improved protocol utilizing the different affinities is described in **Subheading 3.3**.

1.2. Thiophilic Adsorption Chromatography

The term thiophilic adsorption chromatography was coined for gels, which contain low molecular weight sulfur-containing ligands such as divinyl sulfone

structures or mercapto-heterocyclic structures ***(2,3)***. The precise binding mechanism of proteins to these gels is not well understood. However, thiophilic chromatography can be regarded as a variation of hydrophobic interaction chromatography inasmuch as chaotropic salts need to be added to facilitate binding of antibodies to the gel. Therefore, the interaction between the ligands and the antibody is likely to be mediated through accessible aromatic groups on the surface of the antibody.

The major advantage of these thiophilic gels over protein A gels is that they bind **all** antibodies with sufficiently high capacity and very little discrimination between subclasses or species. Furthermore, elution conditions are much milder, which might be beneficial if the harsh elution conditions required for strongly binding antibodies to protein A lead to their denaturation. Thiophilic gels also purify chicken IgY ***(4)***. A general method is provided in **Subheading 3.4**.

The major disadvantage of thiophilic gels is the requirement to add high concentrations of chaotropic salts to the adsorption buffer to facilitate binding. This requirement is not a problem for small-scale purifications at the bench, but it is unattractive at larger scale.

Recently, a major improvement of thiophilic chromatography came about with the utilization of very high ligand concentrations ***(9)***. By immobilizing mercaptoheterocyclics such as 4-mercaptoethyl pyridine at very high concentrations, the need to add chaotropic salts such as sodium sulfate was abolished. All antibodies investigated are adsorbed at neutral pH, independent of the salt concentration. At acidic pH values, the ligand becomes charged and through charge–charge repulsion, the antibody is eluted. This variation of thiophilic adsorption chromatography is highly reminiscent of protein A chromatography in its simplicity, but with the added advantage that it is nonspecific for antibodies. Purities and recoveries obtained range from 90% for antibodies from protein-free cell culture supernatant to approx 75% from ascitic fluid. The method is outlined in **Subheading 3.5**.

1.3. Immobilized Metal Affinity Chromatography

Immobilized metal affinity chromatography (IMAC) is a general term for a variety of different immobilization chemistries and metals utilized ***(10)***. The most commonly used gel for IMAC is nickel-loaded iminodiacetic acid (Ni-IDA) gel, used, for example, in kits for the separation of His-tail modified proteins. Under slightly alkaline conditions, the interaction between the immobilized nickel and proteins is strongest with accessible histidine residues. Ni-IDA binds to the Fc portion of the antibody ***(11)***, and similar to thiophilic adsorption chromatography, it binds all antibodies without discrimination between subclasses or species ***(11,12)***. Depending on the growth medium used, some contamination is apparent, namely transferrin and traces of albumin. The purity of monoclonal antibodies

purified out of ascitic fluid is generally lower than out of hybridoma cell culture supernatant. As described for protein A chromatography, a shift in pH to acidic values leads to the generation of charges on the histidine residues and consequent elution of the protein bound. Alternatively, competitive elution with either imidazole or EDTA yields antibody in good purity. However, the elution with EDTA delivers the antibody with the metal still bound to the protein, while imidazole adsorbs at 280 nm, interfering with UV detection. A general protocol is outlined.

2. Materials

2.1. General Purification of Human IgG, Humanized IgG, and Mouse IgG2a and Mouse IgG2b Using Protein A

1. Buffer A: 50 m*M* Tris-HCl, pH 7.5.
2. Buffer B: 50 m*M* Tris-HCl, 500 m*M* NaCl, pH 8.0.
3. Buffer C: 100 m*M* acetate buffer, 50 m*M* NaCl, pH 3.0.
4. Buffer D: 10 m*M* NaOH.

2.2. General Purification of Mouse IgG1, Rat IgG1, and Rat IgG2b Using Protein A

1. Buffer A: 500 m*M* sodium citrate, ph 8–8.4.
2. Buffer B: 100 m*M* sodium acetate, 50 m*M* NaCl, pH 4.0.
3. Buffer C: 10 m*M* NaOH.

2.3. General Purification of IgG with Removal of Bovine IgG Using Protein A

1. Buffer A: 50 m*M* Tris-HCl, pH 7.5.
2. Buffer B: 50 m*M* citrate, pH 5.0.
3. Buffer C: 50 m*M* citrate, 50 m*M* NaCl, pH 3.0.
4. Buffer D: 10 m*M* NaOH.

2.4. Thiophilic Purification of IgG

1. Buffer A: 50 m*M* Tris-HCl, 500 m*M* sodium sulfate, pH 7.5.
2. Buffer B: 50 m*M* sodium acetate, pH 5.0.
3. Buffer C: 10 m*M* NaOH.

2.5. General Purification of IgG Using MEP-HyperCell

1. Buffer A: 50 m*M* Tris-HCl, pH 7.5.
2. Buffer B: 100 m*M* acetate buffer, 50 m*M* NaCl, pH 3.5.
3. Buffer D: 10 m*M* NaOH.

2.6. Immobilized Metal Affinity Purification of IgG

1. Buffer A: 50 m*M* sodium phosphate, 500 m*M* sodium chloride, pH 8.0.
2. Buffer B: 50 m*M* sodium acetate, 50 m*M* sodium chloride, pH 4.5.
3. Buffer C: 200 m*M* sodium phosphate, 200 m*M* sodium chloride, pH 8.0.

4. Buffer D: 50 m*M* Tris-HCl, 500 m*M* sodium chloride, 50 m*M* EDTA, pH 8.0.
5. Buffer E: Buffer B, 50 m*M* nickel chloride.

3. Method

3.1. General Purification of Human IgG, Humanized IgG, and Mouse IgG2a and Mouse IgG2b Using Protein A (*see* Note 1)

This protocol is designed for the purification of high-affinity IgG monoclonal antibodies from hybridoma cell culture supernatant and ascitic fluid. For lower affinity monoclonals, refer to **Subheading 3.2**. or the other purification methods described below.

For cell culture supernatants that contain fetal calf serum and the separation of contaminating bovine IgG from the monoclonal antibody, please see **Subheading 3.3**.

1. Bring all materials to room temperature.
2. Equilibrate a 10-mL protein A gel with 5 column volumes of buffer A.
3. Load supernatant onto protein A–gel column at 5 mL/min.
4. Load up to 20 mg of antibody/mL of gel.
5. Wash with 10 column volumes of buffer B.
6. Elute antibody with 5 column volumes of buffer C.
7. Reequilibrate column with 2 column volumes of buffer A.
8. Wash with 5 column volumes of buffer E followed by 10 column volumes of buffer A.

The column is ready for the next chromatography run.

3.2. General Purification of Mouse IgG1, Rat IgG1, and Rat IgG2b Using Protein A (*see* Note 2)

For cell culture supernatants that contain fetal calf serum and the separation of contaminating bovine IgG from the monoclonal antibody, please *see* **Subheading 3.3**.

1. Bring all materials to room temperature.
2. Dilute supernatant 1:1 with 1000 m*M* sodium citrate solution. Filter the resulting solution through a 0.2-µm filter (**important**).
3. Equilibrate a 10-mL protein A gel with 5 column volumes of buffer A.
4. Load supernatant onto the protein A–gel column at 5 mL/min.
5. Load up to 12 mg of antibody/mL of gel.
6. Wash with buffer A until the UV baseline is reached.
7. Elute antibody with 10 column volumes of buffer B.
8. Reequilibrate column with 2 column volumes of buffer A.
9. Wash with 5 column volumes of buffer C followed by 10 column volumes of buffer A.

The column is ready for the next chromatography run.

3.3. General Purification of IgG with Removal of Bovine IgG Using Protein A (*see* Note 3)

This method is designed for the purification of human, humanized, and mouse IgG2a and IgG2b monoclonal antibodies from hybridoma cell culture supernatant containing fetal calf serum. It does not work well with weakly binding antibodies such as mouse IgG1.

1. Bring all materials to room temperature.
2. Equilibrate a 10-mL protein A gel with 5 column volumes of buffer A.
3. Load supernatant onto the protein A–gel column at 5 mL/min.
4. Load up to 20 mg of antibody/mL of gel.
5. Wash with 5 column volumes of buffer A.
6. Wash with 15 column volumes of buffer B.
7. Elute antibody with 10 column volumes of buffer C.
8. Wash with 5 column volumes of buffer E followed by 10 column volumes of buffer A.

The column is ready for the next chromatography run.

3.4. Thiophilic Purification of IgG (*see* Note 4)

This protocol is designed for the purification of all IgG from hybridoma cell culture supernatant and ascitic fluids. For cell culture supernatants that contain more than 5% fetal calf serum, the monoclonal antibody will be contaminated with bovine IgG.

1. Bring all materials to room temperature.
2. Dilute supernatant 1:1 with 1000 m*M* sodium sulfate solution.
3. Filter the resulting solution through a 0.2-µm filter (**important**).
4. Equilibrate thiophilic gel with 5 column volumes of buffer A.
5. Load supernatant onto the thiophilic gel column at 5 mL/min.
6. Load up to 10 mg of antibody/mL of gel.
7. Wash with buffer A until the UV baseline is reached.
8. Elute antibody with 10 column volumes of buffer B.
9. Wash with 5 column volumes of buffer C followed by 10 column volumes of buffer A.

The column is ready for the next chromatography run.

3.5. General Purification of IgG Using MEP-HyperCell (*see* Note 5)

This protocol is designed for the purification of all IgG from hybridoma cell culture supernatant and ascitic fluids. For cell culture supernatants that contain more than 5% fetal calf serum, the purity is relatively low at approx 50–65%.

1. Bring all materials to room temperature.
2. Equilibrate a 10-mL MEP-HyperCell gel with 5 column volumes of buffer A.
3. Load supernatant onto the column at 5 mL/min.
4. Load up to 20 mg of antibody/mL of gel.
5. Wash with 10 column volumes of buffer A.
6. Elute antibody with 8 column volumes of buffer B.
7. Reequilibrate the column with 2 column volumes of buffer A.
8. Wash with 8 column volumes of buffer E followed by 10 column volumes of buffer A.

The column is ready for the next chromatography run.

3.6. Immobilized Metal Affinity Purification of IgG (*see* Note 6)

This protocol is designed for the purification of all IgG from hybridoma cell culture supernatant and ascitic fluids. For cell culture supernatants that contain more than 5% fetal calf serum, the monoclonal antibody will be contaminated with bovine IgG.

1. Bring all materials to room temperature.
2. Dilute three parts of supernatant with one part of buffer C.
3. Equilibrate a 10-mL IMAC gel with 5 column volumes of buffer B.
4. Load the column with buffer E until the column is completely colored.
5. Wash with 5 column volumes of buffer B.
6. Equilibrate with 5 column volumes of buffer A.
7. Load supernatant onto the IMAC gel column at 5 mL/min.
8. Load up to 10 mg of antibody/mL of gel.
9. Wash with buffer A for 15 column volumes until the UV baseline is reached.
10. Elute antibody with 10 column volumes of buffer B.
11. Strip column with 5 column volumes of buffer D, followed by 5 column volumes of buffer B.

The column is ready for the next chromatography run.

3.7. Concluding Remarks

All the protocols provided in the yield antibodies in good yield and good purity. If not further specified in the accompanying notes, the protocols are usable with virtually all commercially available gels. Difficulties in using a protein A gel can be overcome by using a different affinity column such as a thiophilic gel or an IMAC gel. In most protocols provided, elution is accomplished at acidic pH values. Therefore, further purification can be accomplished by adsorbing the eluate onto a cation-exchange gel. Most of the impurities will flow through and, when using gradient elution, the antibody is generally the first protein to elute from the column.

4. Notes

1. This general protocol works well with high-affinity antibodies and is independent of the particular protein A gel used. The purity of the antibody recovered can be increased by first dialyzing the supernatant or the ascitic fluid against buffer A. Sometimes, phenol red is difficult to remove and the washing step has to be increased accordingly until no red color can be detected on the gel.
2. No pH adjustments have to be made for the sodium citrate solution as the pH will be between 8.0 and 8.5. It is very important to filter the resulting solution after mixing of the supernatant and the sodium citrate solution. In the case of ascitic fluid, a precipitate is clearly visible, while in the case of hybridoma cell culture supernatant precipitating material might not be visible. The purity is somewhat lower than in the case of high-affinity antibodies, but it is very acceptable in the 85–90% range.
3. The molarity of the citrate buffer used in the intermediate wash is slightly dependent on the protein A gel used. It is possible to wash the protein A gel from Pharmacia with 100 m*M* citrate buffer, pH 5.0, while the higher molarity would start to elute antibody from a protein A gel from BioSepra. A good starting point is the 50 m*M* citrate buffer outlined above, and if no loss of the desired monoclonal antibody is detected in the wash fraction, higher buffer concentrations can be employed.
4. There are only a few thiophilic gels commercially available. Of these, the thiophilic gel from E. Merck is by far the best. The most important precaution in using thiophilic gels is the need to filter the supernatant after adjustment to 500 m*M* sodium sulfate. Other antibody molecules like IgA ***(5)***, bispecific antibodies ***(6)***, and single-chain antibody fragments have been purified using thiophilic gels ***(7,8)***.
5. All antibodies, independent of species and subclass, can be purified with this gel. No separation of subclasses can be achieved, however. It is highly likely that similarly to the thiophilic gels described above, other antibody classes such as IgA, IgE, IgM, and chicken IgY can be purified using MEP-HyperCell. The MEP-HyperCell resin is available from BioSepra Inc., a unit of Ciphergen, Inc.
6. Generally, all chelating and amine-containing reagents such as citrate and Tris buffers should be avoided in the feedstocks and buffers used, as these buffers will strip the column of the immobilized metal. If possible, using a gradient to elute the proteins results in better purity of the antibody sought. Three different metals can be used to purify antibody, namely copper, nickel, and cobalt. A good starting metal of any purification using IMAC is nickel. Other metals that work in the purification of antibodies are cobalt and copper. The use of zinc does not yield any antibody. The addition of a

His-tag allows the specific adsorption and elution of single-chain antibodies and antibody fragments ***(13,14)***.

A Rapid Method for Generating Large Numbers of High-Affinity Monoclonal Antibodies from a Single Mouse

Nguyen Thi Man and Glenn E. Morris

1. Introduction

Since the first description by Kohler and Milstein ***(1)***, many variations on this method for the production of monoclonal antibodies (MAb) have appeared and recent comprehensive books on the subject have included both recombinant and conventional methods (*see* ***Further Reading***). The variation we describe here, however, includes a number of refinements that enable rapid (6–10 wk) production from a single spleen of 10–30 cloned and established hybridoma lines producing antibodies of high-affinity. We initially applied this method to recombinant fusion proteins containing fragments of the muscular dystrophy protein dystrophin ***(2–5)***, and dystrophin-related proteins ***(6,7)***, to hepatitis B surface antigen ***(8)*** and to the enzyme creatine kinase (CK) ***(9)***, and have used the MAb thus produced for immunodiagnosis, epitope mapping, and studies of protein structure and function ***(5–12)***. Epitopes shared with other proteins are common, so availability of several MAb against different epitopes on a protein can be important in ensuring the desired specificity in immunolocalization and Western blotting studies ***(6)***. More recently, we have applied this same technique for nuclear proteins, such as emerin (16 MAbs; ***13***), lamin A (5 MAbs; ***14***), SMN (22 MAbs; ***15***), gemins (35 MAbs; ***16***) and the transcription factor, Six5 (18 MAbs; ***17***), as well as other human proteins as diverse as huntingtin (19 MAbs; ***18***) and dopamine receptors (8 MAbs; ***19***).

In the standard Kohler and Milstein method, Balb/c mice are immunized with the antigen over a period of 2–3 mo, and spleen cells are then fused with mouse myelomas using polyethylene glycol (PEG) to immortalize the B-lymphocytes secreting specific antibodies. The hybrid cells, or hybridomas, are then selected

From: *The Protein Protocols Handbook, Third Edition*
Edited by: J.M. Walker © Humana Press, a Part of Springer Science + Business Media, LLC 2009

using medium containing hypoxanthine, aminopterin, and thymidine (HAT medium) ***(20)***. All unfused myelomas are killed by HAT medium, and unfused spleen cells gradually disappear in culture; only hybridomas survive.

Use of hyperimmune mice is critical for success and we have found this much easier to achieve using recombinant proteins as immunogens, rather than conjugated peptides. Fusion proteins with a bacterial component, such as pET vectors with a thioredoxin fusion (Novagen, Inc), have been especially useful. We have rarely found it necessary to take steps to ensure correct folding of the protein immunogen, since some MAbs that recognize both folded and unfolded protein were usually produced when appropriately screened. An exception that did require special steps in both immunogen preparation and hybridoma screening to obtain MAbs against native protein is described below. Fig.1A illustrates both a weak response to immunogen (little binding at 1:1000 dilution), making MAb production difficult, and a typical strong response (strong binding at 1:1000 dilution) that will make hybridoma production very much easier. The importance of appropriate screening of both mouse test bleeds and hybridoma supernatants cannot be emphasized too often. If the desired antibody is not represented in the mouse serum, there is little chance of its emerging after hybridoma fusions.

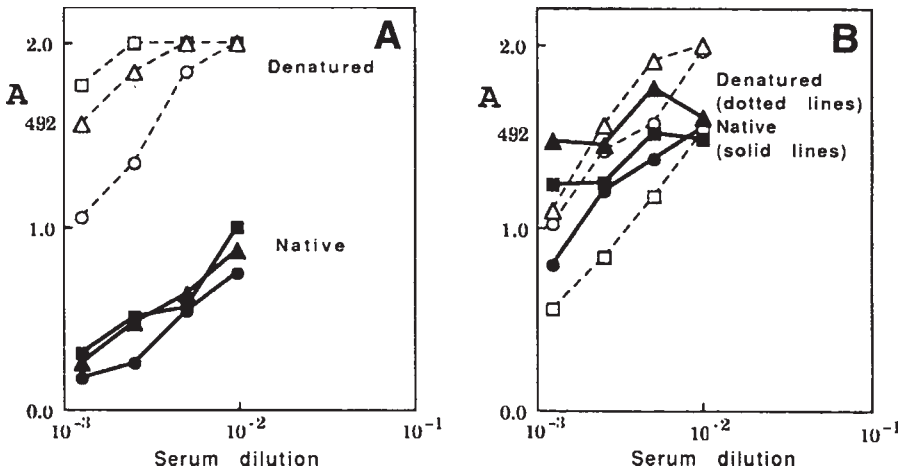

Fig. 1. Effect of aggregation of CK on the immune response in Balb/c mice. Test sera were taken from three mice immunized with untreated CK **(A)**: circles, squares, and triangles represent individual mice) or with glutaraldehyde-aggregated CK **(B)**, and serial dilutions were used as primary antibody in either direct ELISA for denatured CK (dotted lines) or sandwich ELISA for native CK (solid lines). (Reproduced with permission from **ref. *9***.)

Special features of the detailed method to be described here include:

1. A culture medium for rapid hybridoma growth without feeder layers;
2. Screening early to select high-affinity antibodies;
3. Cloning without delay to encourage hybridoma growth and survival; and
4. The use of round-bottomed microwell plates to enable rapid monitoring of colony growth with the naked eye.

In typical fusion experiments, cells are distributed over ten microwell plates (960 wells) and 200–700 wells show colony growth. Of these hybridomas, up to 50% (100–300) produce antibodies that show some antigen binding, though many may be too weak to be useful. After further screening for desired affinity and specificities, we normally select 25–30 as a convenient number to clone. **Table 1** illustrates the results obtained from four fusions by this method. Only occasionally, in our experience, are two or more MAb produced that are indistinguishable from each other when their epitope specificities are later examined in detail.

In the early stages after fusion, a particularly good cell-culture system is needed to promote rapid hybridoma growth in HAT medium. Horse serum, selected for high cloning efficiency, is a much better growth promoter than most batches of fetal calf serum, and HAT medium is prepared using myeloma-conditioned medium and human endothelial culture supernatant, a hybridoma growth promoter. Under these conditions, colonies are visible with the naked eye 7–10 d after fusion, and screening should start immediately. Even unimmunized mouse spleens will produce large numbers of colonies, so the use of hyperimmunized mice, with high serum titers in the screening assay, is essential for generating a high proportion of positive colonies. The screening assays are also of critical importance, because they determine the characteristics of the MAb produced. Both these points are illustrated in **Fig. 1**. CK, a fairly typical

Table 1
Examples of Colony and MAb Yields Using This Method

Antigen	Wells with growth	Wells binding to antigen strongly	Wells with desired affinity//specificity	Final no. of MAb
108–kDa rod fragment of dystrophin in fusion protein ***(2)***	587	136	27	16
59–kDa rod fragment of dystrophin in fusion protein ***(4)***	669	147	30	25
55–kDa C--terminal fragment of dystrophin in fusion protein ***(5)***	700+	42	20	17

"globular" enzyme, is denatured and inactivated when attached directly to ELISA plastic, but it can be captured onto ELISA plates in its native form by using Ig from a polyclonal antiserum ***(9)***. When mice were immunized with untreated CK, antibody titers against denatured CK were high, whereas titers of antibody against native CK were insufficient to produce a plateau in the capture ELISA, even at high serum concentrations (**Fig. 1A**). Seven fusions from such mice (over 1000 colonies screened) produced only two, low-affinity MAb specific for native CK. In contrast, when we immunized with CK aggregated by glutaraldehyde treatment (**Fig. 1B**), titers were higher for native CK antibodies than for those against denatured CK. In a fusion performed with one of these mice, only 2% of the fusion wells were positive in the direct ELISA (denatured CK), but 13% recognized only native CK in the capture ELISA ***(9)***. This illustrates the importance of having both high-titer mice and a suitable screen.

Finally, although the method is rapid and efficient, it is also labor-intensive, especially during screening and cloning. When embarking on the method, one should not be daunted by the prospect of having over 70 culture plates in the incubator simultaneously by the time that the later cloning stages of a single experiment are reached.

2. Materials

1. One or two vertical laminar flow sterile hoods (e.g., Machaire, Bolton, UK).
2. 37°C CO_2 incubator (e.g., LEEC, Nottingham, UK; *see* **Note 1**).
3. Transtar 96 (Corning Inc, Lowell, MA) for plating fusions and removing hybridoma supernatants.
4. Round-bottomed 96-well tissue-culture microwell plates (Invitrogen, Carlsbad, CA, cat. no. 163320) (*see* **Note 2**).
5. Sterile tissue-culture flasks 25 mL (Invitrogen), 75 mL (Invitrogen), and 24-well plates (Invitrogen), 1.8-mL cryogenic vials (AlphaLabs, Eastleigh, UK), and sterile 25-mL universal containers (Invitrogen).
6. Freund's adjuvant, complete (Sigma [St. Louis, MO] no. F-5881) stored at 4°C.
7. Freund's adjuvant, incomplete (Sigma) stored at 4°C.
8. Pristane (2,6,10,14 tetramethyl pentadecane; (Sigma) stored at room temperature.
9. 500X HT: 6.8 mg/mL hypoxanthine (Sigma) and 1.95 mg/mL thymidine (Sigma) in water (*see* **Note 3**). Filter to sterilize. Store in 5-mL aliquots in sterile plastic universals at −20°C (stable for a few years).
10. 1000X Aminopterin (Sigma): 4.4 mg are dissolved in 25 mL of water (*see* **Note 3**). Since the chemical is toxic and teratogenic, it must be weighed with appropriate containment and operator protection. Filter to sterilize. Store in 2-mL aliquots at −20°C, wrapped in aluminum foil to protect from light (stable for years).
11. 50% polyethylene glycol (PEG), mol wt 1500 (Merck, Darmstadt, Germany), is made up by weighing 10 g of PEG in a glass universal and autoclaving. Although the solution is still hot (about 60°C), add 10 mL of DMEM/25 m*M* HEPES

prewarmed in a 37°C water bath. Mix well, and store in 5-mL aliquots at room temperature in the dark; stable at least for 6 mo. The pH should be slightly alkaline (as judged by phenol red) when used for fusion.

12. DMEM/Glutamax I/25 m*M* HEPES. (Invitrogen). This is used as a "physiological saline," not for growing cells.
13. DMEM/Glutamax I/20% HS is prepared by adding to each 80 mL of 1X DMEM-Glutamax I (Invitrogen): 1 mL penicillin-streptomycin (Invitrogen, cat. no. 15070-063), 1 mL nonessential amino acids (MEM) (Invitrogen, cat. no. 11140), and 20 mL selected horse serum (HS). For routine growth and maintenance of both myelomas and established hybridomas, serum is reduced to 10%.
14. Cloning medium: DMEM/20% HS supplemented with 1X HT and 5% human endothelial culture supernatant (HECS) (No longer available from Costar-Corning; *see* **Note 16**).
15. HAT medium: Myeloma-conditioned DMEM-Glutamax I/20% HS with 1X HAT and 5% HECS.
16. Medium for feeding the fusion: DMEM-Glutamax I/20% HS with 5% HECS and 5X HT.
17. Medium for freezing down cells: 90% HS/10% dimethyl sulfoxide (DMSO) (Sigma).
18. Trypan blue (0.1%) (Sigma) in PBS.

3. Methods

3.1. Immunization of Balb/c Mice

1. Purify the protein antigen. With purified antigen, screening is faster and easier, and the yield of MAb is higher, but proteins of 50% purity or less on SDS-PAGE may still give good results.
2. Each of three Balb/c mice (6–8 wk old) is given an ip injection of 50–100 µg of antigen in 0.1 mL PBS emulsified with an equal volume of Freund's complete adjuvant by sucking up and down many times into a disposable sterile plastic 2-mL syringe with a sterile 21-gage 1–1/2 in. no. 2 needle (*see* **Note 4**).
3. Four weeks later, an ip boost of 50–100 µg antigen in Freund's incomplete adjuvant is given.
4. Ten days later, blood (c. 0.1 mL) is taken from the tail vein, allowed to clot, and centrifuged at 10,000 rpm for 5 min. The serum is tested by the method to be used for screening hybridomas. If the titers are high in this assay (*see* **Fig. 1**), the mice should be left to rest for an additional month before fusion.
5. The best mouse is boosted with 50–100 µg of antigen in PBS, ip, and/or iv in the tail vein, 4, 3, and 2 d before fusion.

3.2. Selection of Horse Serum

1. Most suppliers will provide test samples of different serum batches and keep larger amounts on reserve. All sera are heat-inactivated at 56°C for 30 min before use, though this is not known to be essential. Thaw serum in 37°C water bath and swirl to mix before incubating in a 56°C water bath for 30 min with occasional swirling.

We have never yet found a batch of fetal bovine serum that performs as well as horse serum in these tests (*see also* **Subheading 3.8**).

2. Prepare cells of any hybridoma or myeloma line at 1000 cells/mL in DMEM and dilute to 40 cells/mL, 20 cells/mL, 10 cells/mL in DMEM/20% HS of different batches (cloning of established cell lines does not require feeder layers or HT and HECS). For each test serum, plate one 96-well round-bottomed microplate with four rows at four cells in 0.1 mL/well, four rows at two cells in 0.1 mL/well, and four rows at one cell in 0.1 mL/well.
3. From the fifth day onward, note the number of colonies at each cell density for each test serum, as well as the size of the clones. After 2 wk, choose the batch of serum with the highest number and the largest clones. Serum may be stored at −70°C for at least 1–2 yr without loss of activity.

3.3. Growth and Maintenance of Myelomas

SP2/O ***(21)*** myeloma lines grow very fast and do not synthesize immunoglobulins They should be kept in logarithmic growth in DMEM/5% HS for at least a wk before fusion by diluting them to 5×10^4/mL when the cell density reaches 4 or 5×10^5/mL. If thawing myelomas from liquid nitrogen, it is advisable to begin at least 1–2 wk before fusion (*see* **Note 5**). We have never found it necessary to treat lines with azaguanine to maintain their aminopterin sensitivity, which can be checked by plating in HAT medium at 100 cells/well.

3.4. Fusion with Spleen Cells

1. All dissection instruments are sterilized by dry heat (160°C for 5 h), autoclaving (120°C for 30 min) or dipping in 70% ethanol, and flaming in a Bunsen burner. Two separate fusions are done with each spleen as a precaution against accidents.
2. Two days before fusion, set up 2 × 75-mL flasks with 40 mL each DMEM 20% HS and 1×10^5 myeloma cells/mL (Sp2/O).
3. On the day of fusion, place in a 37°C water bath 100 mL of DMEM/25 m*M* HEPES, 10 mL of DMEM/20% HS, and 1 bottle of PEG1500.
4. Count the myeloma cells in a hemocytometer after mixing an aliquot with an equal volume of 0.1% Trypan blue in PBS; cell density should be $4–6 \times 10^5$ with viability 100% and no evidence of contamination.
5. Transfer the myeloma cells to four universals and centrifuge for 7 min at 300 *g* (MSE 4 L). Remove the supernatants with a 10-mL pipet and retain them for plating the fusion later (myeloma-conditioned medium). Resuspend each pellet in 5 mL of DMEM/HEPES, and combine in two universals (2 × 10 mL).
6. The immunized mouse is killed by cervical dislocation outside the culture room and completely immersed in 70% ethanol (15–30 s). Subsequent procedures are performed in sterile hoods. The mouse is pinned onto a "sterile" surface (polystyrene covered with aluminum foil and swabbed with 70% ethanol), and a small incision in the abdominal skin is made with scissors. The peritoneum is then exposed by tearing and washed with 70% ethanol before opening it and pinning it

aside. The spleen is lifted out, removing the attached pancreas with scissors, and placed in a sterile Petri dish (*see* **Note 6**).

7. After removing as much surrounding tissue as possible, the spleen is placed in 10 mL of DMEM/25 m*M* HEPES and held at one end with forceps while making deep longitudinal cuts with a sterile, curved scalpel to release the lymphocytes and red blood cells. This process is completed by scraping with a Pasteur pipet sealed at the end until only connective tissue is left (2–3 min).
8. The spleen cell suspension is transferred to a 25-mL universal, with pipeting up and down five to six times to complete the dispersal. Large lumps are allowed to settle for 1 min before transferring the supernatant to a second universal and centrifuging for 7 min at 300 *g*. Resuspend the pellet in 5 mL of DMEM/25 m*M* HEPES, and keep at room temperature. Usually about 1×10^8 cells/spleen are obtained (*see* **Note 7**).
9. Add 2.5 mL spleen cell suspension to each 10 mL of myeloma cell suspension, and mix gently. Centrifuge at 300 *g* for 7 min at 20°C. Remove supernatants with a pipet, and resuspend pellets in 10 mL DMEM/25 m*M* HEPES using a pipet. Centrifuge at 300 *g* for 7 min. Remove the supernatant completely from one pellet (use a Pasteur pipet for the last traces), and then loosen the pellet by tapping the universal gently (*see* **Note 8**).
10. Remove the DMEM/25 m*M* HEPES and the 50% PEG from the water bath just before use. Take 1 mL of PEG in a pipet, and add dropwise to the cell pellet over a period of 1 min, mixing between each drop by shaking gently in the hand. Continue to shake gently for another minute. Add 10 mL DMEM/25 m*M* HEPES dropwise with gentle mixing, 1 mL during the first minute, 2 mL during the second, and 3.5 mL during the third and fourth minutes. Centrifuge at 300 *g* for 7 min. (This procedure can be repeated with the second cell pellet, while the first is spinning.)
11. Remove supernatant, and resuspend pellet gently in 5 mL of DMEM/20% HS. Place both 5-mL cell suspensions in their universals in the CO_2 incubator for 1–3 h.
12. During this time, take the c. 80 mL of myeloma-conditioned medium and add 4.5 mL of HECS, 90 µL of aminopterin, and 180 µL of hypoxanthine/thymidine solutions. Filter 2 × 40 mL through 0.22-µm filters (47 mm; Millipore [Bedford, MA]) to resterilize, and remove any remaining myeloma cells.
13. To each 40 mL, add the 5-mL fusion mixture from the CO_2 incubator and distribute in 96-well microtiter plates (4 plates/fusion; 100 µL/well) using a Transtar 96 or a plugged Pasteur pipet (3 drops/well) (*see* **Note 9**). Put the plates from each fusion in a separate lunch box in the CO_2 incubator and leave for 3 d.
14. On d 4, add to each well 80 µL of DMEM/20% HS supplemented with HECS and 5X HT. Replace in the CO_2 incubator as quickly as possible.
15. By d 10–14, a high proportion of the wells should have a clear, white, central colony of cells, easily visible with the naked eye. If you want to select for high-affinity MAb (and you would be well advised to do so, unless you have some very special objectives), do not delay screening. If you are using a sensitive screening method, such as ELISA, immunofluorescence, or Western blotting, you will detect

high-affinity antibodies from even the very small colonies. Do not wait for the medium to turn yellow, or your cells may start to die (if you are using a less sensitive screen, such as an inhibition assay, you *may* need to wait longer). A high proportion of the 768 wells (50–100%) should have colony growth by 14 d. If it is <10%, try reducing the PEG concentration. If you regularly obtain over 70%, use 6–8 plates/fusion instead of 4. There should be no microbial contamination (*see* **Note 10**).

3.5. Screening

It would be quite wrong to describe one screening method in detail, since this must be chosen to suit the purpose for which MAb are required. We recommend ELISA as the simplest technique for screening 8 × 96 wells in 1 d, but for coating ELISA plates directly, 10–50 µg of reasonably pure antigen are required. Alternatively, plates can be coated with a capture antibody; we have used this approach to capture CK in its native conformation ***(9)*** and to capture hepatitis B surface antigen from human plasma ***(8)***. The availability of multichannel miniblotters makes direct screening by Western blotting feasible, and with two miniblotters, 224 microwells can be screened in one long day. Immunohistochemistry on cultured cells grown in microwells is also feasible, though we have not used it ourselves. A Transtar 96 apparatus is a rapid and sterile way to remove 10–50 µL of culture supernatant from all 96 wells of a microwell plate. The culture plates have to be open inside the hood for only a few seconds. They should always be wiped with paper tissue soaked in 70% ethanol before opening. Screening the whole plate, including wells without cell growth, by ELISA avoids possible errors when trying to keep track of individual wells. If ELISA-positive wells are to be screened further (e.g., by Western blotting using a multichannel miniblotter), this first 50 µL of supernatant may be diluted into 100 µL or more of PBS; multiple sampling of fusion wells should be minimized to avoid contamination. We usually screen by ELISA on d 10, carry out further screening of ELISA-positive wells on d 11 and 12, and clone about 30 of the best wells on d 12, 13, and 14.

3.6. Cloning by Limiting Dilution

1. Using a plugged Pasteur pipet, transfer the positive clone to a 24-well plate containing 0.5 mL of cloning medium (*see* **Note 11**).
2. Take an aliquot of these cells, dilute with an equal volume of 0.1% trypan blue in PBS, and count cells on at least two chambers of a hemocytometer.
3. Prepare 6 mL of 160 cells/mL and perform serial dilutions to 40 cells/mL and 10 cells/mL. Plate four rows at 16 cells in 0.1 mL/well, four rows at four cells in 0.1 mL/well, and four rows at one cell in 0.1 mL/well. Three drops from a plugged Pasteur pipet are about 0.1 mL.
4. Eight to ten days after plating, clones at 1 cell/well are visible, and screening can start immediately. It is best to screen at least 16–24 wells from each cloning plate.

As soon as positive clones have been identified, they should be cloned a second time, but at 4, 1, and 0.5 cells/well instead of 16, 4, and 1.

5. When these plates are screened again after another 8–10 d, at least one dilution should have <50% of the wells with growth, and *all wells with growth* should be positive in the screening. If any colonies are negative, cloning should be repeated until all wells are positive (*see* **Note 12**).

3.7. Preservation of Hybridoma Lines

1. Hybridoma clones should be expanded slowly from microwells, first into 0.5 mL in 24-well plates, feeding to 1 or 2 mL before transferring to a 25-mL flask in 5 mL of medium.
2. To preserve cell lines indefinitely, centrifuge 1–3 × 10^6 growing cells in a universal, remove all supernatant, suspend cell pellet in 0.3–0.5 mL of ice-cold 7.5% DMSO/HS, and transfer the suspension into a 1.8-mL cryotube.
3. Surround the cryotube with 1 in of polystyrene, and place in a −70°C freezer. Transfer it the next day to a liquid nitrogen container.
4. It is advisable to freeze several vials of the same line and thaw one after a week to ensure viability, while maintaining the cells in culture.
5. To recover cells from liquid nitrogen, thaw the cryovial quickly in a 37°C water bath until only a tiny piece of ice is visible. Transfer the cell suspension immediately to 10 mL of ice-cold DMEM/20% HS. Centrifuge at 300 *g* for 7 min, remove supernatant completely, and resuspend the cell pellet in 3–5 mL of cloning medium. Transfer the cell suspension into a 25-mL flask, reserving about 0.1 mL to count viable cells, and place flask in the CO_2 incubator. If the viable cell count is <1 × 10^4/mL, cloning by limiting dilution should be carried out immediately (*see* **Note 13**).

3.8. Antibody Production

1. Antibody can be generated as culture supernatant by starting a flask culture at 1 × 10^5/mL in DMEM/20% HS and, when the cell density reaches 4–6 × 10^5/mL, diluting to 1 × 10^5/mL. The concentration of horse serum is gradually reduced to 10% in the process of reaching the volume required (*see* **Note 14**). The cells are then left to grow undisturbed until they are all dead (*see* **Note 15**). Culture supernatant can then be harvested by centrifugation, and stored in aliquots at −20°C until required. For routine use, keep an aliquot of 1–2 mL with 0.1% sodium azide at 4°C. Antibody prepared in this way contains large amount of horse Ig which co-purifies with mouse Ig and is undesirable if direct labelling of the purified MAb is planned. Hybridoma cell lines can be switched to growth media containing fetal bovine serum (which has low endogenous Ig levels) or to various proprietary serum-free or protein-free media designed for hybridomas. In our experience, however, MAb levels are at least 10X lower than can be achieved with horse serum. Ascites production is an easy way to produce milligram quantities of MAb of sufficient purity for labelling, but this process is discouraged by regulatory authorities in many countries because of the distress caused to mice. Ascites production is available commercially, but a method is also given here.

2. For ascites fluid, an adult Balb/c mouse is primed with 0.2 mL of pristane ip.
3. After 7–10 d, 1–3 × 10^6 hybridoma cells in logarithmic growth (100% viability) are centrifuged at 300 *g* for 7 min at 20°C and washed once with DMEM/25 m*M* HEPES to remove all serum. The cell pellet is resuspended in 0.2 mL of DMEM/HEPES, and injected ip into a primed mouse using a 21-gage no. 2 needle (green).
4. Ascites development becomes evident by external examination within 7–14 d and mice must be examined twice a day over this period. Mice are killed by cervical dislocation as soon as they show signs of discomfort (advice should be sought and followed). The peritoneum is exposed as in **Subheading 3.4**, **step 6**, and a 21-gage needle on a 5-mL syringe is inserted about 1 cm so that the tip remains visible through the peritoneum and fluid can be withdrawn without blockage. Last traces of fluid are removed after opening the cavity with scissors. The final volume obtained is usually 2–3 mL, though blood from the heart and thoracic cavity can also be collected (about 0.5 mL) and processed separately as a source of antibody.
5. Fluids are allowed to clot and then centrifuged at 3000 *g* for 20 min. Store in aliquots of 200 µL at −20°C or preferably −70°C.

4. Notes

1. Fusions from a single mouse spleen aimed at producing 20–30 cloned hybridoma lines by the method described here can eventually fill a standard size bench-top incubator completely. The floor of the incubator is filled with autoclaved, double-distilled water. The interior of the incubator must be kept as free of contamination as possible; this may necessitate removing the contents, changing the water, and wiping the interior with 70% ethanol on several occasions during hybridoma growth and cloning. Even so, we use large plastic lunch boxes to insulate unsealed culture vessels (e.g., microwell plates) from the turbulent incubator environment (a fan is desirable for uniform temperature and humidity). Holes plugged with cotton wool at each end of the lunch box to admit CO_2 are optional; an alternative is to leave the lids ajar for 1–2 min to equilibrate before closing them. They can be wiped regularly, inside and out with 70% ethanol. Never use toxic chemicals (e.g., bleach) to decontaminate an incubator. Never handle culture plates without gloves.
2. Cells roll to the bottom giving a white colony in the exact center of each well, visible even at early stages; flat-bottomed plates have initially transparent colonies, often at the side of the well and easily overlooked. Use of round-bottomed plates makes it very easy to monitor colony growth after fusion without using a microscope.
3. The mixture does not dissolve by itself, so add 1 *M* NaOH dropwise while stirring until the solution goes clear.
4. Avoid syringes with rubber plunger tips; when the emulsion thickens, they come off the plunger.

5. The myeloma cells should look uniform and healthy by this time with no sign of cell debris.
6. We normally perform all steps up to this point in a separate sterile hood. The mouse is nonsterile externally, and particular care is taken to avoid hairs; the outer skin is torn, rather than cut, for this reason. Mice should not be introduced into the hood used for cell culture.
7. Some protocols remove red blood cells by differential lysis at this point, but we have not found it necessary.
8. The final concentration of PEG during fusion is thought to be critical for the yield of colonies. If initial yields are low, try adding increasing (but small) amounts of DMEM/25 m*M* HEPES to the pellet before adding PEG.
9. Never use unplugged micropipet tips for adding to culture plates; sterile tips can be used for *removing* culture supernatant only.
10. Bacterial and yeast contaminations rarely occur and are usually the result of a major failure in sterile technique (e.g., inadequate sterilization of culture medium or glassware). Sources of any sporadic fungal contamination should be tracked down and eliminated. Some protocols recommend freezing down uncloned or partly cloned cells as a precautionary measure. Following our rapid cloning protocol, however, the first round of cloning and screening is often complete before the original colony is sufficiently expanded for freezing. It is certainly advisable to keep the original culture alive, however, by adding 0.1 mL of cloning medium back to the fusion well and by feeding the 24-well culture, if necessary. Cloning should not be regarded as an ordeal suitable only for healthy cells, but rather as a means of invigorating a failing culture. We always clone twice for this reason, even if the line is evidently clonal after the first round. *As a general maxim*: if in doubt or trouble, clone immediately.
11. There are rare exceptions to the general principle that cloning should be continued until all colonies are positive in the screens. We were once performing an initial screen by ELISA and then testing ELISA-positive wells by immunofluorescence microscopy (IMF) on muscle sections. After cloning one well that was positive in both assays, we found that only half the clones were ELISA-positive and very few of these were also IMF-positive. We recloned wells that were positive in both assays again with the same result. We thought we had come across our first "unstable" hybridoma, but by chance we tested ELISA-negative wells in IMF and found they were all IMF-positive. Only then did we realize that the original fusion well had contained two different hybridomas, one ELISA-positive and one IMF-positive. The purpose of cloning is to separate such lines, but by selecting wells that were positive in both assays (and hence still had two clones), we had been systematically defeating this objective.

12. When very few cells survive after being kept in liquid nitrogen, "cloning" by limiting dilution at about 100 total cells/well may be the only way to recover the cell line.
13. Cells may also be collected by centrifugation and resuspended in 5% fetal calf serum at this stage, if a culture supernatant with low levels of nonmouse Ig is required.
14. Most MAb are stable for long periods in sterile culture medium, but there are undoubtedly some that lose activity rapidly even at 4°C. These are perhaps best avoided, but, if required, bulk culture would have to be monitored regularly and supernatants harvested when their antibody activity is still high.
15. HECS (human endothelial culture supernatant) is no longer commercially available but can be prepared by growing HUVEC cells for 2 days to 80% confluence in Endothelial Cell Growth Medium (Promocell, Heidelberg, Germany, Cat No. C22020) and using the supernatant (store at −20°C).

Acknowledgment

We thank C. J. Chesterton (King's College, London) for sharing with us his enthusiasm for, and experience of, hybridoma technology in 1981.

Polyethylene glycol: purification of IgG, 1759–1760
Ponceau S stain, 236, 730, 743, 952
Porous graphitized carbon (PGC), 1235–1236, 1247–1248, 1263–1264
Prolidase, 990–991
Pronase, 989–990
Pronase E, 1661
Pro-Q diamond stain, 579–584
Pro-Q Emerald dye staining, 563–564
Protease inhibitors, 125
Protein A, 737–738, 1057, 1761–1762, 1951–1952
Protein A mimetic, 1783–1796
Protein G, 134–135, 737–738, 743, 1761–1762
Protein L, 738
Proteins
blotting, 198, 230, 293–297, 617–619, 621–628, 631–633, 635–638, 641–655, 663–670, 1433, 1434
acid-urea gels, 635–638
blocking solutions, 619, 627
blotting (transfer) buffer, 618, 625, 793
capillary, 631–633
detection by ECL, 645, 766, 779–788
detection with antibodies, 737–741, 743–749, 751, 779–781, 786, 792–793, 815, 816
detection with avidin-biotin, 771–775
digestion of proteins on, 919–921, 923, 927, 928, 931, 933, 936, 937, 939
double replica blotting, 651

electroblotting, 617–619, 621, 623–626, 631, 636, 641–655, 663–670
high molecular weight proteins, 293–297, 663–670
membranes, 624, 625
reuse of blots, 617
secondary antibodies, 642, 643, 645, 737–750
semidry, 621–628
staining of blots, 533–540, 717–721, 723–734
digestion, 905–916, 986–988, 1811–1816
electrophoresis of (*see* Electrophoresis)
kinases, 1547, 1567
ladder sequencing, 1131–1137
molecular weight standards, 1030
palmitoylation, 1623–1635
phosphorylation, 1531–1544, 1547–1553, 1555–1563, 1567–1576, 1579–1586
prenylation, 1637–1653, 1657–1674
quantitation of
BCA assay, 11–14, 28–30
Bradford method, 17–23
copper iodide, 723–728
flow cytometry, 55–61, 63–69
in gels, 443–452, 454–464, 470–473, 479–485
kinetic silver staining, 51–54
laser scanning cytometry, 63–69
laser scanning densitometry, 487–495
Lowry method, 7–10, 27, 28
nitric acid method, 35–44
radiolabeled, 443–475
UV absorbance, 3–6
radiolabeling, 279–283, 711, 715, 747, 951, 952, 1602, 1727–1729, 1731–1741
solubilization, 73–81
sumoylation, 1519–1528
stains (gels and blots)
Alcian blue, 571
amido black, 729, 741, 743
calconcarboxylic acid, 515–519
Coomassie brilliant blue, 17, 172, 180, 184, 229–230, 479–481
copper iodide, 723–728
DIG-anti-DIG AP labeling, 560–563
direct blue 71, 729–734
Eosin Y, 575–577
Ferrozine-ferrous, 534
India ink, 637, 638
MDPF, 717–721
metal chelates, 529–544, 550
Nile red, 497–504
periodic acid-Schiffs, 559–560
Ponceau S, 236, 729, 741, 952
Pro-Q diamond, 579–584
Pro-Q emerald, 563–564
silver, 51–54, 235, 445, 521–527
SYPRO Rose, 535–536
SYPRO Ruby, 481, 482, 537–539, 550–552
zinc reverse stain, 505–512
sequencing, 1131–1137
tags, 1930–1935
Proteoglycan staining, 571
Proteolytic activity, detection of, 605–611
Proteotope, 449–477
PVDF membranes, 198, 624–625
Pyridylethylation, 847–850
Pyroglutamic acid, 1064, 1075–1078

Q

Quantitation. *See* Proteins, quantitation of
Quantum dots, 807–816

R

Radiolabeling
assessment of, 1738
Bolton Hunter method, 744, 1608, 1733–1734
cells, 279–283

Radiolabeling (*Continued*)
chloramine T, 450, 453, 955, 1608, 1727–1729
iodo beads method, 710–711
iodogen method, 952, 1735–1741
lactoperoxidase method, 1731–1732
Reuse of protein blots, 617, 787, 789–803
Reverse phase HPLC. *See* RP-HPLC
Reverse staining, 505–512
Rhodamine, 687
RNase treatment, 125, 157
RP-HPLC
of amino acids, 995–999, 1015–1028
of glycans, 1395–1400
of proteins, 1158–1159
of peptides, 941–949

S

Scanning laser densitometry, 487–495
Scintillation counting, 1593
SDS PAGE, 177–185, 187–191, 193–209
Secondary antibodies, 642, 643, 645, 737–750
Semi-dry blotting, 621–628
Sepharose, 1755–1756
SEQUEST, 1459–1460
Serological cross-reactions, 1799–1809
Serum peptides, 1167–1173, 1175–1183
Serum samples, affinity depletion, 132–135, 139–153
Sialic acid, analysis by HPAEC-PAD, 1231–1232
Sialoglycoproteins staining of, 576–577
Silver staining, 51–54, 235, 445, 521–527
Size-exclusion chromatography, 1029–1036, 1160–1162, 1765–1772
Slot-dot blotting, 1852
Small molecule coupling, 1716–1721
Sodium sulphate: IgG purification, 1761–1762
Splenocytes, 1877
Stacking gel, 178–185
Staining of
blots, 547–552, 717–721, 729–734, 737–739
proteins (*see* Proteins, stains; Proteins, quantitation of)
Strep-Tag, 1930–1935
Streptavidin, 696, 771, 807–816
Stripping of blots, 646, 653, 788, 793, 798
Subcellular fractionation, 165–169
Succinylation, 845–846
Sulfo-SMCC, 1705
Sulphydryl groups. *See* Cysteine; Disulphide bridges
SUMO, 1519
Sumoylation, 1521–1524
Surface plasmon resonance, 1313–1319
Swiss, 2D PAGE database, 428
SYPRO Rose staining, 535–536
SYPRO Ruby staining, 482–484, 538–541, 547–552

T

Tandem mass spectrometry, 1095–1113
TCA precipitation, 125
Texas red, 687
Thermolysin, 956, 986
Thin-layer chromatography of peptides, 951–961, 1553, 1629, 1661
Thin-layer electrophoresis of peptides, 951, 1047, 1050
Thiol groups. *See* Cysteine; Disulphide Bridges
Thiophilic chromatography: IgG purification, 1761–1762, 1952–1953
Thiourea, 126, 129
Thyroglobulin, 1706
Towbin buffer, 625, 766
Tributyl phosphine, 76, 79
Tricine, 234
Tris(carboxyethyl) phosphine, 75
Tris-taurine-HCl system, 211–218
Trypsin, 910–913, 931.957, 971
Trypsin autolysis, 987
Tryptophan
cleavage at, 883–888

modification of, 871–872
quantitation of, 47–50
Two-dimensional (2-D) PAGE, 121–129, 131–138, 155–158, 269–277, 285–291, 409–439, 449–477
databases, 410
flicker analysis, 409–439
immobilized pH gradients, 269–277, 305–320
immunoblotting of, 641–655
plants, 109–117
sample preparation,85–107, 109–117, 121–129, 155–158, 204–205, 389–404
yeast, 155–158
Tyrosine
nitration of, 855–858, 1484–1488
sulfation of, 1602–1603

U
Ubiquitination, 1491–1514
Urea, 126, 157
UV absorption, 3–6, 48–49

V
Validation of amino acid analyses, 1015–1028
Vapour phase protein hydrolysis, 997
Vitamin K-dependent proteins, 1431–1448
V8 protease. *See* Endoproteinase Glu-C

W
Western blotting. *See* Proteins, blotting
Western cross-blotting, 1799–1809
WinGene, 1141–1147
WinPep, 1141–1147

X
X-ray film. *See* Autoradiography

Y
Yeast samples, 155–158

Z
Zinc reverse staining, 505–512
Zymogram technique, 175, 607–612
